Publication Date: February 27, 2026

SAN ANTONIO, TX
66TH ANNUAL MEETING
& ToxExpo • March 14–17, 2027

Scientific Sessions
Proposal Submission
Deadline:
May 15, 2026

Session Type Options:

- Continuing Education
- Scientific
- Engagement
- Education-Career Advancement
- Historical Highlights
- Informational
- Regional Interest

www.toxicology.org/2027

Preface

This issue is devoted to the abstracts of the presentations for the Continuing Education courses and Scientific Sessions of the 65th Annual Meeting of the Society of Toxicology, at the San Diego Convention Center, San Diego, California, March 22–25, 2026.

An alphabetical Author Index, cross-referencing the corresponding abstract number(s), begins on page 582.

The issue also contains a Keyword Index (by subject or chemical) of all the presentations, beginning on page 603.

The abstracts are reproduced as accepted by the Scientific Program Committee of the Society of Toxicology and appear in numerical sequence. If a number is missing in the numerical sequence, the abstract assigned to the missing number was withdrawn by the author(s). Author names that are italicized in the author block indicate that the author is a member of the Society of Toxicology. For example, *J. Smith*. SOT members may sponsor abstracts that do not include an author with SOT membership. Authors who are members of designated organizations could serve as the sponsor of the abstract if an SOT member was not a co-author; these types of sponsorships are displayed with an organization name after the sponsor name (e.g., Sponsor: A. Smith, EUROTOX).

Scientific Session Types:

CE Continuing Education Courses	R Roundtable Sessions
EC Education-Career Development Sessions	RI Regional Interest Sessions
IS Informational Sessions	S Symposium Sessions
PL Platform Sessions	W Workshop Sessions
PS Poster Sessions	

Access *The Toxicologist* Online

You can access *The Toxicologist* and *The Toxicologist: Late-Breaking Supplement* anytime on the SOT website's "[Publications and Historical Documents](#)" web page. All the abstracts in this edition of *The Toxicologist* also are available in the 2026 [SOT Event App](#) and [SOT Online Planner](#).

Society of Toxicology
11190 Sunrise Valley Drive, Suite 300, Reston, VA 20191

This abstract book has been produced electronically by the Society of Toxicology. Every effort has been made to faithfully reproduce the abstracts as submitted. The author(s) of each abstract appearing in this publication is/are solely responsible for the content thereof; the publication of an abstract shall not constitute or be deemed to constitute any representation by the Society of Toxicology or its boards that the data presented therein are correct or are sufficient to support the conclusions reached or that the experiment design or methodology is adequate. Because of the rapid advances in the medical sciences, SOT recommends that independent verification of diagnoses and drug dosage be made.

A. Borrel. Sciome, Research Triangle Park, NC.

New approach methods (NAMs), such as quantitative structure-activity relationship (QSAR) models and read-across (RAX) approaches, are intended to rationalize and reduce the need for further experimental testing on animals. Both these approaches rely on the principle of molecular similarity for assessing property profiles of untested chemicals. Software tools to visualize chemical structures and their experimental and predicted properties employing principles of molecular similarity can make the process of reliably assessing the profiles of untested compounds efficient. This course will explore the concept of chemical similarity and chemical space and their application for toxicity assessment. The first speaker will introduce the concept of similarity, covering both supervised and unsupervised methods. The speaker will discuss the context of toxicity studies, detailing common errors and best practices for effectively using similarity approaches. The second speaker will introduce OrbiTox and ChemMaps.com, presenting them as two powerful tools designed for exploring chemical space. The speaker will explain how these platforms provide access to toxicity data and QSAR models, facilitating the reporting of analogue profiles to support decision-making. By the conclusion of this course, participants will possess a better understanding of chemical similarity and chemical space in relation to toxicity assessment. They will be equipped with the necessary expertise to efficiently navigate ChemMaps and OrbiTox for effectively exploring chemical structure and property landscapes. This training aims to empower attendees with practical skills and insights, fostering informed decision-making and enhancing proficiency in utilizing cutting-edge tools for chemical analysis and toxicological assessment. Learning Objectives: (1) Clearly explain the concepts of chemical similarity, chemical space, and their significance in toxicology assessment. (2) Understand the advantages and limitations of current chemical similarity approaches. (3) Develop proficiency in navigating ChemMaps.com and OrbiTox tools for property profiling. (4) Explore and understand limitations of relationships between chemical structures and toxicology properties.

1002 AM02: Advancing Developmental Immunotoxicology: Human-Relevant Models, Adverse Outcome Pathways, and Translational Tools

F. Sillé. Johns Hopkins University, Baltimore, MD.

The developing immune system is particularly vulnerable to environmental exposures during critical windows from prenatal development through adolescence. These exposures can lead to persistent immune dysfunction, including increased risk of allergy, autoimmunity, infection susceptibility, and chronic inflammation. However, traditional in vivo testing methods for developmental immunotoxicity (DIT) are resource-intensive, lack human relevance, and fail to capture nuanced mechanisms across key developmental windows. This course offers an in-depth and timely look at emerging new approach methodologies (NAMs) that address these issues and have the potential to replace or reduce reliance on animal testing for protection of the developing immune system. Participants will strengthen existing knowledge on how in vitro platforms, including stem cell-derived hematopoietic assays and immune organoids, are being developed and optimized to model early immune development. Novel technologies, such as bone-marrow-on-a-chip and lymphoid organoids, provide physiologically relevant systems to assess developmental immune outcomes, offering higher resolution and mechanistic insight. Molecular frameworks such as adverse outcome pathways (AOPs) are also gaining traction in the field of DIT and serve as important organizational tools for integrating mechanistic knowledge and guiding regulatory strategy. This course will highlight critical components necessary to strengthen existing knowledge of NAMs into validated tools for hazard characterization and identification and regulatory use. These include the development of reliable functional endpoints, the identification and use of appropriate reference compounds, and consensus criteria for assay readiness. Attendees will also gain insights into the evolving regulatory landscape that increasingly emphasizes human relevance, transparency, and scientific confidence in NAMs for health risk decision-making. The course will include a brief concluding panel discussion, with an interactive Q&A with all speakers and the audience on remaining challenges, harmonization, and how the field should advance beyond 2026. By bringing together international leaders in toxicology, immunology, and regulatory science, this course aims to build a shared understanding of where the field stands today and where strategic investment is needed to ensure that DIT NAMs are accepted and implemented to improve public health protection. Learning Objectives: (1) Describe critical developmental windows and molecular targets relevant to immunotoxicity. (2) Compare and evaluate various human-relevant in vitro models used in DIT. (3) Understand the development and use of AOPs in immunotoxicity assessment. (4) Identify appropriate reference chemicals and validation strategies for DIT NAMs. (5) Explore regulatory challenges and scientific pathways for integrating DIT NAMs into risk assessment frameworks. Target Audience: Toxicologists, regulatory scientists, risk assessors, developmental biologists, immunologists, and industry stakeholders engaged in safety assessment and NAM implementation.

1003 AM03: Applications of Machine Learning and Artificial Intelligence Approaches to Advance Toxicology and Environmental Health Sciences

Z. Lin. University of Florida, Gainesville, FL.

Machine learning and artificial intelligence (AI) approaches have significantly contributed to progress in many scientific disciplines, including toxicology, risk assessment, and environmental health. A number of machine learning models have been published to predict the absorption, distribution, metabolism, excretion, and toxicity (ADMET) of chemicals; the degree of environmental pollution, such as air quality and water quality; and the human health outcomes due to environmental chemical exposures. Development of machine learning models to study toxicology and environmental health issues requires multidisciplinary expertise, including mechanistic toxicology, pharmacokinetics, environmental health, computer science, programming, and machine learning algorithms. However, there are not many researchers who have all the relevant expertise. It is common and essential for computational scientists and mechanistic toxicology and environmental health scientists to collaborate to complete machine learning-based projects. However, computational scientists often find it challenging to grasp the ADMET mechanisms of xenobiotics, just as mechanistic toxicologists may struggle to comprehend and apply machine learning models. Additional teaching materials and training opportunities are needed to address this challenge. To address this need and further leverage machine learning approaches to advance toxicology and environmental health, a group of scientists recently completed a dedicated textbook entitled Machine Learning and Artificial Intelligence in Toxicology and Environmental Health. This book introduces the fundamental concepts and principles of widely used machine learning and AI techniques relevant to toxicology and environmental health. It provides practical examples of the applications of machine learning and AI methods to predict ADMET properties of chemicals, air quality, water quality, food safety, antimicrobial risk assessment, and chemical risk assessment. It also includes case studies, sample code, and interactive computer exercises to support the practical implementation of these methods in toxicology and environmental health. This course aims to facilitate the dissemination of the scientific knowledge of this textbook to the field of toxicology and environmental health. Note that this book will only be used to relay and support the science of this course, and it is not a requirement or recommendation of speakers for attendees to purchase. This course will start with a brief overview of the book and an introduction on advances in applying machine learning and AI in the regulatory landscape, followed by individual presentations. The first presentation will introduce how to develop and apply machine learning-based quantitative structure-activity relationship (QSAR) models to predict ADME properties of chemicals. The second presentation will introduce how to build machine learning-empowered physiologically based pharmacokinetic (PBPK) models for chemicals and nanoparticles. The third presentation will demonstrate how to integrate machine learning with cell painting to predict bioactivity based on in vitro assays. The fourth presentation will discuss how to develop machine learning-based QSAR models to predict developmental toxicity. The fifth presentation will explore how machine learning models function in human health risk assessment. The sixth presentation will discuss how to apply generative AI for research translation in toxicology and environmental health and the ethical considerations. Most of these presentations will cover both a theoretical introduction to model development and practical examples to demonstrate each application. This course will introduce both theory and many practical example applications of machine learning approaches in different areas of toxicology. It is expected that this course will be beneficial for a diverse population of SOT attendees, including experimental toxicologists and computational toxicologists at different career stages (e.g., students, postdocs, and senior scientists) across various sectors, including academia, industry, and regulatory agencies.

1004 AM04: Biotherapeutics Impurities: Current Practices in Risk Assessment and Analytical Evaluation

V. Kale. Bristol Myers Squibb, New Brunswick, NJ.

Impurities in biotherapeutics include residual host cell proteins (HCPs), high and low molecular weight species, Protein A, host cell DNA and RNA, lipids, aggregates, process-related contaminants, and product-related variants. Due to their intricate nature, potential impurities in biotherapeutics can have a significant potential impact on safety and efficacy profiles. This course will offer a comprehensive overview of risk assessment of impurities in biotherapeutics. The introductory talk will provide an overview of impurities in biologic products, emphasizing the complex nature of these contaminants and the critical importance of understanding analytical methods, testing strategy, and regulatory expectations. This talk will establish a foundational understanding for analytical considerations, impurity risk assessment, and mitigation strategies. One of the speakers will focus on highlighting sophisticated techniques, like high-performance liquid chromatography (HPLC), mass spectrometry, and capillary electrophoresis, essential for detecting and quantifying impurities from various sources, such as host cells and raw materials. This presentation will outline the current state of analytical technology and methods for impurity testing, including challenges and limitations, as well as advancements that are driving continuous improvements in impurity testing. This course will further discuss the framework for assessing biologic impurities of concern with emphasis on the significance of controlling HCPs as critical quality attributes through comprehensive risk assess-

ments. To understand current industry practices in risk assessment of HCPs, the findings of an IQ DruSafe Impurities Safety Working Group industry-wide survey will be discussed in this course. This survey highlights the current challenges, strategies, and regulatory interactions associated with HCPs in biopharmaceutical development and commercialization. Concluding the session, interactive case studies will engage the audience in practical impurity assessment scenarios using polling tools, fostering dialogue and sharing learning among participants. Overall, this course will provide the audience with a clear understanding of the types of impurities encountered with biopharmaceuticals, fit-for-purpose analytical methods, and the conduct of risk assessment for those impurities.

CE 1005 AM05: Chemical Emergencies: Emergency Response, Toxicology, and Exposure Considerations

R. Nocco. Consultant, Danville, CA.

Chemical emergencies may have adverse impacts on public health as evidenced by landmark incidents: the 1984 Bhopal disaster, the 1995 Tokyo subway attack, and the 2023 East Palestine train derailment. Toxicology plays an essential role in successfully managing the associated risks of these emergencies, which could include outcomes from terrorist (CBNR), military, transportation, and chemical plant incidents. This course will cover (1) the evolution and history of public health emergency exposure guidelines; (2) an overview of current guidelines; (3) public health exposure values; (4) the application of toxicology disciplines to emergency response decisions; (5) the role of toxicologists in the incident management system (NIMS); (6) remedies and treatment; (7) exposure measurements; and (8) risk assessment and risk tolerance criteria. Learning Outcomes: Upon completion, the participant will be able to (1) Develop an understanding of chemical emergencies. (2) Discuss the benefits and limitations of exposure guidelines. (3) Explain how public health exposure guidelines differ from occupational exposure guidelines (OELs). (4) Describe how PH exposure values are developed. (5) Apply toxicology guides in ER situations and in proactive ER planning and process safety.

CE 1006 AM06: Systematic Methods for AOP Development and Application: New Technologies and Tools

B. Meek. University of Ottawa, Ottawa, ON, Canada.

Adverse outcome pathways (AOPs) provide convenient integrating organizational constructs for assembling and evaluating mechanistic information at different levels of biological organization in a form designed to support a range of regulatory applications. These include the development of integrated approaches to testing and assessment (IATA) and chemical specific assessment to inform predictive inference and mode-of-action (MOA) analysis. There has been much experience gained in the last thirteen years, since the introduction of the AOP development program by the Organisation for Economic Co-operation and Development (OECD). Guidance and an associated handbook supports developers in the description and evaluation of AOPs via a publicly available knowledgebase. The program also includes formal peer engagement in the form of coaching for AOP development, external scientific review, and endorsement by parent OECD committees on testing and assessment. Increasing experience in AOP development and application contributes to the continuing evolution of the methodology to meet regulatory needs. This course addresses aspects of the application of systematic review tools in the development and application of AOPs. Areas of evolution include the more systematic consideration of supporting evidence, extension of qualitative weight of evidence considerations to quantitation of key event relationships, the integration of emerging data such as 'omics, and increasing experience in application. This course builds on training developed within the OECD program on best practices of documentation and assessment to support regulatory implementation, focusing particularly on the consideration of systematic workflows and tools in AOP development and practical examples of application. Practical exercises include the application of topic modeling in AOP development. The course is designed to promote critical evaluation of data and familiarity with emerging approaches supporting transparent, systematic AOP development for regulatory and research applications. Following a brief introduction of the course outline and learning objectives, the first presentation will update attendees on how the available guidance and tools for AOP development have evolved to reflect experience with increasing and expanding content and biological space. The second presentation will emphasize the importance of transparently and effectively documenting evidence collection and evaluation by sharing tools and best practices with prospective AOP authors and users. The third presentation outlines methodology adopted to systematically consider available data in the development of an AOP as a basis for an integrated approach to testing and assessment by the European Food Safety Authority, while the fourth addresses the application of 'omics in the context of AOPs. The fifth presentation considers relevant approaches to systematic evidence mapping in AOP development, and the final presentation addresses case studies to assess biological plausibility in hazard assessment integrating systematic review methods in AOP development and consideration. A hands-on exercise addresses the application of topic modeling in AOP development.

CE 1007 PM07: Evolution of OECD GL 497; Integration of NAMs for Skin Sensitisation Hazard and Point of Departure for Application in Risk Assessment

E. Reinke. Inotiv, Research Triangle Park, NC.

Developing approaches for assessing skin sensitization potential and potency of chemicals and ingredients has been an area of active research over many years. Regulatory restrictions on animal use in Europe, increased emphasis on nonanimal approaches globally, and understanding of the mechanisms by which skin sensitization occur has accelerated their development and acceptance. This has resulted in a variety of nonanimal new approach methods (NAMs) aligned with key events described in the adverse outcome pathway (AOP) for skin sensitization; many of which have been validated and evaluated for inclusion into the Organisation for Economic Co-operation and Development (OECD) test guideline program. Generally, these methods are not adequately predictive alone; therefore, these methods have been combined in a series of defined approaches (OECD GL 497) that span use cases for hazard classification, sub-potency classification, and, most recently, point of departure (POD) determination for risk assessment. This course is intended to provide attendees with a broad overview of the advances in skin sensitization testing and assessment since the initial publication of OECD GL 497. The first talk will discuss the OECD test guideline program using the development of the skin sensitization test guidelines, anchored to the mechanisms of skin sensitization as an example. This will be followed by a walkthrough of the updates to OECD GL 497, the evaluation undertaken for these updates, and their potential applications and advantages beyond the original guideline. With these changes, there is interest in developing best practices for how to use these additional data sources. The next talk will discuss the concept of best practices and their application to skin sensitization testing and assessment and the lessons learned. This will be followed by a talk on next-generation risk assessment and the tools available for deriving a POD for a skin sensitization risk assessment. This will culminate in a live demonstration and training in how to conduct a risk assessment through the use of freely available tools, such as SARA-ICE, for deriving a skin sensitization POD. The demonstration will showcase how the model can be applied and utilized in integrated frameworks to ensure a thorough assessment of skin sensitization risk for safety assessment, ultimately leading to safer consumer products and improved regulatory compliance. Upon completion, attendees will have a better understanding of how the OECD GL process for validation and implementation is conducted for NAMs and how this process resulted in the updated international guidance on skin sensitization testing and its application to a risk assessment. Attendees will be able to identify where to find and how to apply best practices for skin sensitization testing and assessment.

CE 1008 PM08: Lost in Translation? Navigating Species Selection for Immunotoxicological Assessment in Preclinical Studies

M. Piche. Charles River Laboratories, Senneville, QC, Canada.

Selecting the right species for immunotoxicological assessment in nonclinical studies is essential for ensuring the relevance, reliability, and translatability of immune safety data to human health. However, significant interspecies differences in immune system structure and function present an ongoing challenge to accurately predicting human outcomes. Understanding these differences—and how they affect study design, interpretation, and risk assessment—is critical, especially as biologics, immunomodulators, and other immune-targeting therapies become increasingly common. This course will explore the complexities of species selection for immunotoxicology studies by examining the immunological similarities and differences between commonly used preclinical species—rats, minipigs, dogs, and nonhuman primates—and humans. Each course will focus on the comparative immunology of one species, followed by real-world examples that demonstrate how species-specific immune traits have influenced study outcomes, clinical translation, or mitigation strategies. Speakers will also highlight formulation-specific challenges (e.g., excipient-related immune reactions) and areas where alternative models are gaining interest. The course will offer a practical framework to help participants integrate immunobiology, therapeutic modality, and study design considerations into species selection decisions. The discussion will be enriched by perspectives from health authorities, providing regulatory context around model selection and expectations for translational relevance. These insights will help illustrate how a mechanistic understanding of interspecies differences can inform study design and support scientifically grounded, human-relevant risk assessment. Participants will leave with practical tools and insights to design more scientifically justified, translationally relevant immunotoxicity studies, while learning to anticipate potential gaps or artifacts in translation, leaving with actionable strategies for designing and interpreting immunotoxicity studies with greater confidence. Course Goals: (1) Equip scientists with tools to select the most immunologically and translationally relevant species for biologics and small molecule safety assessment. (2) Highlight where standard models (rat, dog, NHP, minipig) succeed or fall short in predicting human immune responses. (3) Share best practices and real-world case studies for evaluating biologics-related immunotoxicity, including formulation-specific reactions and alternative models. (4) Promote fit-for-purpose study designs that increase human relevance and regulatory confidence.

B. Riffle. BASF Agricultural Solutions, Wake Forest, NC.

Assessing the risks of chronic toxicity and carcinogenicity from long-term exposure to chemicals is a critical part of the regulatory approval process of various chemistries. To evaluate the potential for chronic toxicity and carcinogenicity resulting from exposure to chemicals, regulatory authorities typically require the conduct of long-term rodent bioassays, such as the OECD guideline studies for chronic toxicity, carcinogenicity, and/or combined chronic/carcinogenicity studies. New approach methodologies may provide a less resource intensive and a more rapid means to assess chronic toxicity and carcinogenicity of chemicals with equivalent or better accuracy and resultant human health protection. In some regulatory jurisdictions, regulators have the flexibility to consider a scientific weight of evidence (WOE) based approach that satisfies toxicological data requirements without conducting the lifetime rodent bioassays. Depending on regional legislation, agricultural, industrial chemical, and pharmaceutical registrants can submit scientific rationales addressing the toxicological data requirements for regulatory assessment, which allow for the integration of available information to make data need determinations that are health protective and scientifically sound. A workgroup convened under the Rethinking Carcinogenicity Assessment for Agricultural Project (ReCAAP) to develop a framework building off the ICH S1 WOE, to help structure a WOE based estimation of a point of departure that would be health protective against chronic risk for agricultural safety evaluation, including effects related to carcinogenicity. This course aims to provide an example of implementing the ReCAAP approach for assessing the potential for carcinogenicity to support data requirements for chemical safety assessment. Examining a practical example will provide insight to better understand how to use the available framework and guidelines in a fit-for-purpose manner. The course is not meant to offer technical lectures on WOE methods or the selection of uncertainty factors for risk assessments. Rather, the lectures will be focused on experiences of ReCAAP applications, including a practical example, in decision-making for researchers and the regulated community to consider while developing a WOE-based chemical safety assessment. The first set of speakers will introduce the ReCAAP framework and regulatory implications of rodent bioassays in the risk assessment of a variety of chemicals. Activities related to applying a WOE-based approach to carcinogenicity assessment will be discussed. The next speaker will present the workflow of the ReCAAP framework to discuss the process, key factors considered, and how to address uncertainties with this approach. After the break, the next speaker will provide a presentation on the fundamentals of read-across, followed by a short demonstration of the framework functionality survey to determine which chemicals this framework will work best. The course will conclude with a hands-on evaluation of a case study followed by panel discussion. Participants will be asked to conclude whether one or both of the long-term rodent cancer bioassays should be waived based on the available data set.

1010 PM10: This Is Real: How AI Can Actually be Used in Hazard and Risk Assessments

A. Rooney. NIEHS, Research Triangle Park, NC.

While application of artificial intelligence (AI) approaches has tremendous potential for decision-making and efficiencies in toxicology, questions remain as to reliable and transparent use of AI for hazard and risk assessment. This course will highlight actual use and innovative tools that enhance workflows in conducting hazard and risk assessments. Traditional approaches to risk assessment often involve resource intensive manual processes that can be time and resource intensive, prone to human error, and challenging to scale effectively, particularly with the rapid growth in relevant scientific research. This course will illustrate how AI technologies can significantly streamline these complex activities, while maintaining transparency. By automating routine tasks such as identifying relevant studies, extracting critical data, and systematically analyzing extensive datasets, AI tools offer meaningful improvements. These advancements increase efficiency, scalability, and the robustness of evaluations while simultaneously ensuring accuracy, transparency, and reproducibility—critical factors for maintaining trust and credibility in public health and environmental decision-making. Recent advancements in AI and informatics offer transformative solutions for researchers, regulatory agencies, and public health organizations tasked with assessing human health risks from chemical exposures. Sophisticated computational tools and analytical techniques provide researchers and regulators with enhanced capabilities to process, interpret, and manage the large and complex scientific datasets that underpin modern risk assessments. These methods support more informed, timely, and effective decision-making, allowing regulatory agencies to respond proactively to emerging health threats. However, decision-making on hazard and risk require certainty and transparency in the process such that evidence, workflow, and the basis of scientific judgments are clearly presented. Thoughtfully integrated AI technologies, guided by the key principles of transparency and responsible use of AI methods, not only enhance assessment speed but also bolster the consistency, rigor, and reproducibility of outcomes. Currently, regulatory organizations around the world are actively exploring, testing, and integrating these technologies within their existing processes. This course seeks to facilitate an interactive and collaborative discussion among participants, including regulators, academics, and industry professionals, on the practical implementation of AI within established

risk assessment frameworks. Discussions will highlight real examples of AI in existing workflow, opportunities for progress, clearly define emerging challenges, and encourage the exchange of best practices to optimize successful integration. Goals: (1) Clearly presenting AI capabilities and recognizing practical limitations in public health, environmental safety, and regulatory contexts. (2) Demonstrating cutting-edge informatics solutions that automate and enhance data acquisition, organization, and analysis, particularly in systematic reviews, significantly reducing manual labor and minimizing error. (3) Providing real-world case studies showcasing specific instances where AI has notably improved hazard identification and risk evaluation processes, thereby offering attendees valuable insights into both successes and practical lessons learned. (4) Facilitating dynamic and interactive discussions among stakeholders—industry professionals, regulatory authorities, researchers, and academics—to exchange experiences, share best practices, and discuss strategies to overcome the challenges in integrating AI-driven methodologies in risk assessments. (5) Discuss the importance of developing and applying standards for use of AI in decision-making and each step in the hazard or risk assessment process. (6) Bridging theory with practice by presenting tangible examples of AI currently employed within regulatory environments, designed to inspire broader acceptance and implementation. The session has three segments: (1) foundational insights into key AI methodologies and obstacles encountered in their practical application; (2) demonstrations of state-of-the-art informatics tools that significantly enhance systematic review procedures and handling of expansive datasets; and (3) detailed, real-world case studies exemplifying successful AI integration into regulatory assessment processes. By the conclusion of the course, attendees will possess a comprehensive understanding of how these innovations are effectively reshaping the landscape of risk assessments. They will appreciate the significant enhancements in accuracy, reliability, and efficiency achievable through these methods and recognize how these improvements directly support robust public health protection and environmental stewardship.

1011 Developmental PFAS Toxicity: Leveraging Zebrafish as a Model for Phenotypic, 'Omics, and Organ-Level Studies

S. Dasgupta. Clemson University, Clemson, SC.

Per- and polyfluoroalkyl substances (PFAS) have garnered increasing attention over the past decade due to their widespread environmental persistence and their potential to disrupt biological systems. These synthetic compounds, found in everything from firefighting foams to food packaging, have been dubbed “forever chemicals” for their resistance to degradation in both nature and the human body. As PFAS continue to accumulate in water sources, soil, and living organisms, the urgency to understand their toxicological impacts has never been greater. One of the critical questions that we face is how PFAS exposure during development affects gene expression and organogenesis. Zebrafish (*Danio rerio*) is a powerful model with conserved organ systems and genetic tractability, offering a unique *in vivo* platform to assess toxicity at the molecular, cellular, and organ levels—often with high-throughput efficiency. Within this model, bulk and single-cell ‘omics approaches following whole embryonal exposures can be used to predict pathogenesis in developing organs. Owing to these advantages, zebrafish has been widely used to screen PFAS for phenotypic and genomic responses, as well as examine impacts on organogenesis. The objective of this globally relevant Symposium is to bring together zebrafish investigators that are actively conducting research on prediction and assessment of PFAS toxicity, with focus on gene expression studies and organogenesis. Following a brief introduction, the first speaker will talk about using single cell-sequencing data to study impacts of PFOS (a legacy PFAS) on organogenesis, focused on the pancreas and liver. The second speaker will talk about developmental exposures to PFNA (a long chain PFAS) and their impacts on behavioral phenotypes and gene expression disruption within the eye and brain. The third speaker will talk about developmental PFAS exposures and lipidomic changes associated with mitochondrial disruption and neurotoxicity. The fourth speaker will talk about their work on phenotypic and transcriptomic screening of emerging PFAS that are ubiquitously found in Cape Fear River in North Carolina, with a focus on the kidney as a target organ. The final speaker will present their work on developmental screening of a library of 182 PFAS chemicals, with inflation of the swim bladder as a toxic endpoint. The session will conclude with a panel discussion.

1012 Impacts of PFAS on the Pancreas: Insights from Transcriptomics for Organ Development and Function

A. Timme-Laragy. University of Massachusetts Amherst, Amherst, MA.

Per- and polyfluoroalkyl substances (PFAS) are a superfamily of fluorinated, anthropogenic chemicals used in numerous commercial and consumer products. Epidemiological and animal studies have linked exposure to PFAS to numerous adverse health outcomes, including diabetes, pancreatic β -cell dysfunction and oxidative stress. We have shown that exposure to several PFAS during embryonic development in zebrafish can disrupt transcription of genes involved with key pancreatic functions, corresponding to smaller and mis-shaped islets of Langerhans, truncation of the exocrine pancreas, dysregulation of lipids and digestive enzyme production, and insulin biosynthesis defects. To gain additional mechanistic insight into how PFAS can exert toxicity during early life, we used single-cell RNA-sequencing (scRNA-

Seq) to identify cell and tissue-specific transcriptomic responses to the PFAS legacy member, perfluorooctanesulfonic acid (PFOS), from 3-72 hours post. Findings indicated numerous tissue-specific differences in processes including apoptosis, cell division, epigenetic changes, and hormone secretion, and also identified potential causative pathways that may underlie disruptions to pancreatic development and function. Overall, this work illustrates the enhanced mechanistic understandings of PFAS toxicity that can emerge through integration of transcriptomic and organ-level assessments.

S 1013 Perfluorononanoic Acid Exposure and Light Conditions: A Dual Impact on Developing Eye and Brain Transcriptome in Zebrafish

S. Dasgupta. Clemson University, Clemson, SC.

Perfluorononanoic acid (PFNA) is a synthetic long chain homologue of PFAS which is frequently detected in environment as an emerging contaminant with potential threats to living organisms. It has broad applications in industrial and consumer products including adhesives, water and paint repellent surfaces, non-stick coatings and lubricants. We have shown that developmental exposures (2 h post fertilization to 5 days post fertilization) to PFNA induce significant changes behavioral phenotypes, and these phenotypic changes are strongly dependent on light exposure; incubations in complete dark result in hyperactivity, whereas 14 hr light: 10 hr dark incubations reverse this effect. Surprisingly, our LC-MS data showed that tissue uptake of PFNA was 3 times higher in 14 hr light: 10 hr dark incubations. To assess the impacts of PFNA x light on development of the brain and eye- organs that process light cues- we dissected these organs from PFNA-exposed fish and conducted mRNA sequencing. Our data show significant transcriptomic disruption in both organs with common affected pathways regulating steroid biosynthesis, fatty acid metabolism and PPAR, MAPK and P53 signaling in both light and dark incubations. Follow-up studies with Nile Red staining also showed higher lipid accumulation in PFNA exposures. However, several signaling pathways, such as Notch signaling in brain, were uniquely disrupted in dark incubations and not 14 hr light: 10 hr dark incubations. Collectively, these results suggest that neurotoxic effects of PFNA may be driven by lipid and metabolic disruptions that can be partially protected by circadian rhythms.

S 1014 Lipidomics Links PFAS Neurotoxicity with Mitochondrial Damage, Oxidative Stress, and Dopamine Alterations in Developing Zebrafish

J. Freeman. Purdue University, West Lafayette, IN.

Exposure to per- and polyfluoroalkyl substances (PFAS) has been associated with neurodevelopmental and neurodegenerative disease risk, particularly with changes along dopaminergic and associated pathways. Furthermore, dopamine alterations can occur from impacts to mitochondrial dysfunction, increased oxidative stress, and lipid disruptions; all of which are also implicated in PFAS toxicity. To further investigate mechanisms of PFAS neurotoxicity, developing zebrafish were exposed to select PFAS during embryogenesis [1-72 hours post fertilization (hpf)] at concentrations ranging from 0.004 to 40 ppb (µg/L). At 72 hpf PFAS exposure was ceased and zebrafish either prepared for assessments or allowed to develop until 120 hpf without additional PFAS exposure (i.e., in water only) for assessment. Multiple outcomes were investigated for potential neurotoxicity including lipidomics, mitochondrial distribution and membrane potential, oxidative stress, and alterations associated with dopamine. Biological results were anchored to toxicokinetic profiles of each PFAS to enhance understanding of body burden and comparative translation to other species. Results revealed exposure to select PFAS (e.g., PFOA) resulted in lipid changes associated with mitochondrial damage, oxidative stress, and dopamine signaling. Additional assays supported decreased mitochondrial distribution and membrane potential, an increase in reactive oxygen species and lipid peroxidation, and decreased dopamine concentrations. Overall, findings indicate mechanisms of PFAS developmental neurotoxicity related to increased oxidative stress, lipid disruption, impaired mitochondrial integrity, and dopamine loss.

S 1015 Developmental and Organ Toxicity of Emerging PFAS Compounds

N. Jayasundara. Duke University, Durham, NC.

Per- and polyfluoroalkyl substances (PFAS) and their byproducts pose a significant threat to both human and ecological health. Despite extensive research efforts, the adverse outcomes and mechanisms of toxicity for many emerging PFAS compounds, such as perfluoro-2-methoxyacetic acid (PFMOAA), remain poorly characterized. In this study, we used the zebrafish (*Danio rerio*) model to evaluate the developmental toxicity and nephrotoxicity of PFMOAA and four other compounds ubiquitously found in the Cape Fear River (CFR) in North Carolina—a major drinking water source for millions of residents and a site heavily contaminated with PFAS compounds. In addition to the individual compounds, we also assessed the developmental neurotoxicity of water samples collected from CFR. Our preliminary findings reveal that zebrafish exposed from 6 hours post-fertilization to 6 days post-fertilization to both Cape Fear River water samples containing PFAS mixtures and exposure to individual PFAS

chemicals results in larval mitochondrial dysfunction, altered neurobehavior, and proximal tubular damage in the kidney. Transcriptomic analyses comparing signatures across five PFAS compounds further underscore distinct and common molecular responses. Together, these results emphasize the critical impact of early-life exposures and highlight the need for further research into sensitive developmental endpoints to better assess the risks associated with environmentally relevant PFAS compounds.

S 1016 Zebrafish Developmental Screening of a PFAS Chemical Library

D. Phelps. US EPA/Oak Ridge Institute for Science and Education, Durham, NC.

Per- and polyfluoroalkyl substances (PFAS) are present in environmental matrices as well as many consumer and industrial products. While some PFAS, notably perfluorooctanesulfonic acid (PFOS), are developmentally toxic in mammals, the vast majority of PFAS have not been evaluated for developmental toxicity potential. A concentration-response study of 182 unique PFAS using the zebrafish (*Danio rerio*) medium-throughput, developmental toxicity assay was conducted to investigate chemical toxicity profiles. Embryos were exposed to each PFAS (= 100 µM) beginning on the day of fertilization and maintained at 26°C. At 6 days post-fertilization (dpf), two independent observers blinded to treatment graded developmental landmarks for each larva (e.g., mortality, hatching, swim bladder inflation, edema, abnormal spine/tail or craniofacial structure). Thirty percent of the PFAS were developmentally toxic, with swim bladder non-inflation the most sensitive toxic endpoint. Edema was also commonly noted, but usually secondary to swim bladder non-inflation and at higher concentrations. Moreover, the pattern of developmental landmark malformations did not appear to be dependent on PFAS structural category. PFOS was developmentally toxic in the low micromolar range, however other chemicals were more potent, including perfluorooctanesulfonamide, N-methylperfluorooctane sulfonamide, ((perfluorooctyl)ethyl)phosphonic acid, perfluoro-3,6,9-trioxatridecanoic acid, and perfluorohexane sulfonamide. The developmental toxicity profile for these more potent PFAS is largely unexplored in mammals and other species. Based on these zebrafish developmental toxicity results, additional screening may be warranted to understand the toxicity profile of these chemicals in other species. *This work does not reflect the official policy of the US EPA.*

S 1017 Efforts Toward Building Aligned Physiologically Based Kinetic Models for Thyroid Hormone Homeostasis in Rodents and Humans: Can We Develop "Supermodels"?

B. Riffle. BASF Agricultural Solutions, Wake Forest, NC.

Thyroid hormone (TH) homeostasis is regulated via the hypothalamic pituitary thyroid axis through a coordinated feedback system which alters synthesis of thyroxine (T4) and triiodothyronine (T3), metabolism, clearance, and elimination. In rodents, reductions of T4 and T3 concentrations by various molecular initiating events can result in rodent thyroid tumors that are of limited relevance to humans. However, investigations are ongoing to clarify the human relevance of reductions in THs (especially in rodent offspring) related to impaired neurodevelopment. Physiologically based kinetic (PBK) models are models that simulate biokinetics of a substance within the body by considering the physiological characteristics of pharmacokinetics and pharmacodynamics. Several thyroid PBK models have been developed to attempt to evaluate species differences in internal TH concentrations, TH transport, clearance, presence in brain, and organ-specific TH distributions and to predict effects of thyroid toxicants on hormone homeostasis in humans and rodents. This session explores the potential of developing an aligned PBK model for prediction of effects on thyroid homeostasis in humans following exposure to rodent thyroid toxicants by introducing the regulatory landscape regarding thyroid toxicants, evaluating some of existing individual thyroid PBK models, and concluding with a regulatory perspective on their potential application within the European Union hazard assessment process. The session will begin by introducing regulatory considerations regarding the use of rodent TH data for informing human health outcomes in both a risk- and hazard-based approach and then describing a project within CroPLife Europe exploring the feasibility of integrating existing models and approaches into an overarching mechanistic mathematical model platform, referred to as the "Supermodel," with an aim to represent all biological processes encompassed in the complete thyroid adverse outcome pathway (AOP) network. This will be followed by a presentation of a spatial human PBK model of THs accounting for the contribution of plasma binding proteins, followed by a presentation of a recent example of predictions of the effects in rat and humans using a PBK model for TH homeostasis following exposure to a liver enzyme inducer. A mechanistic modeling approach with a focus on TH receptor occupancy in the brain will next be discussed. The session will end with a presentation of the European regulatory perspective on PBK models, including potential challenges, as well as an overview of European-related work in projects such as the Partnership for the Assessment of Risks from Chemicals (PARC).

S 1018 Development of an Aligned PBK Model (aka the Supermodel) for the Prediction of Effects on Thyroid Homeostasis in Humans Following Exposure to Rodent Thyroid Toxicants

B. Riffle. BASF Agricultural Solutions, Wake Forest, NC.

Most of the data generated to support regulatory decisions regarding hazard identification and risk assessment of potential TH toxicants is generated from animal models including the rodent. Some effects, such as thyroid tumors, are thought to be species-specific due to physiological differences. However, significant alterations in circulating THs are thought to be related to adverse impacts on the neurodevelopment of rodent offspring and more information is needed to assess the human relevance of these findings in rodents. Several thyroid PBK models have been developed by individual Crop Life Europe (CLE) member companies to attempt to evaluate species differences in internal substance concentrations, TH transport, clearance, presence in brain, organ-specific TH distributions and to predict effects of thyroid toxicants on hormone homeostasis in humans and rodents. This presentation will introduce the concept of an integrated singular mechanistic mathematical model (otherwise known as "The Supermodel") that represents all biological processes encompassed in the complete adverse outcome pathway (AOP) network, including quantifiable species-specific parameters linked to specific molecular initiating events (MIEs) and key events (KEs) of the underlying AOP is envisioned where MIEs related to thyroid toxicity (direct or indirect), KEs, and adverse outcomes (AOs) related to developmental neurotoxicity (DNT) are captured. Validation of such a model will be discussed including comparisons of model predictions to rodent and human data. This effort could not only support a potential distinction in classification for rodent thyroid toxicants under the European Chemicals Agency (ECHA) classification process but also assist in risk assessment (relevant for countries with a risk-based approach like the United States) by better predicting human outcomes.

S 1019 Tissue Distribution of Thyroid Hormones by Plasma Binding Proteins and Alteration by Endocrine-Disrupting Chemicals

Q. Zhang. Emory University Rollins School of Public Health, Atlanta, GA.

The thyroid hormones (THs), thyroxine (T4) and triiodothyronine (T3), are under homeostatic control by the hypothalamic-pituitary-thyroid axis and plasma TH binding proteins (THBPs), including thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin (ALB). THBPs buffer free THs against transient perturbations and distribute THs to tissues. With a rigorously parameterized physiologically based kinetic (PBK) model of THs in humans, we explored the roles of different THBPs and how endocrine-disrupting chemicals (EDCs) may perturb TH homeostasis and tissue distributions. The model produces several novel findings. (1) The blood-tissue TH exchanges are fast and nearly at equilibrium especially for T4, providing intrinsic robustness against local metabolic perturbations that may be targeted by EDCs. (2) Continuous exposure to THBP-binding EDCs does not alter the steady-state levels of THs, while intermittent daily exposure to rapidly metabolized TBG-binding EDCs can cause much greater disruptions to plasma and tissue THs and their circadian rhythms. (3) Spatial gradients of TH transporters and metabolic enzymes may produce spatially heterogeneous TH tissue concentrations, which can be modulated by EDCs targeting these proteins. (4) Any of the 3 THBPs alone is sufficient to maintain the spatial patterns of TH tissue distributions, suggesting EDCs targeting THBPs will be ineffective at altering the spatial distribution of THs. In summary, the PBK model provides novel insights into TH kinetics and the homeostasis-disrupting effects of EDCs. Such insights into the spatial and temporal dynamics of THs and their interactions with EDCs are deemed a crucial component for the development of the "Supermodel".

S 1020 Toward a Modular Next-Generation Risk Assessment Ecosystem: A Case Study in Thyroid Disruption Modeling Across Species

S. Schaller. ESQlabs GmbH, Saterland, Germany.

Evaluating disruptions to thyroid hormones (TH), is challenging due to observed differences between human and animal responses. Nevertheless, chemical risk assessments continue to rely on animal studies, underscoring the need to mechanistically understand species-specific responses. This study presents a coupled physiologically based kinetic (PBK) quantitative systems toxicology (QST) platform for assessing disruption of TH regulation in both rats and humans, supporting the evaluation of chemicals by incorporating species specificity for key physiologic properties. An assessment use-case is presented using validated Uridine Diphosphate Glucuronosyltransferase (UDPGT) inducer Phenobarbital (PB) as a reference for assessing a new Pregnane X Receptor / Constitutive Androstane Receptor inducer (PI). The platform is built using the OSP Suite (PK-Sim and MoBi, version 12) and integrates PBK models of thyroid disruptors with QST modules for TH regulation and quantitative adverse outcome pathways (qAOP) modules for thyroid disruption. The QSP modules include pituitary synthesis of thyroid-stimulating hormone (TSH), feedback-controlled Triiodothyronine (T3) and Thyroxine (T4) synthesis, UDPGT-mediated clearance, circadian TSH regulation, and species-specific TH plasma protein binding (Albumin, Transthyretin (TTR), and Thyroxine-Binding Globulin (TBG)—absent in rats).

In rats, T3 clearance involves extensive glucuronidation and deiodination; in humans, T4 metabolism dominates, as well as distinct differences in transport proteins such as TBG. By integration of the PB and PI PBK models with the modular TD platform in an *in vitro* to *in vivo* extrapolation (IVIVE) approach, model assessment showed reduced risk for liver enzyme induction of PI vs PB. This PBK-QST platform exemplifies how a modular NGRA ecosystem enables the "Supermodel" concept. Modular PBK and QST/qAOP libraries allow rapid development, transparent reuse, and automated qualification of models across chemicals, species, and endpoints with shared pathways. Ultimately, this approach empowers regulatory engagement by delivering transparent, reproducible models, and traceable modeling workflows—critical for advancing NGRA as a reliable alternative to traditional toxicology.

S 1021 Modeling Developmental Toxicity via Thyroid Hormone Disruption: Dynamics in the Fetal Brain

J. Leedale. Syngenta Crop Protection LLC, Berkshire, United Kingdom. Sponsor: B. Riffle

Modeling developmental toxicity caused by thyroid hormone (TH) signalling disruption is a complex, multiscale challenge. It encompasses various temporal and spatial scales, from early-stage kinetics of TH-disrupting chemicals (TDCs) to whole-body TH regulation and local TH dynamics within specific tissues. When modelling potential toxicity in the developing brain, several factors must be considered: the effects of TDCs on circulating TH levels based on toxicokinetics and toxicodynamics; whether or not tissues with local regulation and significant biological barriers are resistant to external TH fluctuations; and, if foetal systemic TH levels are impacted, the potential impact on activity in the foetal brain. This study is focused on modelling TH dynamics in the foetal brain, aiming to understand how external TH fluctuations impact TH activity. Due to limited quantitative experimental data, a minimalist mathematical modelling approach has been adopted that incorporates the essential TH feedback mechanisms that maintain homeostasis. Multiple approaches were utilised for model building and validation, including novel neurosphere experiments; read-across from other *in vitro* and *in silico* models; sensitivity analysis and uncertainty quantification; and indirect parameterisation to recapitulate observed phenomena. The model was coupled to a pregnancy Physiologically Based Kinetic (PBK) model to fully explore the multiscale impact of TDCs on foetal brain activity, including mechanisms for placental transfer and regulation of circulating TH in rats. Further downstream applications of the dynamic foetal brain TH model such as specific localisation (e.g., astrocytes, neurons), and protein-mediated transport across the blood-brain barrier can be incorporated or adapted to increase physiological relevance. This model can be a crucial component for the development of the "Supermodel" by contributing to understanding the complex interplay of factors affecting TH signaling in foetal brain development and potential developmental toxicity caused by TDCs.

S 1022 Considerations When Developing Thyroid PBK Models for Regulatory Application: A Perspective from the European Union

P. Marx-Stoelting. Bundesinstitut für Risikobewertung (BfR), Berlin, Germany. Sponsor: B. Riffle

Many compounds affect the thyroid via distinct mechanisms. While a few directly interact with TH (T3, T4) synthesis via the thyroid peroxidase (TPO), many others trigger their effects indirectly via hepatic enzyme induction and increased clearance of T3 and T4. This indirect induction may be different in several species and findings e.g. in rodents may not fully be relevant for humans. Besides the differences in enzyme induction as differences in buffering T3/T4 hormone levels via TH binding globulins (TBG) accounts for pronounced species discrepancies. The intended talk will illustrate such differences upon examples from *in vivo* and *in vitro* studies and in doing so highlight challenges and benefits in the development of an aligned PBK model in addressing substance induced changes in T3/T4 hormone metabolism. The talk will also highlight some general regulatory requirements on PBK models and point out related EU work in projects such as Partnership for the Assessment of Risks from Chemicals (PARC). This perspective will emphasize the importance of aligning PBK models with regulatory needs and discuss how integrating them into a "Supermodel" framework can support hazard and risk assessment.

S 1023 Micro/Nanoplastics, Plastic-Associated Endocrine-Disrupting Chemicals, and Cardiovascular Disease

M. Campen. University of New Mexico, Albuquerque, NM.

Cardiovascular disease (CVD) is the leading cause of mortality and morbidity worldwide despite major advances in diagnoses and treatments in the past few decades. Plastics are fundamental in modern life and have recently been implicated in the etiology of CVD. Plastic-associated endocrine-disrupting chemicals (EDCs), including numerous base chemicals and phthalate plasticizers, are produced in high volume and are consistently associated with the increased CVD risk in large-scale cross-sectional and longitudinal human studies. As plastics age and degrade, they become progressively smaller and more highly oxidized on the surface, leading to the gener-

ation of ubiquitous micro/nanoplastics (MNPs). Emerging evidence demonstrates the accumulation of MNPs in human arteries and carotid artery plaque that may lead to increased cardiovascular events in exposed individuals. Although the associations between MNP and EDC exposures and CVD risk have been well-documented and attracted considerable public attention, the clinical impact and mechanistic insights of MNP/EDC exposures on cardiovascular health remain elusive. Thus, the following presentations provide epidemiological and clinical evidence for these associations and preclinical animal model and mechanism-based evidence for MNP/EDC-elicited CVD: (1) "Plastics: A Threat to Health Across the Lifespan and What We Can Do About It"; (2) "Effects of Plastic-Associated EDCs and Microplastics on Lipid Metabolism and Atherosclerosis"; (3) "Prevalence and Implications of Heightened Plastic Chemical Exposure on Cardiac Health"; (4) "Oral Microplastics Consumption and Atherogenesis"; and (5) "Micro/nanoplastics Impact in Clinical Vascular Disease: From Carotid to Aorta and Beyond." This Symposium brings epidemiologists, clinicians, and translational and basic scientists together to discuss the risks of environmental exposures to MNPs and EDCs on cardiovascular health and will address the critical knowledge gap by providing mechanistic insights explaining how MNP/EDC exposures cause CVD. The Symposium will facilitate collaborations and discussions among investigators in different disciplines targeting this emerging issue.

S 1024 Plastics: A Threat to Health Across the Lifespan and What We Can Do About It

L. Trasande. NYU Grossman School of Medicine, New York, NY. Sponsor: *M. Campen*

From cradle to grave and womb to tomb, plastics and related chemicals and micro- and nanoplastics present serious health concerns. Plastics contribute substantially to disease and associated social costs globally. In the United States, we estimated \$249 billion in health costs for plastic-attributable disease burden in 2018 alone. Globally, 13.5% of all CVD deaths (>350,000 deaths) in 2018 among people ages 55-64 could be attributed to plastic-associated phthalate exposure. The economic burden from the identified CVD deaths was estimated from \$510 billion to \$3.74 trillion. This presentation will present toxicologic and epidemiologic evidence with a focus on cardiometabolic outcomes, and identify US and global policy steps for action.

S 1025 Effects of Plastic-Associated EDCs and Microplastics on Lipid Homeostasis and Atherosclerosis Development

C. Zhou. University of California Riverside, Riverside, CA.

Several ubiquitous plastic-associated EDCs (e.g., base chemical bisphenol A [BPA], phthalates) have been associated with increased CVD risk and atherosclerosis development in humans. We identified many plastic-associated EDCs including BPA, its analogs, phthalate plasticizers, and FDA-approved phthalate substitutes as potent agonists for the nuclear receptor pregnane X receptor (PXR). PXR functions as a xenobiotic sensor regulating key genes involved in xenobiotic metabolism. We recently revealed the novel function of PXR in the regulation of lipid metabolism and atherosclerosis development, and demonstrated that several plastic-associated EDCs increase atherosclerosis and dyslipidemia in a PXR-dependent manner in suitable mouse models. For example, we identified BPA as a human PXR-specific agonist and chronic exposure to BPA led to increased atherosclerosis in the PXR-humanized mice. An understudied phthalate, dicyclohexyl phthalate (DCHP), can also activate PXR and cause dysregulated lipid homeostasis and increased atherosclerosis in mouse models. In addition to EDCs, we also found that exposure to microplastics led to significantly increased atherosclerosis in the LDL receptor-deficient mice. Single cell RNA sequencing analysis of the whole aorta revealed that microplastic exposure affected the proportions and cellular processes of key cell types involved in atherosclerosis development. These results reveal the atherogenic effects of plastic-associated EDCs and microplastics *in vivo* and provide mechanistic insights contributing to our understanding of EDC or EDC-carrying microplastic-elicited atherogenesis.

S 1026 Prevalence and Implications of Heightened Plastic Chemical Exposure on Cardiac Health

D. Guerrelli, and N. Posnack. Children's National Hospital, Washington, DC.

Phthalate chemicals are used to manufacture disposable plastic medical products, including blood storage bags and components of cardiopulmonary bypass circuits. As such, cardiac surgery patients may be inadvertently exposed to phthalate chemicals that are released from these plastic products. In this study, we quantified phthalate chemical exposure in patients undergoing cardiac surgery, examined associations to postoperative complications, and measured the direct effects of phthalates using experimental cardiac models. In pediatric cardiac surgery patients, the degree of phthalate exposure increased in the context of cardiopulmonary bypass with red blood cell (RBC) priming. Patients with heightened phthalate exposure more commonly experienced postoperative complications, including cardiac arrhythmias, low cardiac output, and hypotension. The cardiodepressive effects of phthalates

were validated using both animal and hiPSC-CM models, demonstrating dose (10-100 µg/ml) and time-dependent (15min-3 hour) slowing of heart rate, atrioventricular conduction, and conduction velocity. We demonstrate that phthalate chemical exposure can be (partially) mitigated by using "fresh" RBCs with a shorter storage duration, storing RBCs in alternative blood bags with reduced phthalate leaching, or washing RBCs to remove extracellular contaminants.

S 1027 Oral Microplastics Consumption and Atherogenesis

T. O'Toole. University of Louisville, Louisville, KY.

Small plastic particles of the micro- and nano- sizes are common environmental contaminants and human exposure to these particles (MNP) through inhalation, ingestion or absorption is inevitable. While MNP have now been identified in human vascular and cardiac tissues, and their abundance in these tissues has been correlated with adverse outcomes, their direct involvement in the genesis or progression of cardiovascular disease (CVD) is uncertain. To begin to address this issue, we examined CVD risk and atherosclerotic lesion development in chow-fed ApoE^{-/-} mice supplied with normal water (control) or that containing polystyrene (PS) beads (0.5mm; 1mg/ml) for 20 weeks. At this time we found that mice drinking the PS water had a statistically significant higher level of plasma glucose versus control (1.3-fold). Furthermore the average lesion area in the PS-exposed mice was greater than that in the control mice (0.81mm² vs. 0.57mm²; p=0.01). In related experiments, we supplied additional ApoE^{-/-} mice with a Western diet and normal water (control) or that containing a combination of polyethylene (0.065mm; 2.5ng/ml) and polyvinyl chloride (0.25mm; 200ng/ml) (PE+PVC) beads for 6weeks. These PE+PVC mice likewise demonstrated increased blood glucose (1.2-fold) and lesion area (0.16mm² vs. 0.11 mm²; p=0.02) versus the control mice. These results suggest that exposure to MNP may directly contribute to the development of overt CVD. The mechanistic possibilities and implications of these results will be discussed.

S 1028 Micro/nanoplastics Impact in Clinical Vascular Disease: From Carotid to Aorta and Beyond

R. Clark. University of New Mexico, Albuquerque, NM. Sponsor: *M. Campen*

Micro/nanoplastics (MNPs) in human tissues are recently recognized and the clinical effects have not yet been fully elucidated. Recent reports have associated carotid atherosclerotic plaque MNPs, immune cell deposition and poor long-term clinical outcomes. Investigations detailing MNPs in symptomatic carotid disease, aortic and peripheral artery disease (PAD) lesions are lacking. We examined whole carotid plaques as well as vessel tissue from aortic aneurysm, aortoiliac atherosclerotic occlusive disease and femoral artery plaques and compared them to age-matched control non-atherosclerotic arteries of all types from fresh cadaveric donors. Quantitative MNP concentrations were determined by pyrolysis-GC/MS and qualitative features by electron microscopy. Mean MNP concentrations in control carotid arteries were 57 µg/g. Plaques from subjects with asymptomatic carotid stenosis had significantly more MNPs with mean 895 µg/g (+16 fold, P<0.001) and those from symptomatic carotid stenosis had the highest MNP concentrations at 2888 µg/g (+51 fold, P<0.001). Mean MNPs in femoral plaques was 212 µg/g, compared to 1904 µg/g in atherosclerotic aortic tissue. Aneurysmal aortic tissue demonstrated 943 µg/g compared to 268 in control aortic tissue. Polyethylene and polypropylene were the most common polymers in all vessels and lesions. Single cell RNA sequencing of carotid lesions reveals alterations in pathways related to cellular stress (FKBP5), cytoskeletal organization (TPM1 and HIP1R) and anti-inflammation (CD163) in mesenchymal stem cells and macrophages without association with acute inflammatory markers TNF-alpha and IL-6. These data provide the first evaluation of the clinical effects of microplastics in carotid atherosclerotic plaques, aortic aneurysm tissue, aortic atherosclerotic plaque and femoral artery plaque and demonstrate a clear association with symptom status and specific vascular pathology in multiple vascular beds. The association of MNPs with altered gene expression in plaque mesenchymal stem cells (MSCs), which modulate immune signaling and plaque stability, suggests one possible mechanism by which MNPs influence atherosclerosis development and progression.

W 1029 Cancer Risk from Womb to Progeny Generations: Windows of Susceptibility and the Multigenerational Legacy of Environmental Exposures

X. Hu. Emory University, Atlanta, GA.

Early life environmental exposures are increasingly recognized as critical drivers of long-term health outcomes, including the risk of breast cancer and reproductive and developmental disorders. A growing body of human and mechanistic research shows that the health consequences of exposures can extend far beyond the directly exposed individual, impacting children, grandchildren, and even great-grandchildren through intergenerational and transgenerational transmissions. From metabolic reprogramming to persistent epigenetic modifications, ancestral exposures can shape disease susceptibility across lifespans and lineages, raising urgent questions

for regulatory policy and public health intervention. This session brings together a uniquely diverse panel of experts, which span epidemiology, mechanistic toxicology, epigenomics, public health advocacy, regulatory science, and the history of chemical industries, to examine how environmental exposures during sensitive developmental windows shape the health of future generations. Presenters will draw on landmark multigenerational cohorts, cutting-edge 'omics tools, and real-world case studies that elucidate sex-specific vulnerabilities, molecular mechanisms of inherited risk, and historical patterns of challenges in risk assessment and regulation. A special focus will be placed on the rising incidence of early onset breast cancer and emerging evidence linking both maternal and paternal exposures during pregnancy and fetal development to later-life cancer risk. This Workshop will begin with a brief introduction to the key principles and research tools used in developmental reprogramming and multigenerational inheritance. It will then feature five in-depth presentations: (1) epidemiology findings from a 60-year cohort tracking exposures, cancer, and reproductive outcomes; (2) epigenomic mechanisms linking ancestral exposures to developmental and cancer risk; (3) regulatory insights and gaps revealed through the study of endocrine-disruption mechanisms; (4) a funder's view on advocating transdisciplinary and community-based driven breast cancer prevention; and (5) what history can teach us about modern chemical regulation and cancer prevention. Panelists include a system biologist integrating multi-omic and transdisciplinary approaches to study early life exposure; a reproductive epidemiologist leading a multi-decade, multi-generational cohort; a molecular biologist discovering the epigenetic basis of inherited disease risk; a toxicologist instrumental in shaping national policy on endocrine-disrupting chemicals; a program director funding transdisciplinary and community-driven research; and a historian tracing the legacy of industry influence on environmental regulation. Together, their voices represent academic, governmental, community, and historical reflections on a complex and pressing issue. The session will conclude with a highly interactive panel discussion inviting the audience to engage on shared challenges, research gaps, and opportunities for coordinated action across sectors. By centering breast cancer and developmental health within a generational framework, this session seeks to reframe prevention as a multigenerational responsibility—and a scientific, regulatory, and societal imperative.

W 1030 Multigenerational Clues to the Rise in Early Onset Breast Cancer

B. Cohn. Public Health Institute, Berkeley, CA. Sponsor: X. Hu

The alarming rise in early-onset breast cancer demands a deeper understanding of its origins across time. The Child Health and Development Studies (CHDS), a landmark three-generation cohort, offers an unprecedented opportunity to trace how *in utero* and pregnancy exposures shape breast cancer risk not only in daughters, but also in granddaughters. Leveraging archived maternal and paternal serum samples collected during pregnancy in the 1960s, CHDS examines windows of susceptibility spanning gestation, fetal development, and even the ancestral germline. This presentation will highlight emerging findings from multi-omics approaches, including exposomics, metabolomics, and epigenomics. Results point to dynamic and sex-specific risk patterns, demonstrate the transmission of health risks along both maternal and paternal lineages, and underscore how environmental exposures can leave molecular imprints that persist into future generations. Together, these data provide powerful insights into the shifting landscape of breast cancer risk and inform a new paradigm for personalized prevention that begins long before diagnosis—and sometimes, even before birth.

W 1031 Epigenetic Memory: How Ancestral Exposures Echo Through Generations

J. LaSalle. University of California Davis, Davis, CA. Sponsor: X. Hu

DNA methylation in newborn blood provides a stable, high-resolution record of early-life environmental exposures, offering powerful insight into long-term disease risk. Unlike transient transcriptional changes, methylation marks capture durable epigenetic programming at the interface of genome and environment. This talk highlights the application of whole-genome bisulfite sequencing (WGBS) and the Comethyl network framework to integrate DNA methylation with exposure and health outcome data in both human and animal models. Methylation patterns in placental and newborn blood have been linked to prenatal exposures—including PCBs, phthalates, pesticides, bisphenol A, air pollution, and maternal smoking—all associated with increased cancer and neurodevelopmental risk. Cross-species analysis reveals convergence at key loci implicated in both autism spectrum disorder (ASD) and cancer. New findings also show that DNA methylation networks in F2 newborns are associated with ASD diagnoses and grandparental age and exposures, supporting the feasibility of using multigenerational bloodspots to trace exposome-metabolome-methylome connections to early-onset and heritable cancer risk.

W 1032 Born Vulnerable: What Dioxins and PFAS Teach Us About Chemical Regulation

L. Birnbaum. Duke University, Durham, NC.

Environmental exposures during critical windows of development can shape lifelong health trajectories and, in some cases, impact the health of generations yet unborn. Drawing on decades of research in toxicology and environmental health, the presentation will discuss how early-life exposures to endocrine-disrupting chemicals (EDCs) like dioxins, per- and polyfluoroalkyl substances (PFAS), phthalates, and bisphenol A can disrupt developmental programming during critical window of susceptibility, leading to long-term consequences for reproductive health, immune function, metabolism, and cancer risk. The talk will also draw lessons comparing regulatory efforts on dioxin-like chemicals and PFAS. Dioxins-like chemicals were unwanted byproducts but have been managed through a regulatory framework based on a single receptor. In contrast, PFAS present new challenges due to their complex mechanisms of toxicity and useful applications, which cause resistance to regulation. The comparison underscores the need for innovative regulatory approaches that move beyond chemical-by-chemical assessments.

W 1033 Catalyzing Solutions: A Funder's Perspective on Advancing Environmental Breast Cancer Research and Advocacy

S. Rasanayagam. California Breast Cancer Research Program, Oakland, CA. Sponsor: X. Hu

For over 25 years, the California Breast Cancer Research Program (CBCRP) has led a bold and community-centered approach to understanding and preventing breast cancer, particularly as it relates to environmental exposures. This talk will highlight CBCRP's role as a funder and convener of transdisciplinary research that bridges academia, government agencies, industry, and patient advocacy groups. By supporting investigator-initiated research alongside community-driven projects, CBCRP has advanced knowledge on environmental risk factors—including endocrine-disrupting chemicals, air pollution, and occupational exposures—and how these intersect with social determinants of health and systemic inequities. Key scientific accomplishments include cohort studies that have led to important insights on transgenerational impacts of exposure, collaborative studies identifying windows of susceptibility (including early life, adolescence and pregnancy), mechanistic insights from animal and human models, and innovative biomonitoring methods. The presentation will also discuss how CBCRP's investments have supported multigenerational research, led to policy-relevant findings, built sustained research-community partnerships, and helped shape national dialogues on breast cancer prevention and public health intervention.

W 1034 How to Sell a Poison: A Cautionary Tale for a Safer Tomorrow

E. Conis. University of California Berkeley, Berkeley, CA. Sponsor: X. Hu

To this day, many in the United States recall the 1950s as the height of the era of "better living through chemistry." But it was also the moment when much of the U.S. public became concerned that the growing number of synthetic chemicals in soil, water, air, food, and other consumer products were doing more harm than good. That meant it became, in turn, a time when the nation's chemical industry honed a set of tactics to defend their bottom lines: denying unfavorable evidence about the risks associated with their products, distracting public attention away from such evidence, and producing their own countervailing evidence. This presentation uses the case study of the history of the pesticide DDT to explore how corporate tactics evolved over the course of half a century to defend not just specific chemicals or classes of chemicals but production of consumer goods generally that exposed humans to a broad range of chemical components. Eventually, these strategies evolved to incorporate deliberate dissemination of disinformation, laying the groundwork for the widespread erosion of public trust in science we see today. Even more importantly, these strategies shaped the production and public reception of scientific knowledge in ways that actively undermined regulatory advances from the 1970s onward, as scientific understanding of the nature of risk posed by chemical exposures expanded to encompass concepts like endocrine disruption and other new mechanisms of carcinogenicity.

W 1035 Environmental Exposures and Pulmonary Fibrosis: What Do We Know and Where Do We Go?

E. Corteselli. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Exposure to ambient air pollutants has long been known to contribute to the pathogenesis of respiratory diseases such as asthma, chronic obstructive pulmonary disease (COPD), and cancer. However, there has been historically less focus on the role of environmental exposures in the context of interstitial lung diseases (ILD). ILD encompasses different subtypes, often classified based on the causative agent, and include treatment-induced (chemotherapy, radiation), occupational exposure-related

(dusts, fibers, and fumes), and autoimmune. If no causative agent can be identified, the disease is classified as "idiopathic pulmonary fibrosis (IPF)," which is currently the most common type of ILD. IPF is a devastating disease, with a median survival of three-five years after diagnosis, few effective therapeutic options, and potential for exacerbations with a high mortality rate. There is a growing body of evidence that demonstrates the contributions of environmental exposures to IPF. This includes epidemiological studies that have found increased risk of disease incidence, progression, and exacerbations associated with levels of ambient air pollutants, particularly ozone, particulate matter, and nitrogen oxides. This association is not surprising considering many of the initiating molecular events thought to be involved in IPF are also known to be caused by exposure to air pollutants, including oxidative stress, airway epithelial cell injury, and telomere shortening. Mechanistic studies in animals and *in vitro* models have interrogated the link between exposure to ambient air pollutants and fibrotic phenotypes, finding evidence of lung remodeling, airway epithelial cell dysfunction, and fibroblast activation. Further, the interplay between environmental exposures and genetic predisposition has been recently appreciated, and it has been suggested that exposure to air pollutants in genetically susceptible individuals drives the incidence and progression of IPF. Thus, environmental exposures are of concern to the IPF community, and a greater understanding of the types of exposures and mechanisms by which they influence disease pathogenesis is needed. This Workshop focuses on presenting the current state of knowledge regarding the role of environmental exposures in fibrotic lung disease. Experts will provide insight into the epidemiological evidence linking air pollutants to IPF and the potential mechanisms by which this may occur and will discuss genetic factors that may predispose individuals to development or exacerbation of IPF following environmental exposures. The goals of this session are to highlight research in this emerging area, identify knowledge gaps, and encourage discussion and collaboration among epidemiologists, basic scientists, and clinicians to engage in a multidisciplinary approach to better understand this public health issue.

W 1036 Unmasking Environmental Factors in Interstitial Lung Disease

C. Sack. University of Washington Seattle, Seattle, WA. Sponsor: E. Corteselli

Dr. Cora Sack will review the evidence demonstrating that exposure to air pollution may be a modifiable environmental risk factor for the incidence, progression, and mortality of interstitial lung disease (ILD). Her talk will focus on the short- and long-term impacts of air pollution exposure in ILD and explore potential biologic mechanisms, including epigenetic changes and gene x environmental interactions.

W 1037 Air Pollution Fuels Progressive Pulmonary Fibrosis

J. Larson-Casey. University of Alabama at Birmingham, Birmingham, AL.

Epidemiological evidence indicates that exposure to particulate matter is linked to the development of idiopathic pulmonary fibrosis (IPF) and increases the incidence of acute exacerbations of IPF (AE-IPF). In addition to accelerating the rate of lung function decline, exposure to fine particulate matter (PM2.5) is a risk factor for increased mortality in IPF subjects. Exposure to PM2.5 in mice with established pulmonary fibrosis led to monocyte recruitment and fibrotic progression. In mice with established fibrosis, bronchoalveolar lavage cells showed monocyte/macrophage heterogeneity after exposure to PM2.5. These cells had a significant inflammatory and anti-inflammatory signature. The mixed heterogeneity of cells contributed to the pro-inflammatory and anti-inflammatory response. Although monocyte-derived macrophages were recruited to the lung in bleomycin-injured mice treated with PM2.5, recruitment of monocytes expressing Ly6Chi to the lung resulted in progression of fibrosis, reduced lung aeration, and reduced lung compliance. Ly6Chi monocytes isolated from fibrotic mice exposed to PM2.5 showed enhanced expression of proinflammatory markers compared to fibrotic mice exposed to vehicle. Therapeutically targeting Ly6Chi monocytes inhibited fibrotic progression in mice after PM2.5 exposure, while the adoptive transfer of Ly6Chi monocytes exacerbated established fibrosis. These observations suggest that enhanced recruitment of Ly6Chi monocytes with a proinflammatory phenotype mediates acute exacerbations of pulmonary fibrosis, and targeting these cells may provide a novel therapeutic target to protect against AE-IPF.

W 1038 Ozone, Diabetes, Obesity, and Pulmonary Fibrosis: Is There a Link?

R. Tighe. Duke University, Durham, NC.

Ozone (O₃), a significant component of air pollution, is associated with increased respiratory-related hospital and emergency room visits and elevated overall morbidity and mortality rates. Despite efforts to reduce O₃ exposures, ambient levels continue to escalate globally, posing a substantial public health hazard. Addressing this requires focus on mechanism(s) of O₃-induced host-responses to target with precision in susceptible individuals. While susceptibility has traditionally been attributed to host genetics, recent evidence suggests that co-existing metabolic conditions, such as diabetes and obesity, also play a critical role in influencing sensi-

tivity to air pollution. Given their increasing prevalence, defining the mechanisms by which pre-existing metabolic conditions enhance O₃ sensitivity will focus urgent public health interventions. Epidemiology and rodent studies demonstrate that O₃ exposure exacerbates the incidence and severity of metabolic conditions such as diabetes and obesity. However, it remains less clear whether pre-existing metabolic disorders amplify the severity of O₃-induced inflammation. This presentation will highlight recent evidence suggesting that ozone exposure in diabetic/obese rodent strains drives lung injury and fibrosis and define a mechanism via the impact of adipokine signaling.

W 1039 Pattern Recognition Receptors in Environmental Exposure-Mediated Pathogenesis and Exacerbations of Fibrotic Lung Disease

S. Hussain. West Virginia University, Morgantown, WV.

Environmental exposures are known triggers for exacerbations of fibrotic lung disease. However, their role in disease development and the molecular mechanisms by which they induce exacerbations remain poorly understood. Understanding these mechanisms and pathways can potentially identify novel therapeutic targets. Pattern recognition receptors are an essential component of the innate immune system and play a significant role in the pathogenesis of pulmonary disorders. Over the past decade, we have studied the role of toll-like receptors and Nod-like receptors in the context of environmental exposures and chronic pulmonary disorders, including fibrotic lung disease. In this presentation, novel data demonstrating the role of toll-like receptor 5 (TLR5) and Nod-like receptor X-1 (NLRX1) in the development and exacerbation of pulmonary fibrosis will be presented. We will provide functional, biochemical, and histological characterization of the role of these receptors using organoids and whole-body/cell-type-specific knockout animals, as well as in a human cohort. Finally, evidence of the therapeutic benefit of targeting these receptors in the fibrotic disease will be presented. In summary, in addition to providing the mechanistic role of these receptors in the pathogenesis of fibrotic lung disease, it will provide information on the novel therapeutic targets for fibrotic lung disease in the context of environmental exposure-induced exacerbations.

W 1040 Gene-by-Environment Interactions with Ozone-Induced Fibrosis in the Mouse Collaborative Cross Strain CC002/Unc

G. Smith. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Ozone (O₃) exposure exacerbates and worsens outcomes for people with fibrotic interstitial lung disease (fILD) and evidence from rodent and non-human primate studies show that repeated O₃ exposure causes fibrotic changes in the lung, consistent with fILD. However, there is insufficient epidemiological data to establish a link between O₃ and new onset fILD. Most cases of fILD are thought to be caused by the interplay of genetic and environmental factors (GxE). A thorough understanding of underlying GxE will allow for identification of O₃-exposed individuals at most risk for developing fILD. Compared to methods for studying GxE in humans, GxE studies using rodent models are both more tractable and powerful. However, such studies are limited. In this talk we will describe an investigation of GxE using CC002/Unc (CC002), a strain of the mouse Collaborative Cross (CC) predisposed to O₃-induced pulmonary fibrosis. We found that following a relatively low concentration (0.8 ppm O₃) and short exposure paradigm (4h per day for 9 days), CC002 mice develop an aberrant and exaggerated pulmonary eosinophilic inflammation and centriacinar fibrotic lesions. We identified genetic loci underlying CC002's unique inflammatory and fibrotic responses by phenotyping a population generated from backcrosses of CC002 and a low responding CC strain, CC005/TauUnc and conducting quantitative trait loci (QTL) mapping of BAL eosinophil frequency and fibrosis related gene (Col1a1 and Tgfb1) expression quantification across ten batches of backcross mice (n = 304). For O₃-induced eosinophil frequency, we identified five QTL (Oief 1-5), including a QTL of large effect (Oief 4) on chromosome 11 accounting for 18% of phenotypic variation and encompassing 345 protein coding genes. Additionally, the talk will further highlight the process of prioritizing six candidate genes at Oief 4 based on a tabulation of coding and regulatory variants in CC002, prior annotations in the Mouse Genome Informatics database, and known roles in innate immunity, inflammation, and wound healing/fibrosis. In total, our data demonstrates the use of the O₃-sensitive CC002 strain as a new model for studying the adverse respiratory health effects of O₃ such as fILD. Further genetic and functional analysis of the candidate genes we identified using CC002/Unc will provide new insights on the mechanisms of O₃-induced fILD.

L. Anger. Genentech Inc., South San Francisco, CA.

The future of preclinical research is being reshaped by the convergence of innovation, technology, and scientific rigor. This evolution in preclinical research parallels the adoption of digital measures like wearable sensors and artificial intelligence (AI)-powered monitoring in clinical settings, providing a foundation for building a translational bridge and connecting preclinical studies with clinical outcomes. Broader adoption in preclinical toxicology and safety assessment requires building confidence through validation, addressing data security, and navigating regulatory acceptance. This session explores how AI and digital measures are poised to transform *in vivo* studies, enhancing data quality and reproducibility and enabling real-time, noninvasive assessments. The session will showcase examples of real-world applications of these novel technologies in tolerability/safety studies, efficacy studies, and behavioral neurotoxicology studies. Rapid advances in AI and noninvasive sensor technologies offer unprecedented opportunities to monitor health and disease in animal studies. These technologies, including AI-supported home cage monitoring systems, provide a more precise, cost-effective, and objective alternative to traditional observations. This enables more thorough assessments of therapeutic tolerability and earlier detection of adverse events and supports advancement of the 3Rs (replacement, reduction, and refinement) by improving detection of health and welfare events. Importantly, digital measures can also enhance the translational relevance of preclinical studies by providing more human-relevant, continuous, and objective data. Ultimately, by capturing richer insights from each study, this may reduce the need for repeat or additional studies, helping to lower overall animal use over time. Commercially available systems or in-house developed platforms integrate video capture and other sensors in the home cage to generate detailed measurements of behavior and physiology. These systems offer solutions to issues of reproducibility and subjective measurements in preclinical *in vivo* experimentation by enabling continuous monitoring and reducing natural human bias and, at times, the stress and variance introduced by human influence. The application of machine learning to the extensive data collected can predict potential liabilities of compounds and accurately reflect the onset and severity of symptoms in wild-type or disease models. At the same time, these digital caging technologies will advance computational toxicology research to the next level by providing detailed, real-time data on animal behavior and physiology, enabling the development of more predictive models of toxicity and improving the overall accuracy of risk assessments. This session will provide insights into important contributors to a roadmap for integrating AI-powered digital tools into preclinical research. Experts will share a validation framework for establishing analytical and clinical confidence in digital measures and outline strategies for their integration into preclinical and clinical research. There is a critical need for active efforts toward alignment with regulatory authorities to support the integration and eventual acceptance of digital measures in regulatory filings. Open collaboration and early communication between preclinical and clinical communities, as well as with regulators, are essential to ensure these tools are developed and validated in a way that meets regulatory expectations. Speakers will provide learning objectives, discuss validation strategies, data security, translational decision-making, and regulatory engagement, highlighting how collaborative efforts across preclinical and clinical research and across sectors can establish confidence in digital measures and ensure their suitability for broad adoption. The session will conclude with a panel discussion expanding on these essential topics, including strategies for building confidence and navigating regulatory acceptance.

W 1042 Digital Opportunities in Toxicology and Safety Assessment

B. Berridge. B2 Pathology Solutions LLC, Cary, NC.

Rapid advances in Artificial Intelligence (AI) and non-invasive sensor technologies are offering unprecedented opportunity to monitor health and disease in animal studies. These technologies are increasingly used in academic settings (particularly in neurobehavioral research) but are also finding their way into the more standardized and regulated practice of drug safety and environmental hazard assessment. Precedent adoption of digital health measures in the form of "wearables" in the clinical setting provides the foundation for building a more translational and predictive bridge from preclinical studies to clinical outcomes in patients. A growing portfolio of digital measures that may serve as biomarkers of toxicity can increase the sensitivity of our studies for identifying patient-relevant liabilities, provide insights into the onset and progression of those liabilities, and be translated to the clinics to mitigate those risks. This presentation will provide an introduction and overview of AI-supported, digital sensor-based, invasive and non-invasive technologies that are being applied to animal studies in and outside the home cage environment. It will represent those technologies in the context of usual approaches to drug safety assessment, identify specific application opportunities, recognize challenges to their adoption (e.g. data management, data security, costs, etc.), and share vignettes of the efforts of a multi-disciplinary, multi-sector collaboration (the Digital In Vivo Alliance - DIVA) aimed at building capabilities and an ecosystem to support the application of digital measures and biomarkers. Additionally, it will explore approaches to building confidence in these novel measures in a regulated setting applying a framework for analytical and clinical validation. Also, it will discuss the importance of and approaches to engagement with regulatory stakeholders.

W 1043 Improved Toxicity Screening for New Therapeutics Through Use of Machine Learning and Home Caging Systems

C. Lutz. The Jackson Laboratory, Bar Harbor, ME. Sponsor: L. Anger

The Jackson Laboratory is a non-profit research institute with a large program in preclinical development through the Rare Disease Translational Center. Detecting adverse events in therapeutics during the preclinical stages of drug development is a crucial step in minimizing risks and advancing new products to clinical trials. Typically, the initial tolerability assessment of small molecules and biologics takes place in mouse models during efficacy evaluations. Promising therapeutics are then progressed to more expensive manufacturing and toxicology phases of IND enabling studies, which involve the use of rats, pigs, or non-human primates. While acute toxicity can be identified through urine and biomarkers, as well as pathological examination of organs, subtle signs of intolerance are often overlooked during traditional cage side observations. These technician based observations typically monitor changes in behavior, gait, posture, and response to handling. In this case study, we will demonstrate that utilizing automated home cage monitoring systems equipped with cameras and machine learning tools provides a more precise, cost-effective, and objective alternative to conventional cage side observations. Our monitoring systems and developing software have been integrated into studies involving mice, revealing dose-dependent alterations in behavior and physiology in response to treatment challenges. Our home cage machine learning systems allow for more thorough assessments of therapeutic tolerability at an earlier stage in the drug development process, saving time and dollars. The continuous 24-hour monitoring in the animals' home cage environment eliminates stressors like technician handling, sleep disruptions, and subjective technician-driven assessments, addressing the need for enhanced rigor and reproducibility in preclinical studies. Improving the translational relevance of toxicology assessments can reduce the reliance on larger species and the overall use of animals in preclinical studies, addressing both ethical and cost savings. Importantly, our home cage monitoring systems enhance the detection of adverse events before they progress to clinical trials, ultimately improving the safety profile for patients.

W 1044 Smart Cages, Smarter Insights: Advancing Preclinical Pharmacology and Toxicology with AI-Enabled Digital Biomarkers

M. Potter. Sanofi, Cambridge, MA. Sponsor: L. Anger

Sanofi has made a bold commitment to become the first pharmaceutical company powered by AI at scale. This initiative is a key part of Sanofi's long-term modernization and digital leadership strategy. A comprehensive and translational digital biomarker strategy for preclinical studies, supporting our vast pipeline across therapeutic areas, is a key component of this objective. In the age of precision medicine and AI-driven discovery, the humble rodent home cage has the opportunity to be transformed into a powerful data-generating platform unlocking behavioral insights not feasible through traditional observation techniques. This talk will explore how continuous, 24/7 non-invasive home cage monitoring (HCM), powered by computer vision and AI/ML, is reshaping preclinical research by enabling the discovery of digital biomarkers - quantifiable behavioral signatures that reflect pharmacological and toxicological responses in real time. By capturing subtle changes in activity, sleep, social interaction, and more, these systems offer unprecedented insight into disease progression, drug responses, toxicological indicators as well as animal welfare. Tracking spontaneous behavior 24/7 in a naturalistic setting, HCM improves reproducibility, reduces stress-induced variability, and supports longitudinal monitoring across treatment paradigms. This approach not only refines animal welfare but also strengthens the translational bridge between preclinical and clinical studies. At Sanofi, we are taking a diversified approach to explore several promising HCM technologies, as well as opportunities at our external partners. This presentation will discuss our global strategy and progress on adoption of this technology, covering case studies demonstrating how HCM enhances behavioral phenotyping across neurodegenerative, immunological and muscle disease models, offering unbiased, non-invasive endpoints for efficacy evaluation. Additionally, we will highlight its growing role in toxicology, where subtle behavioral deviations can serve as early indicators of adverse effects, often preceding traditional clinical signs in both mice and rats. The results generated to date indicate that this technology will add significant value to our Immunoscience pipeline and enhance our ability to translate preclinical findings into successful and safe clinical outcomes.

W 1045 Use of Automated Home Cage Technologies in Behavioral Neurotoxicology Studies

J. Cushman. NIEHS, Research Triangle Park, NC. Sponsor: L. Anger

Assessing the neurobehavioral impact of environmental exposures is an essential part of screening putative neurotoxins and investigating the mechanisms of toxicity. Neurobehavioral testing plays an essential role in this, however, it is time consuming, labor intensive and very sensitive to variables that are often difficult to control for, such as the handling technique and skill of the experimenter. Automated home cage technologies have the potential to solve these challenges by allowing investigators to fully automate behavioral phenotyping, which allows for greater throughput, repro-

ducibility, and reliability. Integrating machine vision also allows for more sophisticated assessments of behavior that may reveal behavioral changes that might otherwise be missed. This lecture will discuss recent progress in implementing these technologies to examine the neurobehavioral impact of toxicant exposures in both mice and flies (*Drosophila*), including the organophosphate pesticides chlorpyrifos and terbufos. The learning objectives are to provide a general overview of progress in this field, including both commercial and custom-built systems, as well as a preliminary evaluation of their efficacy and discussion of future directions.

W 1046 Strategies for Clinical Adoption of Patient-Centric Novel Digital Endpoints

I. Karahanoglu. Pfizer Inc., Cambridge, MA. Sponsor: L. Anger

Advancements in digital health technologies (DHTs), combined with advanced analytical tools, offer significant opportunities for drug discovery and development in pre-clinical and clinical studies, and for adoption by regulatory authorities. Capturing measurement of activity and physiological data in naturalistic settings with sensors helps facilitate enhanced safety and efficacy monitoring, streamline various phases of clinical development, improving reliability and replicability. For example, continuous vital sign monitoring can provide valuable insights into toxicity in pre-clinical studies, thereby contributing to the drug safety profile. Additionally, it can help in managing and mitigating the risks of life-threatening conditions, such as cytokine release syndrome, following treatment in clinical trials. The use of advanced AI/ML techniques to derive the novel digital endpoints (NDEs), such as gait and physical activity, from complex digital data rapidly paves NDEs' way into clinical use to establish digital phenotypes relevant to diseases. Traditional clinical outcome assessments are episodic, thus cannot capture day-to-day variation, and might suffer from observer bias. The DHTs can transform clinical trials, enhance diversity through remote monitoring, and improve patient care by providing non-invasive, quantitative measures of quality of life. While the use of DHTs has increased tremendously over the past decade across the drug development life cycle and in multiple indications, only a few novel digital endpoints (NDEs) were accepted by regulatory bodies. The 95th percentile stride velocity for Duchenne's Muscular Dystrophy and moderate-to-vigorous physical activity for Fibrotic Interstitial Lung Disease were endorsed by EMA and FDA, respectively, as primary endpoints. Demonstrating NDEs' reliability and analytical validity with device-agnostic AI/ML algorithms are fundamental steps to increase adoption and bolster the body of evidence supporting their use. It is also important to demonstrate the clinical validity and meaningfulness of NDEs within a target population, to be able to reliably measure treatment effects and determine a success criteria. This talk will include examples of analytical and clinical validation strategies that support the clinical adoption and regulatory acceptance of novel digital endpoints in support of drug development.

IS 1047 Wildland Urban Interface Fire Beyond the Smoke: Exploring the Broader Environmental and Health Impacts

Y. Choo. Chemical Insights Research Institute, Marietta, GA.

As climate change accelerates and human development continues to expand into fire-prone wildland areas, wildfires—particularly those occurring in the wildland-urban interface (WUI)—are becoming more frequent, more destructive, and more chemically complex. These fires now impact not only forests and grasslands, but also densely populated communities, critical infrastructure, and thousands of homes constructed with synthetic and engineered materials. The combustion of these synthetic building materials, vehicles, and household goods during WUI fires releases a unique and poorly characterized mixture of toxic pollutants, including volatile organic compounds (VOCs), polycyclic aromatic hydrocarbons (PAHs), heavy metals, microplastics, etc. While the visible plumes of smoke are often the most immediately noticeable and discussed aspect of WUI fires, the full scope of their effects on communities, the environment, and public health extends far beyond the smoke itself. Despite the growing number of affected communities and the scale of environmental devastation, our understanding of the acute and chronic health consequences of WUI fire exposures remains fragmented. Traditional wildfire research has focused primarily on ambient air quality and biomass-derived emissions; the WUI environment introduces new layers of complexity involving indoor exposures, structural damage, ash and residue toxicity, and emerging contaminants. There is an urgent need for a cohesive, interdisciplinary framework that bridges environmental science, toxicology, epidemiology, and disaster response planning to address this evolving public health threat. This Symposium aims to bring together researchers at the forefront of WUI fire research to present novel findings from recent major wildfire events, innovative exposure models, and cutting-edge environmental analyses. Using real-world case studies, controlled laboratory exposures, and advanced analytical techniques, the session will examine how WUI fires produce unique toxicants, how these toxicants enter environments and human bodies, and how they may lead to adverse health outcomes—particularly in vulnerable populations, such as returning residents, children, and emergency responders.

S 1048 Human and Ecological Risk Assessment: Has the Time Come for Greater Integration of Approaches?

L. Brown. ToxStrategies LLC, Ann Arbor, MI.

Human and environmental health are intrinsically connected; yet, chemical risk assessment has historically proceeded along distinct and separate tracks when evaluating each. This often results in parallel evaluations with minimal coordination between assessors. However, with recent scientific advances, particularly the rapid development and validation of nonanimal, mechanistically based methods, new avenues are opening for integrating human and environmental safety decision-making. At the same time, regulatory initiatives such as the proposed "one substance, one assessment" approach, along with growing pressure to incorporate sustainability principles (e.g., the Safe and Sustainable by Design framework), are challenging (eco)toxicologists to move beyond traditional silos and adopt more holistic, unified approaches to chemical safety evaluations. With these driving forces, it is time to understand what innovations can enable more holistic, efficient, and protective assessments that transcend species boundaries. This session will present current activities and frameworks developed for integrating data across human and environmental health. It will focus on how data derived from new approach methodologies (NAMs) can inform both human and environmental safety. The session will begin with an overview of the international scientific initiative PrecisionTox, which researches species, tools, and models to uncover molecular toxicity pathways shared across the animal kingdom. Initial findings from this project will also be shared. Next, a proposed framework, created by an industry consortium that incorporates both next-generation risk assessment principles and integrated human and environmental health, will be presented, along with a state of the research in this area. Lastly, a case study will demonstrate how one may conduct an integrated human and ecological risk assessment from a cosmetics industry perspective. By bringing together expertise from multiple sectors, this session will pose the question: What would it take to truly unify human and environmental risk assessment? Are we ready to take that step?

S 1049 Searching for the Evolutionary Origins of Chemical Toxicity

J. Shaw. PRECISIONTOX, Bloomington, IN. Sponsor: L. Brown

Regulatory toxicology faces the fundamental challenge of setting chemical exposure safety limits for many species, including humans, based on experimental data obtained from only a few standard test species. This pragmatic approach to testing "representative" species of the animal kingdom cannot achieve the desired protection of human health and the environment without an evolutionary and ecological understanding of why toxicity observed in one species can be extrapolated to other distantly related organisms. PrecisionTox, a European H2020-funded project, provides evidence on the feasibility of understanding the health impact of chemicals on all animals, including ecological keystone species and humans, based on the evolutionary conservation of pathways to toxicity. Additionally, PrecisionTox builds an empirical case for a concerted effort to protect people and the environment from the harmful effects of chemical pollution by leveraging evolutionary theory for an integrated risk assessment approach. The talk will cover PrecisionTox's work creating and assembling transcriptomic and metabolomic data into putative biomolecular key toxicity events which are shared among five biomedical model species (*Danio rerio* embryos, *Xenopus laevis* embryos, *Daphnia magna*, *Caenorhabditis elegans*, *Drosophila melanogaster*) and human cells. Specifically the talk will describe how in PrecisionTox, molecular initiating events for adverse outcome pathways and chemical modes of action are identified using a Multimodal Co-Response Graph Analysis (MOCHA) and how the toxicological results across species are phylogenetically assigned to their common ancestors. The speaker will also provide an overview of the end goal for the project, which will be a data explorer that will allow users to view the results from testing 200 substances to i) view the multi-omics data for each tested substance in each organism by dose and time point, ii) compare results across species to identify functionally homologous genes and metabolites, iii) explore trends for any gene, metabolite or their network interactions across all chemicals, doses, and time points. The speaker will demonstrate how the analysis of a relatively small dataset can provide initial insights into the efficacy of the concept of "toxicity by descent" for cross-species extrapolation of chemical modes of action.

S 1050 Development of an Integrated Human and Environmental Health Safety Assessment Framework: Initial Findings and Progress from a Consortium Effort

L. Brown. ToxStrategies LLC, Ann Arbor, MI.

Given the recent push to more holistic and integrated safety assessments, a team has been formed by the International Collaboration on Cosmetic Safety with the goal of developing a non-animal based decision framework to assess both human and environmental safety in an integrated manner. Given the inherent multi-disciplinary nature of proposing a NAM-based framework which includes both human and ecological health, a diverse working group of cosmetics and personal care companies with varying areas of expertise collaborated to develop a process by

which a safety assessor can consider when data from one field of discipline (e.g., human health toxicology) may inform another (e.g., ecotoxicology) or vice versa. This presentation will cover both the approach used to develop the draft framework and present the framework as it stands in March of 2026. A landscape review of existing frameworks for integrated or NAM-based safety assessments was performed to identify existing frameworks for human and/or environmental health safety assessments, areas of overlap between the two, and data gaps that could be addressed in the development of the integrated framework presented herein. In addition, the talk will cover case studies that are being used to “stress test” the framework to identify both the robustness of available tools and the gaps in our ability to ensure safety of relevant ingredients without the use of animal tests. Further, the talk will discuss available findings as it pertains to NAMs that are available to address relevant biological targets including ones of common interest between human health and environment, along with tools that can be used to evaluate to feasibility of cross-species extrapolation based on knowledge of a compound mechanism of action. These key considerations to integrate human and environmental health include addressing relevance of outcomes in one species (e.g., humans) to other species of interest (e.g., fish, invertebrates), using NAMs to understand metabolic pathways, protein/chemical interactions, and gene similarity. The talk will conclude with planned next steps of the working group in the process of finalizing the framework.

S 1051 Case Study-Led Evaluation of an Integrated Human Health-Environmental Next-Generation Risk Assessment Framework

B. Campos. Unilever, Sharnbrook, United Kingdom. Sponsor: L. Brown

Implementation of NGRA concepts in chemical safety assessment is now increasingly feasible through combining non-animal New Approach Methodologies (NAMs) and high resolution exposure datasets to establish bioactivity exposure ratios. The NGRA paradigm shift offers increased opportunities to integrate human health and environmental safety assessment to improve their efficiency and effectiveness. In this presentation, we will share a case study implementing a novel integrated tiered framework to assess human health and environmental safety, capturing opportunities to integrate across the two fields when performing exposure and hazard characterization to reach a safety decision. By using Benzophenone-3 as an example, the talk will describe various aspects of implementing the framework. This will include demonstrating how in the initial tier of evaluation, *in silico* prediction tools, and available data can be leveraged to predict and establish physico-chemical properties, fate and hazard characterization and mechanisms of toxicity covering both human and environmental species. The presenter will also describe how in tiers 1 and 2, the data generation steps, a battery of non-animal NAMs, inclusive of both human and fish cell-line models, covering a broad biological and taxonomical space can be used to provide protective points of departure for the species of interest. These will include High Throughput Transcriptomics (HTTr) and Phenotypic profilers (HTPP) in human and fish cell lines, *in vitro* pharmacological profiling panel (IPP), TOXCAST/ TOX21 assays, RTGill Acute data (OECD 249) and *in vivo* data in algae and invertebrates. To demonstrate how a safety decision may be made with the generated data, the speaker will outline how the PoDs derived from the battery of NAMs are compared to external exposures using robust Human and Fish PBK models. The speaker will also discuss how genomic conservation of biological targets and/or relevant toxicological processes across species can be evaluated using tools such as SeqAPASS and G2P-SCAN. While the objective of the case study was to test and optimize a common battery of NAMs covering both human and environmental species and how all the information can be organized together to support a robust decision, the speaker will also address the inherent differences in when considering human and ecological risk assessments.

R 1052 Integration of Kinetics and Mechanisms in Safety Assessment

J. Fredericks. Gowan, Yuma, AZ.

As new testing approaches are developed to generate more relevant and reliable toxicological data, a more complete understanding of the intricate relationship between kinetics and mechanisms is needed within the broader toxicology community. The literature clearly shows that mechanisms of direct toxicity are dose-dependent, while some adverse effects occur in a mechanistically indistinct or nonspecific manner secondary to high-dose administration. Clarifying the distinction between direct and nonspecific toxicity has the potential to advance the field by providing a deeper understanding of how dose influences toxicological outcomes. Nonspecific toxicity arises when a chemical dose exceeds the biological and metabolic processing capacity of an organism, leading to effects such as cytotoxicity or physical-chemical disruption of cell membranes causing effects that would not occur without such overload. Several developments and advancements in toxicology present an opportunity to refine how these two forms of toxicity are distinguished. Direct mechanisms of toxicity may involve molecular interactions, such as gene expression modulation, receptor binding, or enzyme activity changes. In contrast, toxicity resulting from overload reflects a loss of physiological equilibrium rather than a targeted molecular event. Two complementary strategies can help differentiate these effects. Mechanistic toxicology studies can identify specific molecular and organ-level targets and characterize their dose-response relationships. Kinetic studies can determine the internal concentrations at which biological systems become saturated, identifying a kinetic

maximum dose (KMD) beyond which nonspecific effects may dominate. Integrating these approaches can provide insight into the dose ranges at which chemicals act through targeted biological mechanisms versus those at which generalized biological stress responses are triggered. This session will feature three concise presentations to introduce the topic and provide key context, followed by a panel discussion designed to promote active audience engagement through questions, comments, and debate. Central discussion points include whether current methodologies can reliably and efficiently distinguish direct from nonspecific toxicity and how these distinctions might shape future research and interpretation of toxicological data. The session will incorporate diverse perspectives from industry, academic researchers, and method developers.

S 1053 AI in Toxicology: Navigating Promise, Pitfalls, and Practical Implementation

S. Auerbach. NIEHS/DTT, Research Triangle Park, NC.

Artificial intelligence (AI) is poised to transform toxicology, offering unprecedented opportunities for accelerating chemical safety assessment, enhancing predictive accuracy, reducing reliance on animal testing, and increasing workflow efficiency. From high-throughput screening analysis to predictive modeling of complex endpoints, AI tools promise significant advancements. However, realizing this potential requires a clear-eyed assessment of profound challenges. This Symposium critically examines the current landscape, moving beyond the hype to address the fundamental limitations inherent in applying AI to complex biological systems. The session will explore the successes of AI in areas like early stage prioritization and data analysis, while dissecting key hurdles, including the pervasive issues of data scarcity, quality, and applicability domain constraints; the lack of predictive granularity essential for human health translation; the persistent “black box” problem hindering interpretability and trust; and the infeasibility of purely *ab initio* prediction for emergent toxicological outcomes. Furthermore, the session will confront the practical implications of these limitations, delineating strategies for leveraging AI as a powerful decision-support tool to maximize efficiency while carefully managing the significant liabilities associated with its misapplication in definitive safety assessments. This Symposium convenes experts to foster realistic dialogue on best practices, validation requirements, and the path toward responsible, impactful integration of AI in toxicology research and regulation.

S 1054 Using Deep Learning to Extract Toxicologically Relevant Information from Cell Images

J. Ewald. EMBL-EBI, Hinxton, United Kingdom.

High-content imaging assays like Cell Painting, as well as histopathology whole slide images, provide rich visual data for understanding cellular responses to chemical exposures. Traditionally, these cellular images have been manually examined by eye or quantified using engineered features that measure specific things like the shape, texture, and intensity of cells and subcellular compartments. In more recent years, various deep learning approaches have been used to learn meaningful, quantitative representations of images. When applied to images of cells and tissues, these learned profiles can improve prediction of biological and toxicological endpoints, suggesting that the deep learning approaches are capturing subtle, complex phenotypes that may be missed by the human-defined features. However, these methods also come with trade-offs—including reduced interpretability, reliance on GPU resources, data leakage, and performance issues when models are applied to data that differ from the training set. The presenter will discuss strategies to mitigate these limitations and explore how deep learning can be integrated into toxicology workflows in a practical way, highlighting both the promise and pitfalls of applying modern computer vision techniques to biological image data for safety assessment.

S 1055 The Role of AI in Advancing Drug Safety

N. Greene. Recursion, Salt Lake City, UT.

Artificial intelligence (AI) has the potential to accelerate drug development at every stage of the process including drug safety. By leveraging machine learning, we could reduce the reliance on animal testing, lower development costs, and discover safer drug candidates. This presentation will examine how AI and machine learning methodologies are being applied in the identification and assessment of toxicity early in the drug discovery pipeline. It will explore applications in virtual screening, high-throughput screening data analysis, and the development of more predictive *in vitro* and *in vivo* models. This presentation will also discuss the challenges and limitations of AI and the future applications of this technology in advancing drug discovery toxicology.

S 1056 Bridging Mechanistic AOP Elucidation Using Knowledge Graph Mining and Machine Learning for Chemical Safety Assessment

A. Tropsha. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Biomedical knowledge graphs (KG) have emerged over the last decade as universal means of re-representing and mining biomedical and clinical knowledge integrated from dozens of databases. For instance, ROBOKOP Knowledge Graph developed in our team, currently integrates data from 40 databases and comprises 10M chemical and biological entities and 140M relationships between them. Knowledge graphs have been used for multiple knowledge mining tasks including drug repurposing, searching for clinical outcome pathways, and of course, elucidation of Adverse Outcomes Pathways of chemical toxicity. We will consider methods of rule mining as well as graph embedding to discover novel linkages between chemicals of concern or molecular initiating events and adverse outcomes. We will also discuss approaches to automated discovery of adverse outcome pathways via KG mining that discuss how integration of QSAR models developed for different elements (key events) in the AOP can improve the overall accuracy of *in chemico* to *in vitro* to *in vivo* extrapolation (ICIVIVE). As part of the presentation, we will discuss the value of data curation and model validation in assuring external predictive accuracy of machine learning models.

S 1057 Transforming Drug Safety Reviews: Integrating AI Models into the US FDA DILI Assessment Process

W. Tong. US FDA/NCTR, Jefferson, AR.

The FDA Modernization Act 2.0 promotes alternatives to animal testing in drug development. The release of the FDA Roadmap to Reducing Animal Testing in Preclinical Safety Studies further reinforces the FDA's commitment to advancing the 3Rs principles in drug reviews through New Approach Methodologies (NAMs). To support the FDA's efforts, we established SafetAI Consult to assist the FDA's Drug-Induced Liver Injury (DILI) Team, a specialized group responsible for assessing DILI-related risks during drug safety reviews. SafetAI Consult utilizes a broad range of in-house developed AI models trained on large-scale, validated datasets, including chemical structures, FDA labeling documents, and synthetic data, to predict DILI risk in new drug candidates. The platform's objectives align with three main goals in supporting the FDA DILI Team: (1) To analyze historical drug approval data (e.g., chemical structures and prior adverse event profiles), we provide regulatory reviewers with relevant data by helping identify DILI risk patterns and guiding the review of new drug applications based on previously approved drugs; (2) To assess the likelihood of human DILI concerns early in the review process with the SafetAI models that provide predictive insights, enabling the DILI Team to identify potential safety concerns and alert reviewers to request additional clinical or preclinical data before approval; (3) To guiding labeling recommendations by using integrated insights from both AI model results and other related information, the DILI Team can suggest data-driven adjustments to drug labeling language, ensuring that the drug's safety profile is accurately reflected, and potential risks are communicated clearly to healthcare professionals. The fit-for-purpose AI models undergo a rigorous validation process, comparing them with animal models and other NAMs to assess effectiveness in real-world drug safety assessments. This presentation will discuss how SafetAI Consult's AI models are specifically integrated into the FDA review process, and share lessons learned from their application in supporting the DILI Team's work. Through these efforts, SafetAI Consult plays a critical role in enhancing the FDA's regulatory review process, helping to identify potential risks earlier in the drug development lifecycle while reducing reliance on animal testing through NAMs.

S 1058 Knowing What You Know and Don't Know: Progress Toward Interpretable and Uncertainty-Aware Machine Learning for Chemical Points of Departure

W. Chiu. Texas A&M University, College Station, TX.

Lack of points of departure (PODs) representing the dose at which toxicologically-relevant effects begin to manifest are a major bottleneck in the evaluation and management of chemical human health risks and impacts. Widespread use of machine learning (ML)-based *in silico* predictions of PODs has been hindered in part by the desire for greater biological interpretability, more consistent applicability across chemicals, and improved quantitative characterization of uncertainty. We demonstrate recent progress towards addressing these challenges through novel ML approaches. To address interpretability, we implemented a "two-stage" ML framework whereby physical, chemical, and biological properties predicted from "first stage" ML models are used as features in a "second stage" ML to predict PODs. To address applicability and uncertainty, we have demonstrated how "uncertainty-aware" ML models can quantify both data- and model-related uncertainty and provide uncertainty estimates that are closely aligned with observed prediction errors, assigning more "unfamiliar" chemicals higher prediction uncertainty.

S 1059 Extracellular Vesicles as Mediators of Environmental Stress in Carcinogenesis and Other Human Diseases

W. Bisson. Integrative Toxicology and Cancer Prevention, Research Triangle Park, NC.

Extracellular vesicles (EVs), found in blood or other biological human fluids, play key roles in intercellular communication in both normal cell physiology and in disease processes, including inflammation, neurodegenerative and carcinogenic signaling. Nomenclature for EVs varies according to the cell, tissue of origin, size, and subcellular origin. EV cargo contains (and can transfer to host cells) cell components such as RNA, DNA, receptors, proteins, and lipids that are involved in intercellular signaling and cellular processes. Together, EVs and extracellular signaling make up a significant focus of current investigation for mechanistic basic research, discovery of new biomarkers, and clinical applications (e.g., early detection and diagnosis, safer drugs). Biomarkers detectable in body fluids (i.e., liquid biomarkers) offer the unique advantage of being identified by minimally invasive methods compared with markers found in samples prepared from tissues. There is rapid growing interest in (1) studying the roles for EVs in altering cell-cell communication in response to environmental stress; (2) identifying EVs function in environmentally related diseases; (3) discovering EV biomarkers involved in human health and disease; and (4) characterizing EV signaling in environmentally related health conditions. This Symposium is composed of scientists from academia, government, and the private sector, with high expertise in the field of EVs—from methods development, including EVs isolation and separation, and mechanistic basic research to clinical applications and translational toxicology. The first presenter will discuss the carcinogenicity of 1,4-dioxane, a probable human carcinogen, that is largely dependent on Nrf2 activation, which drives the biogenesis of EVs with epithelial-to-mesenchymal transition (EMT)-promoting functions. The next speaker will focus on endothelial EVs as biological messengers and indicators of lung carcinogenesis upon exposure to polycyclic aromatic hydrocarbons (PAH)s. In addition, the speaker will report findings suggesting that an integrative approach combining 'omics and imaging techniques with machine learning could enable the detection and isolation of a specific subpopulation of EVs of interest. The third speaker will then demonstrate how EVs using *in vitro* 3D cell models can serve both as a route for propagating toxic phenotypes and as a source of biomarkers for precision prevention of carcinogenesis and other diseases or the development of safer therapeutics. The fourth speaker will discuss how circulating ex-miRNAs contain tissue-specific signals from EVs and non-EV components and the composition varies by tissue type. As robust biomarkers of tissue health and diseases, these signals enable the tissue-specific assessment of pathophysiological responses to environmental stress, representing a significant advancement toward precision prevention. Finally, the last speaker will explore the clinical application of blood brain-derived EVs (BEVs) as a powerful tool for discovery of biomarkers of disease risk and monitoring neurodegenerative pathologies. To conclude the Symposium, there will be a panel discussion with Q&A.

S 1060 1,4-Dioxane Induces Carcinogenesis Through Nrf2-Dependent Extracellular Vesicle Release

F. Chen. Stony Brook Cancer Center, Stony Brook, NY.

The carcinogenic potential of the environmental pollutant 1,4-dioxane (1,4-D) in humans is not yet fully understood or recognized. In this study, we provide evidence that 1,4-D acts as a carcinogen in human epithelial cells. Using the human bronchial epithelial cell line BEAS-2B, with or without CRISPR-Cas9-mediated Nrf2 knockout, we demonstrate that continuous exposure to environmentally relevant concentrations of 1.25-20 ppm 1,4-D over two months induces malignant transformation in an Nrf2-dependent manner. Transformed cells exhibit enhanced anchorage-independent growth in soft agar, increased migration and invasion, and tumorigenic potential in a xenograft mouse model. Integrated RNA sequencing (RNA-seq) and proteomics analyses reveal that 1,4-D robustly activates Nrf2 signaling, driving the biogenesis and cargo loading of extracellular vesicles (EVs) with syndecan 4 (SDC4) and other proteins, including COL12A1, CAPG and NNMT, associated with epithelial-mesenchymal transition (EMT) and metastasis. Nrf2 knockout reduces SDC4 expression and its incorporation into EVs, leading to diminished EV uptake in recipient cells. Unlike EVs from 1,4-D-transformed WT cells, which enhance the proliferation, migration and invasion of recipient cells, EVs from 1,4-D-transformed Nrf2 KO cells show a reduced ability to promote these EMT properties. Furthermore, we provide evidence that the Nrf2 target gene SDC4, which is induced by 1,4-D and enriched in EVs, plays a critical role in EV uptake by recipient cells, thereby facilitating the propagation of EMT. Overall, our findings suggest that 1,4-D is a human carcinogen, with its carcinogenicity largely dependent on Nrf2 activation, which drives the biogenesis of EVs with EMT-promoting functions.

S 1061 Endothelial Extracellular Vesicles: Biological Messengers and Indicators of Lung Carcinogenesis upon Exposure to Polycyclic Aromatic Hydrocarbons

E. Le Ferrec. Institut de Recherche en Santé, Rennes, France. Sponsor: W. Bisson

Polycyclic Aromatic Hydrocarbons (PAHs) are pollutants to which humans are commonly exposed through breathing or diet. Increasing amount of evidence suggests that air pollutants can modify the production of EVs, induce EV-mediated communication, and facilitate a tumor-promoting microenvironment during the development or progression of non-small cell lung cancer (NSCLC). Furthermore, tobacco-smoke, air pollution (PM2.5) and PAHs have been shown to trigger EV release from different cell types in the lung tissue (e.g., macrophages, bronchial epithelial and endothelial cells). Specifically, EVs derived from endothelial cells in the stroma are also often associated with inflammation, immune activation, and angiogenesis. We have demonstrated that individual PAHs such as benzo[a]pyrene (B(a)P) or mixtures of PAHs are able to increase EV levels in plasma and urine *in vivo*, as well as EV production *in vitro* by endothelial cells, human peripheral blood mononuclear cells or hepatocytes. Among the EVs overproduced by endothelial cells in response to PAHs, we identified vesicles containing intact mitochondria and glycolytic enzymes. These EVs can thus generate extracellular ATP, which is associated with cancer development and resistance, notably through the Warburg effect that we have previously linked to PAHs toxicity. Endothelial EVs can thus be considered as: indicators of cancer risk or cancer pathological states; contributors to disease propagation or exacerbation; biomarkers of exposure or toxic effects; and even as vehicles and mediators of toxicity. To investigate EVs specificities and assess their alterations in pathological contexts such as carcinogenesis upon exposure to environmental contaminants, it is essential to identify and sort EVs (based on size, surface markers, or cargo content) both qualitatively and quantitatively. Recently, the combination of Raman microscopy and tip-enhanced Raman spectroscopy with omics and machine learning allowed us to identify phenotypic alterations (particularly lipid modifications) in EVs produced by endothelial cells exposed to a low concentration of B(a)P. This ability to detect a specific signature proved to be a means of identifying EVs derived from B(a)P-exposed cells. These findings suggest that an integrative approach could enable the detection and isolation of a specific subpopulation of EVs of interest.

S 1062 Extracellular Vesicles in Disease Etiology and Precision Biomarker Discovery

E. Tokar. NIEHS/DTT, Research Triangle Park, NC.

Cells can communicate with one another within the microenvironment and systemically by secreting extracellular vesicles (EVs). These EVs are released both during normal growth and development and in response to toxicity, playing key roles in intercellular communication and signaling mechanisms. Accumulating evidence shows that EV signaling can play critical roles in the development and progression of a wide spectrum of diseases, such as cancer. However, the role of EV signaling in environmental toxicant-induced disease etiology remains poorly understood. We have used several *in vitro* 2D and 3D cell models to investigate the role of EVs in toxicant-induced developmental cardiotoxicity and neurotoxicity and in carcinogenesis. Using a 2D non-contiguous cell co-culture model, we demonstrated how arsenic, a common environmental human carcinogen, affects EVs to impact the tumor microenvironment. Exposure to arsenic increased both the secretion of EVs by the cells and the packaging of myriad cancer-associated cargo molecules (i.e. miRNAs, KRAS, inflammatory cytokines, anti-apoptotic genes) that play key roles in the recruitment of stem cells to a cancer stem cell phenotype. EVs were also isolated from 3D cerebral or cardiac organoids and their cargo (RNA) was characterized using ddPCR and NanoString. Characterization of the cargo in these organoid-derived EVs identified miRNAs known to target several pathways involved in neural or cardiac development and neurodegenerative diseases. Together, the studies and data presented here will highlight the use of various 2D/3D model systems for studying carcinogenesis as well as brain- and cardiac-related diseases and show their utility as tools for the discovery of EV-associated cargo involved in disease and toxicity. The presentation will demonstrate how EVs can serve both as a route for propagating toxic phenotypes and as a source of precision biomarkers for various diseases. Elucidating how EV cargo and signaling properties change during dynamic cellular events and disease etiology and progression may aid precision prevention of toxicity and development of safer therapeutics.

S 1063 Circulating microRNAs as Tissue-Specific Biomarkers of Human Health and Disease

W. Li. Columbia University Mailman School of Public Health, New York, NY. Sponsor: W. Bisson

Early pathological changes in many organ systems are difficult to detect, creating challenges in disease prevention, diagnosis, and treatment. MicroRNAs are highly tissue-specific and constantly released into circulation, either encapsulated in extracellular vesicles (EVs) or bound to proteins, presenting new opportunities to capture early pathophysiological changes in diverse tissue types. We leveraged total circulating extracellular microRNAs (ex-miRNAs) and EV-encapsulated miRNAs (EV-miRNAs) and applied deconvolution to derive miRNA-based tissue specificity scores (ex-TS

and EV-TS scores, respectively) for 17 tissues (e.g. heart, lung, pancreas). We validated these scores against a variety of clinical markers and phenotypes, disease trajectory, and exogenous exposures in population-based cohorts. We then examined whether the proportion of ex-miRNA that were encapsulated in EVs modified the observed effects. Both ex-TS and EV-TS scores were robustly associated with indicators of health across cohorts, with each score uniquely and specifically linked to health outcomes related to the tissue of origin. Interestingly, we observed opposite directions of associations for artery and kidney ex-TS scores versus EV-TS scores, suggesting EV-miRNAs may represent distinct signals as compared to total ex-miRNAs. This is reinforced by composition analysis, which showed that brain and liver-derived ex-TS were mainly enriched in the EVs, whereas artery and kidney-derived ex-TS were correlated with depleted EV signals. Using prospective data, the ex-TS scores also functioned as predictive biomarkers that preceded significant health events including acute myocardial infarction, cerebrovascular accidents, cognitive impairment, and the onset of airflow limitation. Finally, we showed that ex-TS scores can capture acute toxicity and recovery of the liver following acetaminophen overdose, and long-term health effects of smoking and smoking cessation on the lung, with high tissue specificity. Circulating ex-miRNAs contain tissue-specific signals from EVs and non-EV components, and the composition varies by tissue type. As robust biomarkers of tissue health and diseases, they enable the tissue-specific assessment of pathophysiological responses, representing a significant advancement toward precision medicine.

S 1064 Blood Brain-Derived Extracellular Vesicles as a Biomarker Platform for Identification of Neurodegenerative Disease Pathologies

E. Eitan, and O. Volpert. NeuroDex Inc., Natick, MA. Sponsor: W. Bisson

Most neurodegenerative diseases involve mixed pathologies; for instance, 80% of dementia patients show multiple pathological features, while fewer than 5% present with pure Alzheimer's pathology (amyloid beta and tau only). Shifting disease definitions from symptom-based to pathology-based would enable precision medicine (intervention and prevention) and improve drug development. Blood brain-derived extracellular vesicles (BEVs) offer a minimally invasive platform for accessing molecular brain information. Using BEV profiling, we identified Lewy body pathology in dementia patients with 100% specificity and 80% sensitivity (AUC=0.87) across four cohorts (N=140), including postmortem-confirmed cases. BEV-associated alpha-synuclein was also significantly elevated in Parkinson's disease and multiple system atrophy (MSA), with BEV-amyloid-beta in MSA significantly correlating with shorter survival time, highlighting the effect of mixed pathologies across diseases. In ALS, BEV-TDP43 was significantly increased, with 85% sensitivity and 82% specificity (AUC=0.82, N=95), and elevated levels were also observed in dementia (N=310). BEVs also enable measurement of functional pathways: brain lysosomal activity can be assessed via Cathepsin D, while insulin resistance and other metabolic functions are captured through AKT pathway proteins. In a GLP-1 agonist (liraglutide) trial (N=15), BEV-AKT protein levels showed significant modulation. Together, these findings highlight BEVs as a powerful tool for discovery of biomarkers of environmentally related disease risk and monitoring neurodegenerative pathologies. Our automated, scalable platform is now integrated into multiple clinical trials.

S 1065 From Correlation to Causation: Development and Application of Novel Approaches to Implicate Epigenetic Mechanisms in Toxicological Responses

P. Allard. University of California Los Angeles, Los Angeles, CA.

Toxicoeugenetics seeks to understand how toxicant exposures interact with the epigenome to influence disease risk. However, while most environmental epigenetic studies have successfully uncovered associations between a multitude of environmental factors—such as diet, toxicants, or stress—and epigenetic changes, proving that these modifications are directly implicated in the etiology of outcomes is challenging. This difficulty is compounded by confounding variables, individual genetic variability, and the dynamic nature of the epigenome, which can respond to multiple environmental cues simultaneously and over time. Consequently, the field often struggles to move beyond correlation to definitive causality via mechanistic insights. This session will bring together an exciting slate of speakers who have significantly contributed to advancing the field of epigenetics into mechanistic epigenetics through epigenetic editing, drug targeting, and other approaches. The first speaker will describe strategies to show how piRNAs act as mediators of early lead (Pb) exposure in the disruption of placental function and their alteration of gene regulation in a sex- and tissue-specific way. The second talk will be technology focused and will describe the development of a new technological platform, Tagmented, Indexed and Pooled ChIP-Seq, built to overcome current limitations in mechanistic research caused by low-throughput and sample size. The third talk will show how in-depth profiling and comparative analyses across toxicants and tissues can be used for mechanism identification. The speaker will discuss results from the NIEHS TaRGET II Consortium showing that early life exposure to various environmental toxicants causes lasting epigenomic reprogramming and disrupts adult liver gene expression. Despite different modes of action, toxicants like BPA, TBT, TCDD, and PM2.5 produced similar aging-related transcriptomic changes, particularly in genes tied to liver function and disease. These findings suggest early exposures can reshape epigenomic aging and increase long-term disease risk. The fourth talk

will show how epigenetic drugs can be used for environmental epigenetic reversal. Specifically, the speaker will show that treatment with a weak epigenetic modifier reverses BPA-induced transgenerational NAFLD in the medaka and corrected associated molecular changes, suggesting potential for mitigating environmentally induced metabolic disorders in future generations. Finally, the fifth talk will discuss seminal studies on epigenetic editing to induce discrete changes in DNA methylation and monitor their behavior during cellular differentiation and across generations. Together, the session will be of high interest to SOT members for demonstrating how classic and novel strategies can be leveraged to directly implicate epigenetic mechanisms in the etiology of environmentally induced outcomes.

S 1066 Reversal of Environmentally Induced Transgenerational Metabolic and Reproductive Impairments Through Reprogramming of DNA Epimutations

R. Bhandari. University of Missouri, Columbia, MO.

Epigenetic inheritance of environmentally-induced phenotypes has been demonstrated in many model organisms in a laboratory setting, suggesting that individuals in current generations could be harboring ancestral environmental exposure-induced molecular memories. Thus, it is essential to develop strategies to correct transgenerational abnormalities before they are transferred to offspring via germline transmission. As a proof of concept, using medaka fish as an aquatic model organism of human and ecosystem health, we investigated whether the environmentally induced transgenerational non-alcoholic fatty liver disease (NAFLD) can be reversed by epigenetic modifier treatments. Ancestral bisphenol A (BPA) exposure (10 µg/L) caused transgenerational NAFLD leading to nonalcoholic steatohepatitis (NASH) in offspring at F2 generation, which persisted for five generations. The severity of the disease was sexually dimorphic: with females affected more than males. Past F2 generation, the transgenerational NAFLD started after puberty, developed in adulthood, and progressed toward NASH and fibrosis as the fish aged. We performed transcriptomic, metabolomic, and methylome analyses to understand the mechanisms involved. DNA methylation profile of the F1 paternal sperm predicted the DNA methylation and transcriptional landscape of the F2 offspring liver revealing distinct pathways associated with NAFLD. A larger percentage of transgenerational differentially methylated promoters (DMPs) present in the NAFLD liver at the F2 generation were removed in the F4 generation during germline transfer. Still, the phenotype persisted but with comparatively reduced severity. Treatment of the F4 fish with a weak epigenetic modifier resulted in: 1) A reversal of NAFLD phenotype to normal, 2) Correction of the majority of BPA-induced DMRs, irrespective of their methylation status, and 3) restoration of transcriptional network comparable to that in untreated controls. The present results suggest that low-concentration nutritional epigenetic modifiers may be useful for correcting EDC-induced transgenerational liver injury. Results open avenues for further research towards understanding the role of environmentally established epigenetic landscape in metabolic health and disease and the mitigation of this multifactorial metabolic disease in humans.

S 1067 Early Life Environmental Exposures Reprogram Epigenomic Aging to Alter Gene Expression Trajectories

C. Walker. Baylor College of Medicine, Houston, TX. Sponsor: P. Allard

To understand how early-life environmental exposures shape health and disease risk across the lifecourse, the NIEHS TaRGET II Consortium exposed mice to diverse toxicants from pre-conception through weaning, and followed individual animals into adulthood, generating over 800 epigenomic and transcriptomic profiles. These profiles revealed that early-life exposures induced persistent epigenomic reprogramming and significantly disrupted the adult transcriptome. Notably, despite their diverse mechanisms of action, the exposure signatures of the xenoestrogen BPA, obesogen TBT, dioxin TCDD, and air pollutant PM2.5, all converged on genes normally differentially expressed during liver aging. Epigenetic histone modifications at enhancers—and, to a lesser extent, promoters—emerged as key targets for this reprogramming. Despite differing mechanisms of action, these four toxicants imparted similar “fingerprints” on the adult liver, characterized by direction- and cell type-specific polarization of the transcriptome. Hepatocyte genes that typically increase with age, particularly those in metabolic pathways, were downregulated, while conversely, non-parenchymal cell genes that typically decrease with age, such as those involved in extracellular matrix production, were upregulated. A similar anti-correlation with programmed aging was also found in the transcriptome of patients with liver disease and hepatocellular carcinoma (HCC), and was effective at distinguishing healthy from diseased human livers. These findings demonstrate that the plasticity of epigenomic aging is vulnerable to early-life environmental exposures, which can reprogram the epigenome with lasting impacts on the transcriptome, and disease risk, later in life.

S 1068 DNA Methylation Editing to Study the Transgenerational Inheritance of Epigenetic Memory at CpG Island Promoters in Mammals

Y. Takahashi. Kumamoto University, Kumamoto, Japan. Sponsor: P. Allard

Whether transgenerational epigenetic inheritance occurs in mammals, to what extent epigenetic information can be passed to offspring, and whether it is associated with disease heritability have been attractive scientific questions. We demonstrated that DNA methylation of promoter-associated CpG islands (CGIs) can be transmitted from parents to their offspring in mice. We generated DNA methylation-edited mouse embryonic stem cells (ESCs) in which CGIs of two metabolism related genes, the Ankyrin repeat domain 26 (Ankrd26) and the low-density lipoprotein receptor (Ldlr), were specifically methylated and silenced using our DNA methylation editing strategy. DNA methylation-edited mice generated by microinjection of the methylated ESCs exhibited abnormal metabolic phenotypes. Both the acquired methylation of the targeted CGI and the phenotypic traits were maintained and transmitted across multiple generations. The heritable CGI methylation was subjected to reprogramming in parental PGCs and subsequently reestablished in the next generation at post-implantation stages. This indicates that it was not the DNA methylation itself, but rather an epigenetic memory that was transmitted—one that can lead to the reestablishment of CGI methylation. In this presentation, I would like to discuss the underlying mechanisms and how such epigenetic editing strategies may be applied to the study of environmental alterations of the epigenome.

S 1069 Deciphering Epigenetic Mechanisms of Lead Exposure During Mouse Development

B. Perera. University of California Berkeley, Berkeley, CA.

Environmental lead (Pb) exposure during critical developmental periods can have long-lasting health effects through epigenetic mechanisms. Despite extensive research on Pb toxicity, the epigenetic pathways through which Pb exposure influences long-term health remain poorly understood. The current work investigates (1) the effects of gestational Pb exposure on the placental weight and expression profiles of imprinted genes, and (2) sex- and tissue-specific effects of perinatal Pb exposure on PIWI-interacting RNA (piRNA) pathways in adult mice at 5 months. Gestational exposure to Pb significantly increased placental weight regardless of fetal sex, with subsequent RNA-seq revealing substantial Pb-induced changes in placental gene expression, including those related to genomic imprinting. Perinatal Pb exposure identified differentially expressed piRNAs specific to the male mouse cortex. Despite cessation of Pb exposure at weaning, the piRNA downstream target Taok3 exhibited decreased DNA methylation and increased gene expression in adult mouse brains. Collectively, these findings suggest that Pb exposure disrupts placental function and fetal development, likely through imprinting dysregulation. Perinatal Pb exposure also has long-lasting effects on longitudinal piRNA expression in a tissue- and sex-specific manner, potentially via DNA methylation-directed mechanisms. This work highlights piRNA as a potential disease biomarker and as a promising candidate for interventions through epigenome-editing mechanisms.

S 1070 Overcoming Sample Limitation in Mechanistic Epigenetics: Introducing TIP-ChIP, a High-Throughput Alternative to ChIP-seq

S. Traynor. Active Motif, Carlsbad, CA. Sponsor: P. Allard

Difficulty in accessing sufficient experimental material is a common bottleneck in the assessment of epigenetic changes and often informs the number of conditions that can be simultaneously tested and which epigenetic mark will be examined. In this method-oriented talk, we will present Tagmented, Indexed and Pooled ChIP-Seq, or TIP-ChIP, to generate high throughput, multi-sample results from low input samples. TIP-ChIP is a novel chromatin profiling method designed to overcome the limitations of traditional ChIP-seq. Capable of processing up to 96 samples simultaneously in a single reaction, TIP-ChIP significantly reduces batch effects and sample-to-sample variation while requiring substantially lower input material. The streamlined workflow minimizes hands-on time and increases overall efficiency. A robust barcoding strategy enables accurate sample deconvolution without compromising resolution. TIP-ChIP has been validated across multiple cell types, including human primary cells, and shows strong concordance with conventional ChIP-seq data. This high-throughput method provides a powerful and scalable solution for mapping histone modifications in large-scale epigenomic studies.

S 1071 Rebuilding Immunity in the Lab: Complex *In Vitro* Models for Smarter Safety Science

M. Collinge. Pfizer Inc., Groton, CT.

The immune system is one of the most complex and dynamic networks in the human body—and one of the most challenging to evaluate in toxicological risk assessment. Traditional approaches to immunotoxicity testing have relied heavily on animal models, which often fail to capture the nuance of human-specific immune responses, especially in cases of immune sensitization or dysregulation or immunosuppression. As scientific and regulatory communities pivot toward more human-relevant, mechanism-based safety assessment, new approach methodologies (NAMs) are becoming essential tools in the evolving immunotoxicology toolbox. This session explores the cutting-edge application of NAMs, including complex *in vitro* models such as microphysiological systems (MPS), immune-competent organoids/ spheroids, and 3D co-culture systems, in the context of immuno-safety assessment. These models enable the recapitulation of key immune functions—such as antigen presentation, cytokine signaling, immune cell trafficking, and barrier integrity—in a controlled and human-relevant environment. When integrated with high-throughput screening, 'omics technologies, and computational modeling, these approaches offer powerful new ways to predict, detect, and understand immune system perturbations caused by pharmaceuticals, chemicals, biologics, and environmental agents. Speakers will present recent breakthroughs in the development and validation of NAMs for key immune assays, with a focus on early stage de-risking and compound selection through assays intended to reduce animal studies and support a regulatory package. The session will address critical questions around translational relevance, regulatory uptake, and model standardization. The session will also include discussion of regulatory frameworks that are beginning to incorporate or accept NAM-based data. This session aims to bridge scientific innovation with practical application, offering toxicologists, immunologists, and risk assessors a forward-looking view of how NAMs are redefining the landscape of immuno-safety across academia, industry, and government. Attendees will leave with a deeper understanding of both the scientific potential and the implementation challenges of complex NAMs, as well as opportunities for future collaboration across sectors.

S 1072 New Approach Methodologies in Immunotoxicology: Current Landscape and Future Directions

E. Corsini. Università degli Studi di Milano, Milan, Italy.

The ability of chemicals to alter immune function—causing immunosuppression or inappropriate activation—is a significant public health concern. Immune disruption has been linked to asthma, autoimmune diseases, cancer, and increased infection risk, highlighting the need for reliable, human-relevant immunotoxicity assessments. Historically, such evaluations have relied on animal models using tiered testing strategies to assess various immune components. While these models have advanced understanding, they present ethical concerns, high costs, and limited predictive value for human outcomes. Driven by the goal of reducing animal use, recent efforts focus on New Approach Methodologies (NAMs), including *in vitro* assays, *in silico* models, and systems biology tools. These approaches aim to enhance mechanistic insight and human relevance. However, the complexity of the immune system means no single method can cover the full spectrum of potential adverse effects. Nonetheless, progress is evident. Alternative assays—such as cytokine profiling, T-cell proliferation, and dendritic cell function tests—are gaining validation and regulatory interest. Similarly, *in vitro* and *in silico* sensitization models have advanced, with some incorporated into OECD guidelines. This lecture will highlight recent scientific and regulatory advances in alternative immunotoxicity testing, address persistent challenges such as assay standardization and applicability domains, and explore future directions including Adverse Outcome Pathways and systems immunology. Together, these innovations support a more predictive, ethical, and human-centered approach to immunotoxicity evaluation.

S 1073 The Future Is Adaptive: Modeling Immune Diversity and Function in Microphysiological Systems

R. Pompano. University of Virginia, Charlottesville, VA. Sponsor: M. Collinge

Although the past decade of advances in animal studies and human multi-omics platforms yielded dramatic advances in understanding of immune processes, effective vaccines and immunotherapies remain challenging to develop. One reason is the lack of accurate models that recapitulate immune responses in human disease. Microphysiological systems (MPS) offer the potential to fill this gap, but integration of adaptive immune function into MPS is still in early stages. In addition, factors such as sex and other aspects of human variation are rarely considered in MPS models, but significantly impact immune responses to infection and vaccination. This lecture will briefly review current MPS models of lymphoid function and describe our recent work on an MPS that predicts antibody production from naïve human lymphocytes. The model starts with purified naïve T cells and B cells from human blood, co-cultured in a 3D matrix in a microfluidic chip that allows the option to pattern cells into T cell and B cell regions. Naïve CD4 T cells were differentiated into T follicular helper cells

and allowed to interact with B cells. This model yielded plasmablast and plasma cell differentiation, spontaneous formation of lymphoid clusters, and IgM production in response to model (super)antigens, making it applicable to donors with a broad range of HLA alleles. In ongoing work, we are advancing the system to predict the response to vaccine-relevant antigens, and incorporate elements of human variation such as age and sex.

S 1074 Reconstructing Human Lymph Node Function *In Vitro* Using a Microphysiological System

L. van den Broek. MIMETAS, Oegstgeest, Netherlands. Sponsor: M. Collinge

Lymph nodes play a crucial role in orchestrating immune responses in the human body. However, existing *in vitro* models fall short of replicating the full complexity of human lymph node architecture and function. Microfluidic technology presents a promising solution to bridge this gap by enabling stable chemical gradients, continuous perfusion, and membrane-free stratified co-cultures. These features provide physiologically relevant signals and support complex 3D tissue organization that closely mimics *in vivo* lymph node. To advance this field, NC3Rs and four pharmaceutical companies funded a CRACK IT Challenge aimed at developing a human *in vitro* T-cell dependent antibody response (TDAR) assay. In this talk, we present the human lymph node-on-a-chip platform developed in this challenge. This platform co-cultures human adaptive and innate immune cells (PBMC derived), along with supporting stromal cells (eg. endothelial cells and fibroblasts), in a 3D configuration. The immune cells in the 3D lymph node model were assessed by flow cytometry to look at the state of the immune cells and different subtypes and assessed by immunofluorescent staining to look at their interaction. Upon exposure to the SARS-CoV-2 spike protein, the *in vitro* human lymph node showed changes in immune cell development and humoral immune responses, including plasma cell differentiation. Additionally, B and T cell activation and proliferation were observed, along with dynamic reorganization of immune cells. Fluorospot was performed to look at specific SARS-CoV-2 IgG and total IgG production. In 50% of the experiments specific IgG for SARS-CoV-2 were detected upon exposure to the SARS-CoV-2 spike protein. This is demonstrating the potential of microfluidic platforms for modeling human-specific immune responses *in vitro*.

S 1075 From Simple to Complex: Leveraging a 2D *In Vitro* Assay for Primary Antibody Response to KLH

L. O'Donnell. Pfizer Inc., Groton, CT. Sponsor: M. Collinge

Lack of an *in vitro* assay capable of measuring a primary antibody response, equivalent to the *in vivo* T cell-dependent antibody response (TDAR), is an important gap in immunosafety assessments. While development of 3D and microphysiological systems (MPS) are advancing our understanding of many aspects of the immune system, development of successful complex models of a functional primary immune response remains a challenge. 2D approaches, with their relatively simple composition of defined immune cells co-cultured in suspension, are often considered less relevant since they lack the architectural and spatial complexity of immune organs. But the assays can be sufficient to generate relevant immune functional data and the higher throughput and versatility of 2D assays can be leveraged to establish the necessary components for higher complexity approaches, such as antigen-priming, co-culture cell type composition, provision of exogenous factors, etc. In this talk, we present the development of a 2D *in vitro* assay, using human PBMC and cells differentiated from human PBMC, capable of generating antibody responses to the neo-antigen KLH. Findings that support successful generation of a KLH-specific immune response including critical cell responses (such as activation and/or proliferation of dendritic cells, B cells and T cells), provision of exogenous factors and anti-KLH IgM production, will be presented. Efforts to transfer the 2D assay to more physiological 3D and MPS models and development of an alternative 2D assay using immune tissue (ie, tonsil) will be discussed.

S 1076 Regulatory Considerations for Incorporating NAMs-Based Immuno-safety Assessments into the Drug Development Process

R. Wange. Aclairo Pharmaceutical Development Group, Bethesda, MD.

The immuno-safety assessment of new drug has always been a somewhat challenging endeavor. This, in part, derives from differences in the immune system between species, as well as the tiered approach to the assessment of immuno-safety, which generally does not directly query the effects of a pharmaceutical on functional aspects of the immune system. Appropriately constructed and qualified NAMs hold the promise of being able to bridge the gap from both of these shortcomings. This presentation will consider some of the regulatory considerations and expectations regarding incorporation of NAM-based immuno-safety assessments into the drug development process.

W 1077 **Reevaluating Adversity and the Maximum Tolerated Dose in the Modern Regulatory Environment**

F. Sewell. NC3Rs, London, United Kingdom.

While alternative approaches are rapidly being developed, animal testing remains a regulatory requirement as part of safety assessment for many sectors. It is essential that where *in vivo* studies are required, they are performed to ensure the highest standards of animal welfare. Establishing appropriate scientifically justified high dose levels or maximum tolerated dose (MTD) in regulatory toxicology studies conducted in animals is essential to generate meaningful data for human risk assessment while minimizing unnecessary harm and distress for the animals. This is especially important when data are used in hazard-based regulatory environments, as data from underdosed studies are not considered informative for hazard identification purposes. Increased regulatory focus on this topic has led to concerns around the definition of the MTD and increased the potential to test at excessively high dose levels that risk flawed data and present welfare concerns. This session will discuss regulatory expectations in terms of dose level selection and establishing adversity, focusing on differences across geographies and within OECD test guidelines, and the need for more alignment and guidance in this area to ensure humane endpoints whilst maximizing the scientific validity of the data. The first presentation will provide the background to this topic, information on how consistently the MTD concept is applied across CROs and why these well-established principles on adversity are now being revisited. Other presentations will discuss considerations for dose level selection, including body weight loss versus reduced body weight gain, food consumption, and other clinical signs, calling for more tailored and objective guidance on humane endpoints for specific study types and/or life stages to better inform decisions. Finally, case studies from CROs and industry will be presented to illustrate the complexities of dose level selection and the consequences of inappropriate dose level selection and provide alternative approaches to refine dose selection using data-driven approaches with the predictive power of NAMS in hazard-based environments.

W 1078 **Introductory Background on Dose Selection of *In Vivo* Studies Within Hazard-Based Regulatory Environments and Why First Principles of Dose Adequacy Are Now Being Reevaluated**

E. Richmond. Exponent, Harrogate, United Kingdom.

Establishing adversity levels within *in vivo* toxicity studies for chemical regulatory purposes is fundamental both scientifically and legislatively. Despite being a common principle established for many decades, in recent years there has been increased European regulatory focus on suitability of dose levels to fulfil these requirements and reliably inform on hazard endpoints for human safety. European regulatory concerns arose from evidence of underdosed studies rendering data meaningless for classification purposes. However, establishing adversity has to be balanced against the flawed scientific data and ethical issues arising from dosing at excessive levels exceeding the Maximum Tolerated Dose (MTD). Whilst OECD guidance exists to define humane endpoints, this only reflects frank effects clearly exceeding the MTD, and there is no guidance to establish more refined evidence of adversity across a spectrum of change. Reflecting this lack of guidance and perceived increases in risk over regulatory acceptability, there are emerging patterns for *in vivo* testing at excessive doses in an effort to empirically prove the eventual high dose has been fully maximized. In order to reverse this concerning trend, and support better regulatory confidence in dose setting, there is now a pressing need to reevaluate adversity and the concept of the MTD in the modern testing paradigm and it is proposed that harmonized guidance be developed. To facilitate discussion, and provide background, this introductory workshop session will outline what information already exists to support dose selection and adversity within European guidance and legislation, and provide context to why this well-established principle on identifying adversity setting is now being revisited. This session will also present information on a data scoping exercise conducted across CROs to establish how consistent the concept of the MTD and humane endpoints are applied across laboratories.

W 1079 **Refining Humane Endpoints by Providing More Objective Guidance**

F. Sewell. NC3Rs, London, United Kingdom.

The use of appropriate humane endpoints to minimise pain and suffering is a key consideration when conducting *in vivo* studies, including for making decisions regarding dose selection, to determine the maximum tolerated dose (MTD) and/or the need for interventions. Whilst there is debate around what constitutes an MTD in terms of limits for body weight loss and/or reduced body weight gain, some guidance exists within the OECD guidance document on limits relating to humane endpoints (OECD Guidance Document 19, 2000). However, this is generic and subjective, and not specific to different study types, duration, species and/or life stages (e.g. juvenile or pregnant animals). This subjectivity can mean differences in opinions, and therefore decision-making, which can impact the in-life experience of the animals involved. There is a need to update current advice on humane endpoints to support

the use of tailored and objective humane endpoints that are appropriate for the species used, the procedure/study performed, and the organ/body system involved. This can be used to inform study designs and in-study decisions, and to better define early interventions to avoid and/reduce suffering in animals. This presentation will present the need to update current guidance on humane endpoints that considers factors such as the duration and severity of clinical signs that can help provide a more objective definition of humane endpoints.

W 1080 **Evaluation of Adversity and Selection of Dose Levels for Toxicology Studies Using Clinical Signs, Body Weight, and Food Consumption**

M. Beekhuijzen. Charles River Laboratories, Den Bosch, Netherlands. Sponsor: F. Sewell

In the last couple of years there has been a lot of debate on the selection of dose levels and evaluation of adversity between industry and ECHA. Working at a contract research organization (CRO) we are in the midst of this discussion, with scientific arguments against regulatory arguments. A resolution for this problem is urgently needed. With this workshop we would like to start moving towards consensus and produce a guidance document that aligns the approach for dose level selection and adversity evaluation. In this presentation, several case studies will be presented with examples of clinical signs and effects on body weight and food consumption. These will be put against published literature and regulatory guidance (for pharmaceuticals, industrial chemicals and pesticides), followed by a discussion with the audience. Examples from both general toxicology as developmental and reproductive toxicology studies will be presented as well as rat and rabbit data.

W 1081 **Evidence-Based Dose Level Selection for Toxicology Studies Using Prior Knowledge and New Approach Methodologies**

D. Cowie. Syngenta Crop Protection, Bracknell, United Kingdom. Sponsor: F. Sewell

Toxicology studies are crucial for assessing the safety of novel compounds, informing regulatory decisions, and protecting human and environmental health. A critical aspect of study design is dose selection, which must balance hazard identification with ethical considerations and resource efficiency. Traditionally, identifying the Maximum Tolerated Dose (MTD) involved initially testing high doses that were subsequently reduced if found excessive, often resulting in unnecessary animal testing and potentially misleading toxicological profiles. This presentation introduces a systematic, evidence-based framework for optimizing dose selection that integrates historical knowledge with modern technologies. We demonstrate how comprehensive analysis of existing toxicological databases—including clinical pathology parameters and organ toxicity profiles—can establish scientifically justified starting points for toxicology studies. These data-driven approaches can be further refined by the implementation of physiologically based pharmacokinetic/pharmacodynamic (PBPK-PD) modeling to extrapolate *in vitro* findings to *in vivo* scenarios across species. In combination, these tools enable the extrapolation of *in vitro* and *in vivo* data to predict potential effects across different dose levels and species, thereby refining dose selection and reducing reliance on extensive animal testing. By integrating prior knowledge with the predictive power of NAMS, this presentation will demonstrate how to design more scientifically sound, ethically responsible, and resource-efficient toxicology studies.

W 1082 **Petroleum Substance Testing Strategy and Results: Trying to Demonstrate Use of the “Highest Possible Dose Without Severe Suffering or Death” and Still Obtain Meaningful Results**

N. Synhaeve. Concawe, Brussels, Belgium. Sponsor: F. Sewell

Petroleum substances are complex hydrocarbon substances with unknown and variable composition (i.e. UVCBs), posing significant challenges for toxicity assessment. To evaluate their safety under the REACH legislation, *in vivo* toxicological tests are mandated, particularly for reproductive and developmental toxicity endpoints. Historically these substances have been assessed by dermal and inhalation routes of exposure, as the main routes of (limited) human exposure. Over the years further knowledge has been built on the overall properties of the various petroleum streams and the constituents that cause toxicity (e.g. 3+ ring poly-aromatic hydrocarbons). For UVCBs it is difficult to demonstrate systemic exposure, and per regulatory request new testing via the oral route of exposure was initiated. We conducted a series of OECD TG 422 screening studies for 14 gas oil substances with the aim of selecting suitable candidates for higher tier testing, provide range finding for further work and, to demonstrate biological similarity for read across. We will discuss how and why we amended our study design to accommodate the new guidance from ECHA on dose-level selection for the conduct of reproductive toxicity studies. Following the OECD TG 422 studies, we have conducted a number of higher tier tests which have included the limit dose of 1000 mg/kg/day. In some of these studies we have observed (predictable) secondary effects due to reduced bodyweight gain and

food consumption as well as excessive liver hypertrophy. We will also discuss the difficulties encountered due to dosing levels in differentiating adaptive and non-adverse findings from potentially toxic observations.

W 1083 Talking the Tox: Effective Risk Communication of Toxicological Hazards for Public Consumption

B. Cummings. Wayne State University, Detroit, MI.

This Workshop uses an interactive approach with case studies to help attendees develop critical strategies for effectively communicating the risks that environmental toxicants, pollutants, medical devices, and therapeutics pose to humans. Attendees will gain knowledge of initial steps in risk communication, development of communication teams, and implementation of communication plans that inform the public of the risk of toxicants during health emergencies, environmental disasters, and drug development. Case studies presented will aid attendee's understanding of key steps in the initial design and implementation of risk communication using scientific rationale. Attendees will be first be exposed to an overview of risk communication and will be introduced to stakeholders in risk communications and to the ethical frameworks that serve as guiding principles for scientists to engage and communicate with the community-at-large. The following presentations will focus on risk communication from the pharmaceutical, government, and emergency response perspectives and will utilize case studies to emphasize concepts introduced in the initial presentation. An interactive format will be utilized allowing attendees to identify key concepts using their mobile devices and review these concepts audience-wide after each study is presented. The Workshop will end with a roundtable allowing panel members to share sound practices and barriers to effective risk communication. Attendees will be provided test cases as part of the engagement activity and will be encouraged to present their approach to communication of risk to the panel to aid their understanding of key strategies of effective risk communication.

W 1084 Critical Strategies in Effective Risk Communication of Adverse Outcome Events That Threaten Public and Environmental Health

W. Al-Delaimy. University of California San Diego, CA. Sponsor: *D. Germolec*

Science involves several processes from design to implementation, and communication of potential risks or hazards to human health requires proper and ethical community engagement. This is more critical in environmental health research where results can lead to adverse impacts on the livelihood and well-being of impacted communities. Furthermore, in environmental health there are many stakeholders with vested interest that do not support open scientific evidence if it harms their industry or livelihood of communities exposed to such risks. In this session, real-life scenarios will be shared with the audience and address the process of engaging, as well as reporting results of studies. The ethical frameworks will be the guiding principles for scientists to engage and communicate to study participants and the community at large.

W 1085 Risk Communication in Pharmaceutical Development: Educating the Government and the Public on Drug Safety and Development

L. Lehman-McKeeman. Bristol Myers Squibb, Princeton, NJ.

This presentation will inform attendees about approaches used by pharmaceutical companies to communicate the application of hazard identification and risk assessment to drug discovery and development. Relevant stakeholders include non-toxicology colleagues, government regulatory agencies, medical practitioners and the public. Examples will be used to highlight the combination of a broad spectrum of research tools and approaches that can be used to determine human safety. Discussion of communicating findings on mechanistic research to define the relevance of animal data for human risk assessment for mouse lung tumors observed with the antiviral drug entecavir (hepatitis B) will be highlighted. The critical need to discuss exposure-related adverse effects at margins that exceed therapeutic exposures will be discussed with examples including anti-coagulant therapies and kinase inhibitors. These examples will highlight effective communication strategies for exaggerated pharmacology or dose-dependent off-target effects. Strategies for communicating these approaches in a cogent, integrated and simple manner will be discussed and will align the case study with key concepts from the first presentation.

W 1086 How Do Governmental Agencies Communicate the Risk of Environmental Chemicals to the Public?

L. Birnbaum^{1,2}. ¹Duke University, Durham, NC; and ²NIEHS (Retired), Research Triangle Park, NC.

This presentation will inform attendees about approaches used by government research and regulatory agencies to communicate the risk of regulated and emerging environmental toxicants to human and animal health. PFAS are known as "forever" chemicals because they are environmentally persistent, mobile, and often toxic. They

represent a huge class of synthetic chemicals which have multiple uses but have also been associated with a plethora of adverse effects in multiple animal species as well as people. This speaker will highlight the communication of hazards and risks of exposure to "forever" chemicals, PFAS, and align the strategies with key concepts presented by the first speaker.

W 1087 Communication of Risk on the Frontlines: Lessons from High Profile Chemical Emergency Responses

P. Nony. Center for Toxicology and Environmental Health, Little Rock, AR.

This presentation will inform attendees about approaches used to assess and communicate risk during some of the highest profile chemical emergency responses of the past 20 years, including the 2010 Gulf Oil Spill. It will highlight crisis communication during emergency situations and strategies used when dealing directly with key stakeholders, such as emergency responders and private citizens. It will also present strategies from a toxicologist with over 20 years of expertise in emergency response to spills impacting the public and align these strategies with key concepts in risk and crisis communications.

W 1088 Toxicological Risk Assessment of Medical Devices Used for Neonatal and Pediatric Populations

S. Rawat. Becton Dickinson, Irvine, CA.

Medical devices can be used to treat patients across the lifespan, from infancy to old age. However, there are particular challenges associated with the development of pediatric devices, both in terms of clinical applicability and the potential toxicological risk posed by patient exposure to compounds released from the devices. Clinically, innovators must modify adult-sized products to address the smaller size of the patient and their rapid changes in growth. From a toxicological perspective, the need exists to derive tolerable intake (TI) values that are protective of adverse effects that may occur in this potentially more sensitive subpopulation of patients. While instrumental updates have recently been made to the ISO 10993-17 standard to address the potential risk posed by exposure of pediatric patients to compounds released from device materials, there are still unique challenges that exist when conducting toxicological risk assessments for neonatal and pediatric populations. The goal of this workshop is to explore the clinical challenges associated with developing pediatric devices; provide an overview of considerations that need to be accounted for when performing toxicological risk assessments for neonatal and pediatric populations; and provide case studies that illustrate approaches that can be used to address the challenges.

W 1089 Regulatory Overview and Discussion of the Challenges and Benefits Associated with Developing Pediatric Devices

A. Komiya. Bluestocking Health LLC, San Diego, CA. Sponsor: *S. Rawat*

Few medical devices are designed and marketed specifically for children. Instead, adult devices are often repurposed and used off-label in pediatrics. The innovation gap between pediatric and adult devices is complex and multifactorial. This talk will provide an overview of the medical device landscape, describe barriers (and benefits) to pediatric device development, and include strategies that are available to help overcome these obstacles. Key topics include the complexities of designing devices that accommodate the anatomical and physiological differences in pediatric patients, the importance of well-designed biocompatibility studies, and strategies for addressing the limited availability of clinical data in this population. Participants will also learn about the latest FDA guidelines and initiatives aimed at fostering innovation while maintaining rigorous safety standards.

W 1090 Overview of Challenges Related to the Toxicological Risk Assessment of Infants and Children from Exposure to Medical Devices

S. Parker. SParker Toxicology Consulting LLC, Davie, FL.

The presentation will describe the differences in neonate and general population systemic toxicity associated with medical devices. Further, the challenges with evaluating the toxicological risk of extractable and leachable compounds to neonates and children will be outlined. This will include a discussion of ISO 10993-17 risk assessment principles and a description of how each step of the risk assessment paradigm needs to be adapted for neonates and children. Specifically, the challenges will be discussed in deriving TI values for infants and children; establishing actual clinical use scenarios; and considering foreseeable misuse as a new focus of ISO 10993-1.

W 1091 Availability and Use of Developmental Toxicity Data for Evaluating the Risk of Adverse Events to Infants and Children

K. Ehman. Eurofins Lancaster Laboratories, Saint Paul, MN.

Ideally, data derived from studies in which neonates are exposed to a potentially hazardous material are preferable when calculating TIs for medical devices intended for use by neonates. However, to capture different developmental milestones in a human, multiple animal studies may need to be considered. This presentation will provide an overview of commonly available developmental and reproductive study designs as well as the reported endpoints that define effect levels. The objective is to provide toxicologists with an understanding of the strengths as well as the limitations to be able to effectively select a point of departure (POD) and appropriate uncertainty factors (UF) for the population being evaluated.

W 1092 Is an Additional UF Needed for the Derivation of TI Values Intended to Be Protective of Infants and Children?

R. Brown. Risk Science Consortium, Arnold, MD.

ISO standards and technical specifications have been developed to provide guidance on methods to derive Health Based Exposure Limits (HBELs) for compounds released from medical devices. These HBELs include Tolerable Intake (TI) values and Threshold of Toxicological Concern (TTC) values. The method for deriving TI values is described in the ISO 10993-17:2023 standard. Specifically, the TI and TE values for compounds released from devices intended for use in children should include consideration for the potential immaturity of the principal routes of elimination of the material and the potential for higher accumulation. Ideally, data derived from studies in which neonates are exposed to the hazardous material are preferable when calculating TIs for medical devices intended for use by neonates. However, data from toxicity studies conducted in juvenile animals are not readily available, therefore, ISO 10993-17:2023 outlines the application of an uncertainty factor (UF) of 3 for derivation of TI using data from studies conducted in adult animals. This talk will explore whether the existing UF to account for interindividual variability is sufficient to account for the potential increased sensitivity of neonates and children to extractable and leachable compounds.

W 1093 Case Studies Evaluating Neonatal Susceptibility to Chemical Exposures from Medical Devices and Implications for Toxicological Risk

J. Cohen. Gradient, Boston, MA.

Medical devices intended for neonatal populations are typically evaluated for potential systemic toxicity and carcinogenicity risks via chemical characterization and subsequent toxicological risk assessment of the extractable chemicals profile. In accordance with ISO 10993-17:2023, chemical specific tolerable intakes require an additional uncertainty factor of 3 to account for immaturity of the metabolic capacity and renal function for this specific patient population (infants <6 months of age). The immaturity of neonatal toxicokinetics (metabolism, distribution and elimination) can potentially yield blood levels that are higher for longer durations than those typically observed in older populations. Furthermore, neonatal susceptibility is a concern for several commonly observed medical device extractables. For example, neonatal exposures to benzyl alcohol are associated with metabolic acidosis, respiratory distress and neurological toxicity. Isopropyl alcohol is associated various toxic effects including central nervous system depression in neonates. Potential susceptibility to di-(2-ethylhexyl) phthalate (DEHP), a reproductive toxicant in animals, is of particular concern in light of its frequent use in medical tubing and blood storage bags found in neonatal intensive care units. In this presentation, case studies detailing specific mechanisms of neonatal susceptibility, and the implications for potential toxicological risk associated with exposures associated with chemical released from medical devices will be discussed.

W 1094 Considerations in the Toxicological Risk Assessment of Gas Pathway Devices for Neonates and Children

R. Nguyen. Philips, Perrysburg, OH.

Medical devices with breathing gas pathways intended for neonates and infants present unique challenges in biological and toxicological risk assessments. These challenges are due to the route of exposure via the respiratory tract with different forms of potential hazards such as Volatile Organic Substances (VOS), particulate matter, and leachables found in the condensate, and warrant special consideration as they are coupled with the susceptibilities of low body weight patient populations. This presentation will provide an overview of the anatomical and physiological differences between the respiratory system and metabolism of adult and infant populations, and how these differences influence toxicological risk assessment for gas pathway devices. It will also review current approaches for evaluating VOSs and

aldehydes (ISO 18562-3), leachables in condensate (ISO 18562-4), and derivation of tolerable intakes (TIs) and tolerable exposures (TEs). Approaches for calculation of exposure and inhalation doses for neonates and infant population per ISO 18562-1:2024 and ISO 10993-17:2023 will also be discussed.

R 1095 Chemical Exposures and At-Risk Populations in California

A. Reddam. OEHHA, Oakland, CA.

California is a large state with a heterogeneous population and wide-ranging topography. Populations in California have multiple and varied environmental exposures that can impact health. These can include exposures from oil and gas refineries, air pollution, pesticides, and extreme weather events such as wildfires. We need a better understanding of California's unique chemical exposure patterns, with the goal of identifying potential sources and reducing exposures by implementing policy changes. Furthermore, this information can help inform how populations are exposed to similar environmental exposures in other regions of the US. This session brings together scientists from academia, government, and nongovernmental organizations to discuss the different ways in which Californian's exposures to chemicals are being assessed, with a focus on the role of biomarkers as an exposure tool. Following a brief introduction to the topics covered in this session, the first speaker will discuss the development of analytical methods used to assess both chemical exposures and metabolic profiles indicative of birth defects in amniotic fluid. Next, we'll hear from speakers on the implementation and findings from biomonitoring studies carried out in different regions and communities within California. The second speaker will discuss metals exposures in urban communities that live near oil drilling sites in Los Angeles using toenails, a noninvasive biological matrix. The third speaker will talk about biomarkers of air pollution exposure and biomarkers of response in a population in the Central Valley of California. Finally, the fourth speaker will discuss community experiences and real-world impacts of biomonitoring data in California, with a focus on a community of farmworkers in the Central Valley and firefighters who were first responders to wildfires across the state. The session will end with a panel discussion. This session will provide a well-rounded discussion on novel methods and approaches used in biomonitoring and the value and impact of the data generated from these studies.

R 1096 Prediction of Birth Defect Cases in Amniotic Fluid Using Machine Learning on Non-targeted HRMS Features: Integrating Metabolomics and Environmental Contaminants in the Exposome

X. Ji. CalEPA Department of Toxic Substances Control, Berkeley, CA. Sponsor: A. Reddam

Birth defects remain a major global public health concern, with growing evidence implicating environmental exposures alongside genetic factors. The full range of exogenous chemicals linked to adverse fetal outcomes remains unclear. Amniotic fluid, reflecting both maternal and fetal exposures, offers a valuable matrix for profiling metabolic and chemical signatures relevant to fetal development. We applied LC-HRMS-based non-targeted analysis (NTA) to amniotic fluid from pregnancies affected by birth defects to: (1) assess metabolic differences between case and control samples and predict status via machine learning; (2) annotate discriminative features using database searches and *in silico* fragmentation; (3) identify altered metabolic pathways; and (4) investigate exogenous chemicals and their associations with disrupted profiles. Although specific contributors could not be confirmed, several significantly different features (Mann-Whitney U test, $p < 0.01$) showed decreased signal in cases. These represented diverse metabolite classes, with 76% remaining unidentified. Pathway analysis revealed pronounced changes in long- and medium-chain fatty acid metabolism, phospholipid metabolism, and tryptophan metabolism. Network analysis highlighted metabolites in primary bile acid biosynthesis and fatty acid metabolism intersecting with purine metabolism, amino acid exchange, and the acetyl-CoA pool from nitrogen metabolism. We identified exogenous chemicals positively correlated with altered endogenous metabolites, suggesting potential interference with lipid and mitochondrial enzymatic function during pregnancy. Notable examples include butyl levulinate (solvent, fuel additive, fragrance ingredient), oleic acid methyl ester (industrial, agricultural, cosmetic, biodiesel uses), and lauryl sulfate (anionic surfactant). Our findings demonstrate the potential of NTA-integrated exposomics to inform early diagnostics and clarify links between environmental exposures, pregnancy complications, and fetal development disorders.

R 1097 Metal Exposures in Residents Living Near Urban Oil Drilling in Los Angeles, California

J. Johnston. University of California Irvine, Irvine, CA. Sponsor: A. Reddam

Los Angeles (LA) California, is situated atop one of the largest urban oil fields in the United States. Land development, population growth, and oil exploration occurred concurrently, leaving a patchwork of thousands of active oil wells operating in very close proximity to homes, schools, and parks. There is limited informa-

tion about potential biomarkers of exposures. As part of community-based participatory research, we assessed exposure to arsenic (As), cadmium (Cd), mercury (Hg), manganese (Mn), nickel (Ni), lead (Pb), and antimony (Sb) in toenail clippings collected from two cohorts in South LA. We used non-negative matrix factorization (NMF), a dimension reduction technique, to identify potential sources of toxic metal exposures, and to understand how these metals cluster. In the LAS VOCES cohort, consisting of adults living within 1 km of an active oil drilling site on the Las Cienegas oil field (n=239), we identified three factors, including a Ni and Mn factor, which is hypothesized to be related to oil drilling. Ni is the most abundant trace metal in oil and Mn has been linked to oil drilling; both Mn and Ni have been found together in particulate matter near drilling sites in the LA area. Expanding this work to the BELLA cohort, consisting of Latina women living throughout South LA neighborhoods (n=369) we found this same factor. Moreover, we observed a statistically significant increase in the Ni-Mn factor score with increased oil and gas production within 1 km of the participants home in the prior 12 months. This research builds evidence of clustered Ni and Mn exposures near active oil and gas production in LA. Utilizing NMF, we identified a source factor high in Ni and Mn in residents living near oil and gas production in urban LA.

RI 1098 Urinary Biomarkers of Air Pollutants in Two Communities in the San Joaquin Valley

A. Reddam. OEHA, Oakland, CA.

The San Joaquin Valley (SVJ) in California (CA) has some of the nation's worst air quality, often failing to meet federal standards. Exposure to air pollutants is associated with serious health effects, with children being particularly vulnerable. The objective of the Biomonitoring Component of the SVJ Pollution and Health Environmental Research Study (BiomSPHERE) was to measure biomarkers related to air pollution exposure in Stockton and Fresno, CA. Urine samples were collected from 64 parent-child pairs in 2023. Metabolites of four polycyclic aromatic hydrocarbons (PAHs), six volatile organic compounds (VOCs), and nicotine were measured in urine by LC-MS/MS. Additionally, four biomarkers of response (8-isoprostane, 8-OHdG, PGE2, and CC16) were measured by ELISA. A survey was administered to collect information on demographics and potential exposure sources of PAHs and VOCs. The average age of adults and children was 42 and 9 years, respectively. Most participants were Hispanic/Latino (69%). Metabolites of fluorene (2-hydroxyfluorene), naphthalene (2-hydroxynaphthalene (2-naphthol)), phenanthrene (1-hydroxyphenanthrene), and pyrene (1-hydroxypyrene) were detected in more than 85% of samples. Metabolites of acrolein (3-hydroxypropyl mercapturic acid), acrylonitrile (2-cyanoethyl mercapturic acid), crotonaldehyde (3-hydroxy-1-methyl-propyl mercapturic acid), and propylene oxide (2-hydroxypropyl mercapturic acid) were detected in more than 90% of the samples. Levels of PAH and VOC metabolites in urine were similar or lower than NHANES, except for 2-naphthol. Concentrations of 2-naphthol were around 3 times higher than NHANES and significantly positively correlated between adults and children suggesting a common exposure source. Additionally, 2-naphthol levels had a high interclass correlation coefficient, suggesting consistent exposure to naphthalene. 2-naphthol levels were significantly higher in Hispanic/Latino participants and in participants who used cleaning products, air fresheners, and scented products. Each of the biomarkers of effect were detected in all participants. Average levels of 8-isoprostane, 8-OHdG, and CC16 were higher in adults compared to children, and PGE2 was higher in children. Further work is needed to identify exposure sources for naphthalene and associations between the biomarkers of exposure and response.

RI 1099 Report-Back of Environmental Exposure Data and Impacts of Biomonitoring Studies in California

S. Patton. Commonweal Biomonitoring Resource Center, Bolinas, CA. Sponsor: A. Reddam

This presentation will examine two case studies of community-based biomonitoring research projects in California. The first case study will focus on firefighter exposures to PFASs and other chemicals and the second case study will explore pesticide exposures in a farmworker population in the Central Valley. This presentation will report on the different steps of community-based participatory research, from requests for biomonitoring, to sample collection in the field, to dissemination of results. We will highlight how the "exposure experience"—the embodied, personal experience and understanding of chronic exposure to environmental pollutants—is shaped by community context and the report-back process itself. We analyze themes of expectations and learning, trust, and action and how these may differ depending on various facets of the community. This presentation unravels the complex relationship between lay experience and lay understanding of science and discusses the importance of community-based participatory research for policy development and/or social change in California and beyond.

S 1100 It's Time to OVARY-Act: New Insights into the Effects of EDCs on Ovarian Function

B. Rickard. North Carolina State University, Raleigh, NC.

Endocrine-Disrupting chemicals (EDCs) have the potential to disrupt normal ovarian functioning by interfering with key processes such as hormone regulation and ovulation. Impairment of these processes is detrimental, as, locally, it can lead to menstrual irregularities, infertility, and polycystic ovarian syndrome, while, more broadly, hormone imbalances can contribute to osteoporosis and cardiovascular disease. In some cases, EDC exposures can also contribute to the onset and metastatic progression of ovarian cancer, the deadliest gynecologic malignancy largely due to the limited effectiveness of existing therapies. This Symposium brings together scientists of varying expertise and career stage to discuss the latest research on EDCs, ovarian health, and their underlying mechanisms. The session will begin with a brief introduction of normal ovarian processes and organ-specific targets of EDCs. The first speaker will then provide an overview of the effects of EDCs on ovarian health from a pathologist's perspective. Next, the second speaker will highlight the effects of environmentally relevant phthalate mixtures on ovulation in multiple primary ovarian cell culture models. The third speaker will follow by providing new evidence of mechanistic pathways driving phthalate-induced adverse effects on several ovarian cell types and fertility outcomes using a single-cell approach. Shifting gears to another class of EDCs, the fourth speaker will present compelling findings illustrating the adverse effects of gestational exposure to the herbicide atrazine on ovarian follicle health in a porcine model. Finally, shifting the focus to ovarian cancer, the fifth speaker will share novel findings suggesting that chronic (35-day), human-relevant perfluoroalkyl substance (PFAS) exposures drive chemotherapy resistance through enhancing mitochondrial functionality. Altogether, this session will highlight the importance of considering the impact of EDC exposures on the ovary over multiple life stages (i.e., *in utero*, early life, and later cancer outcomes) and will shed light on the novel mechanisms driving such effects. A 10-minute discussion led by the Chair and Co-Chair will conclude the session, providing time for additional questions from audience members and a chance to discuss future research topics of importance, such as emerging EDCs or potential therapeutic interventions for effects discussed during this session.

S 1101 Introduction: New Insights into the Effects of EDCs on Ovarian Function

L. Sapienza-Lundie. University of North Carolina at Chapel Hill, Chapel Hill, NC. Sponsor: B. Rickard

This session will cover EDCs and their effects on normal ovarian function and overall women's health. Humans are exposed to EDCs through multiple routes on a daily basis, such as through use of personal care products and even in drinking water supplies. While awareness of EDCs, like phthalates or PFAS, and their adverse health impacts has increased in recent years, further research is needed to fully identify how these environmental chemicals alter ovarian cell types and functions, such as menstrual cyclicity, hormone levels, and fertility. Throughout this session, we will explore how exposure to EDCs shapes ovarian function and women's health, mechanisms driving alterations, and ways to change the trajectory of women's health for the future.

S 1102 Endocrine-Disrupting Chemicals and the Ovary: A Pathologist's Perspective

B. Dray. Charles River Laboratories, Ashland, OH. Sponsor: B. Rickard

Endocrine disrupting chemicals (EDC) are ubiquitous in the environment and there are a multitude of ways in which they can impact ovarian function. Females are born with a finite number of oocytes and therefore EDCs that effect oocyte/follicular health can have a permanent impact on fertility and hormonal regulation. Furthermore, some EDCs have been shown to cause multigenerational effects. The effects of EDCs on the ovary vary depending on the particular chemical and exposure level, but often include altered follicular growth, increased follicular atresia, abnormal luteal regression, poor oocyte quality, alteration to ovarian steroidogenesis, and/or inhibition of ovulation. These effects can differ depending on when the exposure occurs in relationship to reproductive maturity. The ability to avoid exposure to EDCs is nearly impossible, so identifying and characterizing the impact of these chemicals is of critical importance. Veterinary pathologists play a key role in evaluating the endocrine disrupting potential of these chemical compounds. Evaluation of the female reproductive tract can be complicated by the cyclical changes that occur in hormone levels and in the morphology of the organs, along with notable differences in reproductive anatomy and physiology between species. Depending on the length of the study and the life stages examined, differences in reproductive maturity and senescence can be important considerations. Thorough knowledge of the different estrus cycle (or menstrual cycle) stages and common background findings in each species is essential when evaluating the ovary for potential test substance-induced changes. Although organ weights and histopathology are the most obvious endpoints evaluated by pathologists on regulatory studies, there are several other

endpoints that are important to consider when evaluating potential EDC impact on the female reproductive tract which may include hormone levels (FSH, LH, E2), age at vaginal opening and first estrus, estrus cyclicity over time as measured by vaginal lavage, ovarian follicle and corpora lutea counts, implantation sites, and fertility indices. Integration of all available end points is vital in determining which chemicals exhibit endocrine disruption and potential far-reaching effects on reproduction and health.

S 1103 Exposure to an Environmentally Relevant Phthalate Mixture Inhibits Ovulatory Prostaglandin Function in Human Ovarian Granulosa Cell, Cumulus Cell, and Endothelial Cell Models

K. Land. University of Kentucky, Lexington, KY.

Exposure to phthalates, ubiquitous EDCs, is unavoidable, and is now recognized as contributing to the prevalence of infertility in women. Measurable levels of phthalates are found in human ovaries, and since previous studies established that phthalates disrupt ovarian function, exposures may also impair steroidogenesis and ovulation. While many studies have focused on individual phthalate exposures in animal models, little is known regarding the mechanistic effects of phthalate mixtures on ovulation in women. This is alarming since ovulatory defects are the leading cause of infertility. Ovulation is characterized by immense production of prostaglandins (PGs). PGs are vital mediators of ovulation due to their involvement in cumulus-oocyte complex (COC) expansion (stabilized matrix for egg transport to the site of fertilization) and angiogenesis (proliferation and migration of endothelial cells to the ovulating follicle). PGs, specifically PGE2 and PGF2a, are synthesized by granulosa and cumulus cells within the ovulating follicle. PGs bind to their receptors, PTGER1-4, on cumulus and endothelial cells to facilitate COC expansion and angiogenesis, respectively. Primary human granulosa cells, cumulus cells, and ovarian endothelial cells (hOMECs) were collected from women undergoing IVF to test the hypothesis that exposure to an environmentally relevant phthalate mixture (MPTmix) inhibits PG production and function. MPTmix was derived from urinary phthalate metabolite measurements in pregnant women. In human granulosa cells, ovulatory increase in PGE2 and PGF2a levels was inhibited by MPTmix exposure compared to controls. In human cumulus cells, MPTmix exposure decreased PGE2 levels compared to controls. In hOMECs, MPTmix exposure decreased PTGER1 mRNA levels and altered PTGER4 mRNA levels (dose-dependent) compared to controls. These data suggest that MPTmix exposure decreased PG production in granulosa and cumulus cells, which can disrupt expansion of the COC necessary for ovulation. These data further suggest that MPTmix exposure altered the levels of PG receptors on endothelial cells, which can disrupt angiogenesis that is vital for ovulation. Ultimately, exposure to an environmentally relevant phthalate mixture disrupted the essential ovulatory PG pathway in 3 human ovarian models; thus, exposure to phthalates may impair women's fertility.

S 1104 Single Cell Insights into Chemical Toxicity in Human Ovaries

P. Damdimopoulou. Karolinska Institutet, Solna, Sweden. Sponsor: B. Rickard

Human-made chemicals have become an unavoidable part of modern life. The estimated 350,000 chemicals on the market have contributed to an increased standard of living; however, historically poor regulations of their use now jeopardize human health. For example, although the EU has the strictest chemical legislation in the world, 70% of chemicals on the European market have not been assessed for safety. These chemicals end up as contaminants in the environment throughout their life cycle: manufacture, transport, use, and waste handling. As a result, individuals are continuously subjected to complex mixtures of poorly characterized chemicals, including persistent organic pollutants and EDCs. These exposures have been linked to various adverse health outcomes, including infertility. Our analyses of northern European women have revealed complex mixtures of persistent pollutants, parabens, and phthalates in ovarian follicular fluid. These exposures correlated with altered ovarian sensitivity to gonadotropin stimulation during medically assisted reproductive technology. Notably, phthalates were linked to disrupted cholesterol and steroid biosynthesis as well as increased inflammation in somatic cells of the follicles. To provide causal evidence for these observed epidemiological links, we conducted controlled exposure studies using human ovarian tissue culture as a model. As human ovaries are composed of multiple cell types, we analyzed the impacts at a single-cell resolution. We discovered that although ovarian stromal cells exhibited the highest number of significantly differentially expressed genes in response to phthalate treatment, the fold changes were modest. In contrast, rare cell types in the ovary, such as glial cells, immune cells, and endothelial cells, responded to phthalate treatment with high fold changes, suggesting elevated susceptibility. The targeted cellular processes were similar across cell types, relating to metabolism, mitochondria, cell cytoskeleton, and cell-to-cell signaling. Altogether, this study provides novel insights into the molecular pathways through which phthalates may disrupt human ovarian function and highlights sensitive cell types. Several somatic cell populations were found to be more responsive than follicles. This emphasizes the need to assess ovarian toxicity holistically, considering all components, not just follicles.

S 1105 Maternal and Female Offspring Ovarian Follicle Number and Chemical Metabolism Protein Abundance Are Altered by *In Utero* and Perinatal Atrazine Exposure

A. Keating. Iowa State University, Ames, IA.

Atrazine (ATZ) exposure during perinatal development is linked to reproductive dysfunction, which is proposed to be attributed to endocrine disruption. Also, gestational ATZ exposure can lead to adverse outcomes, including low birth weight, delayed fetal growth, and delayed onset of puberty. To investigate the effects of ATZ exposure on the maternal and female offspring ovary in a porcine model, timed pregnant nulliparous sows were provided *ad libitum* access to water that contained an environmentally relevant concentration of ATZ (20 µg/L) or vehicle control [0.002% (v/v) ethanol] to achieve a final ATZ dose of ~0.0014 mg/kg BW. Piglets were exposed to control or ATZ *in utero* from gestation day 28 through birth and lactation (~127 days total). The number of ovarian follicles and abundance of chemical biotransformation and steroidogenic proteins in postnatal day 10 offspring and maternal ovaries were assessed. In offspring, ATZ exposure did not alter the abundance of primordial, primary, and secondary follicles but tended to decrease the abundance of atretic follicles. In sows, ATZ exposure did not affect primary, secondary, antral, or atretic follicle number, however, the number of preantral follicles decreased due to ATZ exposure. Phase I and III chemical biotransformation proteins were also evaluated and found to be altered in both piglets and sows, and there were also impacts on steroidogenic proteins. Taken together, ATZ exposure during gestation and lactation may impact female fertility due to altered ovarian follicle number and ovarian abundance of chemical biotransformation and steroidogenic proteins.

S 1106 Chronic Perfluoroalkyl Substances Exposure Induces Chemoresistance in Ovarian Cancer Cells via Promoting Mitochondrial Alterations

B. Rickard. North Carolina State University, Raleigh, NC.

Ovarian cancer is the deadliest gynecologic malignancy due to high rates of recurrent disease characterized by resistance to platinum-based chemotherapeutics. Thus, identifying drivers of chemoresistance is critical to improving survival outcomes. Environmental exposures have long been studied in the context of oncogenesis, but few studies have examined the link between environmental exposures and therapy response. Since environmental exposures occur daily and toxicants bioaccumulate over time, it is plausible that the exposure to and buildup of toxicants over a lifetime may interfere with response to treatment. Our lab focuses on exposures to perfluoroalkyl substances (PFAS), which are global drinking water contaminants that have been linked to adverse reproductive outcomes. To evaluate the effects of human-relevant PFAS exposures on ovarian cancer cells, we developed a PFAS chronically-exposed ovarian cancer cell line (35 days) and measured response to carboplatin (first-line therapy) and doxorubicin (second-line therapy for platinum-resistant disease). Compared to shorter durations of PFAS exposure (2-6 days), where cell survival increased by up to 50% following chemotherapy treatment, survival fractions increased by an average of 200% in PFAS chronically-exposed ovarian cancer cells treated with chemotherapy. These findings suggest that PFAS induce chemoresistance in a duration-dependent manner and motivated us to understand mechanisms driving this malignant adaptation. Studies have shown that mitochondrial health is pivotal for determining whether an ovarian cancer cell will respond to chemotherapy. As a result, we evaluated mitochondrial structural and functional parameters in PFAS chronically-exposed ovarian cancer cells and found that mitochondrial content and mitochondrial DNA copy number significantly increased compared to controls. Additionally, PFAS-exposed cells demonstrated increased maximum respiratory capacity and extracellular acidification rates, indicative of remodeled metabolism. These findings are critical, as increased mitochondrial content and metabolic reprogramming have been implicated in chemoresistant ovarian cancer. Altogether, this research provides novel insight into the mechanisms underlying PFAS-induced effects on chemotherapy efficacy and may be used to inform personalized treatment regimens based on PFAS exposure levels.

S 1107 Milk Matters: Assessing Breast Milk Through an Environmental Health Perspective

J. Zelikoff. NYU Grossman School of Medicine, New York, NY.

Breast milk is an infant's primary source of water, vitamins, minerals, and fats but also a potential source of environmental toxicants. Maternal exposures can directly translate to infant exposures in milk, particularly in the case of lipophilic compounds. This Symposium will gather experts in breast milk toxicology research from throughout the country to discuss exposure assessment and biological effects of contaminants commonly found in breast milk, such as the per- and polyfluoroalkyl substances (e.g., PFAS, PFOA), microplastics, and brominated fire retardants (BFRs). A brief overview will introduce the topic and speakers and provide a five-minute summary of the overall content of the program. After the introduction, the first presentation will focus on microplastic contamination in breast milk, with a discussion of the physiochemical characteristics and distribution of microplastics in human milk. The second presen-

tation will discuss methods for quantifying BFRs and PFAS in human breast milk and the current levels seen in North American populations, while the third talk will focus on the relationship between PBDE-47 exposure and extracellular vesicle miRNA in human breast milk samples. The fourth presentation will provide insight regarding a possible intervention strategy wherein clay sorbents could be used to remove PFAS from human milk prior to feeding. All speakers will participate at the end of the Symposium in a panel discussion to address preselected and audience-based questions regarding common toxicants in breast milk and their potential short- and long-term health effects, risk-benefits of breast feeding, and potential interventions to protect infant health.

S 1108 Quantitative Analysis of Microplastics in Breast Milk Using Integrated Microscopy and Spectroscopic Approaches

L. Barela, and M. Garcia. University of New Mexico School of Medicine, Albuquerque, NM.

The pervasive presence of micro- and nanoplastics (MNPs) in the environment has raised growing concerns about their potential effects on human health, particularly during vulnerable life stages such as infancy. MNPs are the result of widespread plastic production and degradation, infiltrating ecosystems, food chains, and the environment. Recent studies have identified MNPs in various human biological samples, including blood, lungs, and placenta, suggesting that no organ system is entirely protected from exposure. While previous research has detected MNPs in human breast milk using techniques such as infrared imaging and Raman micro-spectroscopy, these approaches are limited by particle size detection thresholds and potential misidentification of polymer types. To date, no studies have employed a combination of chemical digestion and Pyrolysis Gas Chromatography/Mass Spectrometry (Py-GC/MS) for identifying and quantifying a broad range of polymer types in breast milk analysis. This study addresses that gap by analyzing breast milk samples, including both donor milk and infant formula, collected in 2022 through a collaboration with the NYU Grossman School of Medicine. By optimizing detection sensitivity for 12 distinct polymers, this work provides a comprehensive assessment of microplastic presence in breast milk. The results raise critical questions about potential links between MNP accumulation and maternal lactation challenges, with preliminary associations observed between MNP presence and conditions such as breast engorgement, mastitis, and low milk supply. These findings have broader implications for maternal and infant health, as well as for ongoing research into how plastic-derived pollutants could influence human physiology. Ultimately, this study not only expands the current understanding of MNP distribution in human tissues but also underscores the urgent need for environmental and public health policies aimed at reducing plastic exposure during critical developmental stages.

S 1109 Legacy and Emerging Contaminants in Breast Milk from United States Mothers

A. Salamova. Emory University Rollins School of Public Health, Atlanta, GA. Sponsor: J. Zelickoff

Recent research demonstrates that nursing infants are exposed to a mixture of legacy chemicals that have been phased out from production and use, along with chemicals that replaced them. This presentation will focus on the occurrence, patterns and trends of legacy and replacement chemicals in breast milk from North America, focusing on per- and polyfluoroalkyl substances (PFAS) and brominated flame retardants (BFRs). Breast milk was analyzed for 39 PFAS, including 9 short-chain and 30 long-chain compounds, and 37 polybrominated flame retardants (PBDEs), 18 bromophenols, and 11 other BFRs. Sixteen PFAS compounds were detected in 4-100% of the samples, with several short-chain PFAS detected in the majority of the samples. A total of 26 BFRs were detected, including 9 PBDEs, 8 bromophenols, and 8 other BFRs. Analysis of available breast milk PFAS data from around the world (between 1996-2019) revealed that while the levels of phased-out PFAS have been declining, the detection frequencies of current-use short-chain PFAS have been increasing with a doubling time of 4.1 years. Analysis of time trends in PBDE concentrations in North American breast milk indicated a significant decline since 2002, with a halving time of 12.2 years; comparison with previous samples from the northwest U.S region showed a 70% decline in median levels. Overall, these results demonstrate that while the levels of the phased-out chemicals in milk from US mothers are dropping, the levels of replacement chemicals are increasing, posing continuing health risks for nursing infants.

S 1110 Adverse Effects of Maternal PBDE Exposure on Milk EV-miRNA Profile and Infant Neurodevelopment

R. Khan. NYU Grossman School of Medicine, New York, NY.

Though PBDEs were discontinued in the US in 2009, as stable, persistent contaminants they still exist both in the environment and as body burdens. PBDE exposure has been linked to preterm birth and adverse neurological consequences in exposed infants. Preterm birth has also been independently linked to neurological

consequences. Studies have shown that PBDEs can alter miRNAs within extracellular vesicles (EVs) and that EVs can be stably absorbed by the infant gastrointestinal epithelium. This study examines the relationship between breast milk PBDE levels and EV-miRNAs that support infant neuronal development. Milk PBDE levels were quantified by GC-MS from preterm, full-term, and donor human milk. The average PBDE level of donor milk samples, which are aggregate samples of full-term milk, were used to establish a high PBDE threshold. Results indicate that ~30% of preterm breast milk samples contain high levels of PBDEs. Within this population, there is also an inverse correlation between PBDE level and neuroprotective EV-miRNAs, as quantified by droplet digital PCR. These data suggest a multiple hit scenario for preterm infant neurodevelopment resulting from direct toxicant exposure, preterm status, and decreases in protective EV-miRNA.

S 1111 Novel Sorption Strategies to Reduce Per- and Polyfluoroalkyl Substances in Milk

K. Dinh. Texas A&M University, College Station, TX.

Given the growing concern regarding PFAS contamination in human breast milk, there is a need for mitigation strategies that do not impact milk nutrient composition. Currently, technologies to reduce PFAS in milk, including human breast milk and cow's milk, are absent. This presentation details the application of calcium montmorillonite clays as an innovative solution to remove PFAS from milk. Our approach entails comprehensive kinetic studies to evaluate binding efficiency and milk nutrients post-filtration. Findings demonstrate the initial proof-of-concept that clay-based sorption effectively reduces PFOA and PFOS, two legacy PFAS, in milk without compromising its nutritional composition. Findings highlight clay-based sorption as a viable strategy for mitigating infant PFAS exposure through milk.

S 1112 New Insights into Manganese Neurotoxicity: From Molecular to Clinical Studies

R. Tjalkens. Colorado State University, Fort Collins, CO.

The neurotoxicity of manganese (Mn) has been well-described for over a century, but key molecular events linking cellular and systemic dysfunction across the CNS have remained elusive. Manganese neurotoxicity, or manganism, is characterized by a spectrum of neuropsychological and neuromotor deficits that map heavily to the basal ganglia of the midbrain, although centers for cognitive function and memory are also involved, such as the cortex and hippocampus, among other regions. This Symposium will bring together a diverse group of experts to highlight recent findings in this field to shed new light into the underlying cellular mechanisms of manganese neurotoxicity, including changes in metabolism and gene regulation that impact innate immune function and behavior. In addition, the Symposium will feature lectures on new population and clinical studies that provide insight into how these molecular alterations influence neurological disease status at a population level, as well as how neuroimaging studies shed light on molecular mechanisms relevant to clinical outcomes. The first speaker will provide an overview of the Symposium and then describe the consequence of mutations in the critical Mn transporters SLC30A10 and SLC39A14 and how SLC30A10 functions as the only specific Mn efflux transporter that controls cellular and organismal Mn levels via efflux activity. This talk will examine how HIF signaling modulates expression of this transporter by inducing metabolic reprogramming that generates neurotoxic metabolites of the kynurenine pathway. The second speaker will discuss emerging evidence that Mn-induced dysregulation of transcription factor RE1-silencing transcription factor/neuron-restrictive silencer factor (REST/NRSF) is linked to neurotoxicity, including TH reduction and oxidative stress in neuronal cultures. Using a combination of over-expression studies and cell-specific knockout studies, the speaker will discuss how REST directly modulates the cytotoxic effects of Mn in dopaminergic neurons. The third speaker will discuss how Mn stimulates mitochondrial-dependent activation of the cGAS-STING pathway in astrocytes, a key activator of type-I interferon responses in immune cells as well as in glia. This talk will examine how exposure to Mn in the developing brain leads to activation of innate immunity in glia through cGAS-STING that promotes immune memory through altered genome stability and DNA methylation. The fourth speaker will discuss how Mn exposure at a population level in children affects rates of attention deficit hyperactivity disorder (ADHD). These findings will be compared to parallel animal models of ADHD, with a focus on novel pharmacological interventions that modulate long-term changes in attention, learning, and sensorimotor functions by modulating both neuroinflammation and neurochemistry. The final speaker will discuss new clinical sequelae of Mn exposure in a population of welders, focusing on cutting-edge neuroimaging modalities to understand changes in dopaminergic neuronal function, as well as neuroinflammation, that result from exposure to Mn. These studies will describe the use of PET and MRI to identify key molecular changes in Mn-exposed Parkinsonian patients that correlate closely with the Unified Parkinson's Disease Rating Scale, Motor Subsection Part 3 (UPDRS3) and with a cognitive battery. Collectively, the presentations in this Symposium will highlight new research that aims to link changes in key molecular events in CNS following exposure to Mn that underlie the development of chronic neuropsychological and

neuromotor disease. Speakers in the Symposium bring together expertise in clinical neurology and epidemiology, public health and environmental exposures, and mechanistic neurotoxicology.

S 1113 HIF Signaling at Crossroads of Manganese Homeostasis and Neurotoxicity

S. Mukhopadhyay. University of Texas at Austin, Austin, TX.

While Manganese neurotoxicity is recognized since the 1800s, it is only over the last 12 years that a defined understanding of mammalian Mn homeostasis is emerging due to the discovery of hereditary forms of Mn neurotoxicity that occur as a consequence of mutations in the critical Mn transporters SLC30A10 and SLC39A14. Our previous work characterized SLC30A10 as the only specific Mn efflux transporter that controls cellular and organismal Mn levels via efflux activity. More recently, we have discovered a novel interaction between the hypoxia inducible factor (HIF) signaling cascade, SLC30A10 expression, and Mn homeostasis. Elevated Mn activates HIF signaling by directly blocking HIF degradation. HIF activation has two consequences – first, it directly upregulates SLC30A10 expression to lower cellular and organismal Mn levels as a protective response; and simultaneously, HIF activation induces metabolic reprogramming that generates neurotoxic metabolites of the kynurenine pathway, which induce neurotoxicity. This presentation will discuss novel data on the mechanisms and consequences of Mn-induced HIF activation in the homeostatic control and neurotoxicity of Mn, and present possibilities for leveraging these basic science findings for therapeutic development.

S 1114 Role of REST/NRSF in Manganese-Induced Neurotoxicity

E. Lee. Florida A&M University, Tallahassee, FL.

Recent emerging evidence reveals that dysregulation of transcription factor RE1-silencing transcription factor/neuron-restrictive silencer factor (REST/NRSF) is linked to several neurological disorders. We found that REST was critically involved in manganese (Mn)-induced neurotoxicity. Mn decreased REST expression concomitant with its toxicities in neuronal cultures, while REST overexpression attenuated Mn-induced toxicities, including TH reduction and oxidative stress, in neuronal cultures. To understand the role of REST in Mn toxicity *in vivo*, we generated dopaminergic neuron-specific REST knockout (REST-cKO) mice, since Mn preferentially accumulates in the basal ganglia of the brain and causes dopaminergic toxicity. Mn-induced neurotoxicity and behavioral deficits in wild-type mice were exacerbated in REST cKO mice, along with a further decrease in dopamine levels and oxidative stress in nigrostriatal regions. In addition, REST restoration in the substantia nigra of Mn-exposed REST-cKO mice with neuronal REST AAV vectors mitigated Mn-induced neurotoxicity, dopamine reduction, and behavioral deficits. Tamoxifen, a selective estrogen receptor modulator, induced protection against Mn toxicity, at least in part by REST upregulation via activation of Wnt signaling. These novel findings suggest that dopaminergic REST in the nigrostriatal pathway is critically involved in Mn-induced neurotoxicity and could be a potential target to develop therapeutics for Mn toxicity.

S 1115 Manganese Stimulates Release of Damage-Associated Molecular Patterns in Glial Cells to Activate Innate Immunity in the Developing Brain

R. Tjalkens. Colorado State University, Fort Collins, CO.

Developmental exposure to manganese (Mn) results in immune priming of glial cells that amplifies neuronal injury to other neurotoxic exposures later in life. Using a 'two-hit' model approach, we have previously reported that mice orally exposed to Mn from weaning through puberty were more sensitive to Mn when re-exposed as adults. Likewise, early-life exposure to Mn has a similar immune priming effect on reactive gliosis and neuronal damage following secondary exposure to other neurotoxins, such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and rotenone, as well as neurotropic viruses. This suggests that Mn-induced immune priming of glial cells broadly impacts the resulting inflammatory response to other neurotoxic exposures, but the basis for this heightened immune sensitivity in the brain is poorly understood. In probing the molecular basis for these effects, cell-specific knockout of critical inflammatory pathways in astrocytes, such as NF- κ B/I- κ B kinase β (I κ B2), is profoundly neuroprotective, but the signaling factors responsible for activation of this critical inflammatory pathway remain poorly defined. We therefore examined the effect of Mn on mitochondrial-dependent activation of the cGAS-STING pathway (cyclic GMP-AMP synthase), a key activator of type-I interferon responses in immune cells as well as in glia. Mn directly increases the sensitivity of cGAS for dsDNA and increases binding affinity for STING. In addition, Mn increases levels of mitochondrial calcium in response to ATP stimulation, resulting in release of ds mitochondrial DNA (mtDNA) that amplifies activation of STING and increases expression of both INF β and TNF. Both increased STING activation and ROS from mitochondrial injury alter genome stability and DNA methylation patterns that may underlie the immune priming effects of Mn in glia. Astrocyte-specific knockout of STING greatly attenuates

these changes. Understanding how Mn alters innate immunity in glial cells within the neuro-immune axis to coordinate inflammatory responses of the brain to environmental exposures may therefore help to delineate the etiology of early prodromal neurological disease.

S 1116 Congruence of Human and Animal Model Findings Shows that Developmental Manganese Exposure Causes Lasting Neurodevelopmental Deficits Accompanied with Prefrontal Cortex Dysfunction

D. Smith. University of California Santa Cruz, Santa Cruz, CA.

Neurodevelopmental disorders, including attention deficit hyperactivity disorder (ADHD), are among the most prevalent disorders among children worldwide. Developmental manganese (Mn) exposure from contaminated drinking water, diet, and/or air pollution is associated with deficits in attention, inhibitory control, and psychomotor function in children and adolescents, though the causal relationship(s) between Mn exposure and these deficits, their underlying mechanisms, and efficacy of potential for therapeutic treatments are not known. We conducted epidemiological studies to determine the risk of cognitive, behavioral, and psychomotor deficits in children and adolescents exposed to ferromanganese alloy plant emissions and their legacy impact on environmental Mn levels. In parallel, we developed a rat model to determine whether developmental Mn exposure causes lasting deficits in attention, impulse control, and sensorimotor function, and their underlying mechanisms, and whether pharmacologic treatment with methylphenidate (Ritalin) and guanfacine ameliorates the Mn deficits. Results: Our epidemiological studies established a suite of biomarkers for environmental Mn exposure that are associated with cognitive, behavioral, and psychomotor deficits in children and adolescents. Our animal model studies show that developmental Mn exposure causes lasting impairments in attention, impulse control, and sensorimotor functions that are associated with a proinflammatory cellular environment, altered morphology of PFC-VTA and sensorimotor cortex brain areas, and an overall hypofunctioning catecholaminergic system in fronto-striatal regions. Disrupted mTOR and Wnt signaling is identified via transcriptomics and methylomics as a key regulatory pathway underlying the lasting catecholaminergic system deficits. Finally, methylphenidate and guanfacine are efficacious in ameliorating the behavioral impairments. Conclusions: 1) Elevated environmental Mn exposure in children and adolescents presents a significant public health threat by causing lasting neurodevelopmental, ADHD-like and psychomotor deficits; 2) These Mn deficits are associated with a hypofunctioning catecholaminergic system in the PFC; and 3) A clinically-relevant oral regimen of methylphenidate or guanfacine is fully efficacious in ameliorating these deficits.

S 1117 Multimodal Imaging of Manganese Neurotoxicity

B. Racette. Barrow Neurological Institute, Phoenix, AZ. Sponsor: R. Tjalkens

Manganese (Mn) is an environmental neurotoxicant that causes a clinical syndrome that overlaps with Parkinson's disease. The role of the nigrostriatal system in manganese toxicity remains controversial. The clinical phenotype of Mn-exposed workers overlaps substantially with PD. To investigate the pathophysiology Mn neurotoxicity, we performed multi-modal neuroimaging using positron emission tomography (PET) and brain MRI. We performed 385 PET scans in Mn-exposed welders and non-welder controls, using the radioligands FDOPA, NMB, and DTBZ. We also performed 288 multi-sequence brain MRIs, including standard T1 weighted MRI and Diffusion Basis Spectrum Imaging (DBSI), to quantify brain Mn concentrations and investigate the role of neuroinflammation in the pathogenesis of Mn neurotoxicity. Participants were examined by a neurologist using the Unified Parkinson's Disease Rating Scale, Motor Subsection Part 3 (UPDRS3) and with a cognitive battery. Compared to controls, mean caudate FDOPA uptake was 0.0014min⁻¹ lower in Mn-exposed welders, indicating pre-synaptic dopaminergic dysfunction. In cross-sectional analyses, dopamine type 2 receptor (D2R) nondisplaceable binding potential (BPND) in the substantia nigra (SN) had the greatest discriminant power among exposure groups. Age-adjusted SN D2R BPND was 0.073 greater in Mn-exposed welders compared to non-welder controls. After adjustment for age, SN D2R BPND was 0.0021 higher for each year of Mn-exposure. Each 0.10 increase in SN D2R BPND was associated with a 2.65 increase in UPDRS3 score. Longer term Mn exposures resulted in a dose-dependent reduction in SN D2R BPND. On brain MRI, basal ganglia region of interest analyses revealed higher average caudate DBSI-derived nonrestricted fraction and DBSI-derived radial diffusion values in Mn-exposed welders relative to non-welder controls. Caudate DBSI-derived nonrestricted fraction was also associated with greater cumulative Mn exposure and higher UPDRS3 scores. Multi-modal brain imaging demonstrates that Mn-exposed welders have dose-dependent dopaminergic dysfunction and inflammation in the basal ganglia, including the substantia nigra. With short term exposures, the dopaminergic system upregulates to maintain homeostasis, but this compensation fails with long term exposure consistent with a neurodegenerative pathophysiology.

W 1118 Assessment of Oncogenicity Risk Associated with Cell Therapies: From Preclinical Studies to the Clinic

J. Clingan. Sonoma Biotherapeutics, South San Francisco, CA.

Cell therapies encompass a broad range of therapeutics, including engineered autologous or allogeneic cells (e.g., CAR T cells), as well as iPSC-derived cells. Although cell therapies have great therapeutic potential and some have been approved for a number of indications, there are theoretical risks for malignancy upon administration of cell therapies that could result from either genetic engineering of transferred cells or due to the differentiation state of the cell product (in the case of iPSC-derived cells). In particular, this topic has come under attention recently due to identification of CAR-positive lymphomas in cancer patients treated with CD19- or BMCA-directed CAR T therapies and the resultant label changes applied to some cellular therapies highlighting a malignancy risk. It is especially important to understand the risk of product-related malignancies in the context of non-oncology indications (e.g., autoimmune disease) where a much larger and younger population may be treated with different risk/benefit considerations. A number of methods have been used to evaluate the tumorigenic potential of cell therapies preclinically and in post hoc root-cause analyses to predict the risk of malignant transformation in the product and determine causality in tumors arising following cell therapy treatment, respectively. This session will discuss the current understanding of malignancy risk arising from engineered T cell therapies, and the preclinical evaluation of oncogenicity risk of engineered T cell and iPSC-derived cell therapies. Discussion of preclinical analyses will encompass evaluation of risks associated with genetic integration (insertion site analysis), cytokine- and antigen-independent growth (cytokine-independent growth assay), and oncogenicity potential assessment for *in vitro* and *in vivo* engineered CAR T and iPSC-derived therapies. The session will end with a discussion aimed at understanding how to perform a root-cause analysis in case of a clinically identified malignancy following cell therapy. Following this session, participants will have a thorough understanding of observed malignancy risk associated with cell therapies and common methods used to evaluate oncogenic risk of cell therapies preclinically.

W 1119 The Illusion of Precision in Assigning Risk of Secondary Malignancies Post-CAR T-Cell Therapy

B. Levine. University of Pennsylvania, Philadelphia, PA. Sponsor: J. Clingan

Since the 1990's, we have conducted clinical trials of gene modified T cells. Chimeric antigen receptor (CAR) T cells targeting CD19 on B cells leukemias and lymphomas have induced durable complete responses in patients who are relapsed or refractory to all other available treatments. Determining the critical quality attributes, dose, potency, and anticipating pharmacokinetics of a living, dividing drug presents unique challenges. Another challenge is dissecting potential toxicities, causality and risk. The US FDA has been investigating cases of T cell malignancies following BCMA-directed or CD19-directed CAR T cell immunotherapies. The relative risks of conventional chemotherapy, stem cell transplantation, lymphodepletion, and gene insertion of CAR need to be considered in the context of refractory cancers for which patients might be eligible for CAR T cell therapy.

W 1120 Assessing Insertional Oncogenesis Risk in Gene and Cell Therapies

T. Lanz. Pfizer Inc., Groton, CT. Sponsor: J. Clingan

Gene therapies and many cell therapies involve transferring therapeutic nucleotide cargo into patient cells, which may pose a risk of insertional oncogenesis depending on the modality. Chimeric antigen receptor (CAR) T-cell therapy and the use of lentiviral or retroviral vectors inherently establish insertional mutagenesis, though not necessarily with oncogenic risk. Similarly, transforming patient or autologous cells with adeno-associated viral (AAV) vectors, transposons, or gene editing tools results in genomic insertions, albeit at a lower frequency. Various next-generation sequencing tools have been developed to analyze insertion site patterns. While the recommended analytical methods and interpretations depend on the modality, the ultimate goal of any insertion site analysis is to understand the risk of a particular therapy causing insertional oncogenesis. This talk will provide an overview of current methods, suggest best practices for method validation, and highlight key elements of secondary analysis to aid in risk assessment.

W 1121 Standardized Protocol for the Cytokine Independent Growth Assay for Gene Modified CAR T Therapy

S. Xu. Bristol Myers Squibb, Seattle, WA. Sponsor: J. Clingan

Genetic engineering in CAR-T therapy has raised concerns of secondary malignancies. As the CAR-T therapy moves to treat solid tumors and autoimmune diseases with extensive genomically edited cells, there is a need to have tools to understand the risk of genomic changes. The cytokine-independent growth (CIG) assay is recognized by health authorities as a critical component of non-clinical safety evaluations

for CAR-T cells, as a positive result in this assay would be a biomarker of transformation. Despite its extensive use, there is not a standardized protocol including the absence of an established positive control. We developed a modified CIG assay with a biological relevant positive control, defined the assay length, specific culture conditions and other standardized culturing parameters. This defined protocol is being assessed by multiple pharmaceutical companies within HESI consortium and has the capability to assess the transformational risk associated with gene-edited CAR-T products.

W 1122 Nonclinical Safety Assessment of *In Vivo* CAR T-Cell Therapy Products

A. Brandes. Umoja Biopharma, Seattle, WA. Sponsor: J. Clingan

Autologous CAR T cell therapies have transformed treatment paradigms for B-cell malignancies; however, many challenges remain that limit patient access to these therapies, including operational and logistical complexity and high manufacturing and distribution costs. Recently, CAR T cell therapy has demonstrated clinical efficacy in non-oncology indications such as autoimmunity, thus, demand for these therapies is anticipated to increase as these modalities expand into new indications. To address this, "off-the-shelf" therapies that directly engineer CAR T cells within the patient's own body are an area of active development. These *in vivo* CAR T cell therapies utilize targeted technologies such as lipid nanoparticles or viral vectors to deliver a CAR payload directly to patients' T cells to engineer CAR T cells *in vivo*. Here, we will discuss the primary safety risks associated with these types of therapies, with a focus on the nonclinical assessment of oncogenicity risk evaluation. These considerations differ by modality (i.e. integrating versus non-integrating gene delivery mechanisms) and take into account details specific to *in vivo* CAR T products, such as the specificity of targeting T cells and potential oncogenic risk following transduction of off-target cell types. A case study will cover IND-enabling nonclinical assessment of a surface-engineered lentiviral *in vivo* CAR T cell therapy product, which assessed oncogenicity risk by evaluating genetic integration (insertion site analysis and vector copy number determination), cytokine- and antigen-independent growth (cytokine-independent growth assay), and specificity of on- and off-target transduction using *in vitro* and *in vivo* models.

W 1123 Evaluating Safety Risks of iPSC-Derived Cell Therapies

G. Rao. Genentech Inc., South San Francisco, CA.

Induced pluripotent stem cells (iPSCs) offer transformative commercial potential for off-the-shelf cell therapies (CTs), and iPSC-derived CTs are increasingly being tested in clinical trials. However, the clinical use of iPSC-derived CTs requires comprehensive preclinical risk assessments to address unique safety concerns, including teratoma formation from residual undifferentiated iPSCs and tumorigenic potential due to genomic instability and mutation accumulation. Various methodologies are used to assess tumorigenicity during the development of iPSC-derived CTs, including *in vivo* teratoma assays as well as more sensitive *in vitro* assays such as the Highly Efficient Culture assay, digital PCR, and transcriptomic analyses to detect residual undifferentiated cells. For regenerative CTs, teratoma formation is also assessed in dedicated tumorigenicity studies in immunodeficient rodents. Genomic integrity is evaluated using techniques such as G-banding, digital PCR, and next-generation sequencing to identify structural variants, copy number variations, and point mutations that may arise during reprogramming, culture, differentiation, or expansion. In the absence of clear regulatory guidelines, a thorough weight-of-evidence approach must be employed, integrating multiple data sources to assess the safety risks of iPSC-derived cell therapies during preclinical development.

W 1124 Diet and Toxicology: Examining the Novel and Underappreciated Interaction

K. Gowdy. Ohio State University, Columbus, OH.

The interaction of diet and toxicology is an emerging area of investigation. However, it is still unclear how dietary intake, deficiencies, or supplementation alter toxicological responses in multiple organ systems. This Workshop will bring together multidisciplinary researchers, including nutritional and dietary experts, and toxicologists with expertise in different exposure routes and xenobiotic-induced pathologies to discuss the current state of science regarding nutrition and the biological responses during health and diseases and to identify critical research gaps, challenges, and opportunities. The primary goal of this Workshop is to advance nutrition research in the field of toxicology and ensure that future investigations are conducted to best model human dietary intake. Diet is an underappreciated contributor to toxicant effects, acting as a partner in a complex exposure. The first speaker will give an epidemiological overview of nutrition and how current dietary patterns are modulating biological responses to xenobiotic exposures. The second speaker will provide data highlighting interactive effects between diet and the toxicological responses to PFAS. In the third talk, effects of air pollution and diet will be presented. The fourth presenter will describe results from animal studies investigating synergistic effects

of diet, sex, and microplastics exposure. The final talk will focus on how to model diet and xenobiotic synergistic interactions, taking into account the dietary needs of the animal models used. The diversity of speaker expertise in mechanistic toxicology, human cohort studies, nutrition, and epidemiology will enhance comprehension of the complex interplay between xenobiotics and diet and provide guidance on how to apply this information to improve inputs for risk assessments to best protect public health. This will provide valuable insights for research planning, funding allocation, and surveillance practices, as well as policy development.

W 1125 Nutrition to Mitigate the Adverse Impact of Exposures

S. Sumner. University of North Carolina, Kannapolis, NC. Sponsor: K. Gowdy

While exposures to medications, specific diets, supplements, or natural products can have beneficial effects, some exposures (e.g., pollution, tobacco use, drugs, foods, environmental chemicals) can individually or collectively damage our DNA, change how our proteins function, cause dysbiosis of the microbes in our gut, and lead to disruptions of our normal metabolic processes. Untargeted metabolomics of the internal exposome provides a means to reveal how exposures perturb our normal metabolic state, and how these perturbations are associated with states of health and wellness. Using a nutritional pharmacology/toxicology workflow, the high-information metabolomics/exposome data can be evaluated to design intervention strategies: such as needs in exposure reduction, or the formulation of nutrient cocktails that could protect against adverse exposures. This presentation will cover applications in areas of drug addiction, inflammation, and pregnancy complications that lead to informing nutritional guidance. Intervention with nutrient cocktails presents an opportunity to modify the effects of environmental exposures for more beneficial health outcomes. Ultimately, the nutritional pharmacology/toxicology approach will have a significant impact on public health by reducing the burden of disease caused by environmental exposures, and by enhancing the beneficial effects of specific diets or prescription drugs.

W 1126 PFAS and Diet Interactions: The Good, the Bad, and Maybe the Ugly

J. Schlezinger. Boston University, Boston, MA.

People are exposed to per- and polyfluoroalkyl substances (PFAS) in drinking water, food, air, dust, and by direct use of consumer products. Perturbation of lipid and cholesterol homeostasis are important adverse effects of PFAS in people. Yet, the vast majority of studies on these endpoints are conducted in animal models fed a rodent diet (57% carbohydrate, 23% protein, 21% fat as %kcal with low cholesterol, 12-15% fiber by weight). Dietary fat and cholesterol significantly modify the physiological handling and synthesis of these macromolecules. And dietary fiber significantly impacts lipogenesis-, lipid oxidation-, and cholesterol metabolism-related genes. We conduct our experiments with PFAS in female and male mice fed a diet based on the "What we eat in America" analysis in NHANES (47% carbohydrate, 16% protein, 37% fat as %kcal with 0.13% cholesterol, 5.5% fiber by weight). We find perfluorooctanoic acid significantly increases serum cholesterol in mice on this diet, but that effects on lipids in the liver depends upon time on the diet (6 vs 14 weeks). Furthermore, the effect of fiber supplementation in the diet depends upon the characteristics of the fiber (e.g., insoluble versus soluble, viscous vs non-viscous), both in terms of metabolic characteristics of the mice fed each diet and their response to a mixture of PFAS, as well as the sex of the mouse. Our results highlight the need for more careful consideration of diet as a variable that modifies the toxicological response to PFAS and the use of more human-relevant diets.

W 1127 Diet and Eating Pattern as Determinants of Air Pollution Susceptibility

P. Haberzettl. University of Louisville, Louisville, KY.

Inhalation of polluted air has emerged as an independent risk factor for developing cardiometabolic disease. It is also known that choosing either an unhealthy diet or bad sleep habits that consequently change eating pattern have adverse consequences on cardiometabolic health. The impact of these lifestyle choices on the susceptibility to ambient fine particulate matter (PM_{2.5}) exposure, however, is still unclear. To investigate this, we exposed mice maintained on either a high fat diet (60% kcal from fat; diet-induced obesity, DIO) or a disturbed light cycle (18/6h, light/dark; light-induced circadian dysynchrony, LICD) to concentrated ambient PM_{2.5} (CAP, 30 days, 6h/d). Control mice (12/12h, light/dark; 12% kcal from fat) inhaled either CAP or HEPA-filtered air (30days, 6h/d). Changes in adiposity, systemic glucose handling, tissue specific insulin sensitivity and inflammation as well as systemic and pulmonary redox changes were measured. While CAP exposure did not change any metabolic parameters, changing the light cycle impacted activity and feeding pattern. In male mice, exposure to CAP exacerbated systemic glucose intolerance, insulin resistance and inflammation in both DIO and LICD without increasing adiposity. Interestingly, CAP exposure did not impact cardiometabolic health in female mice. Testing for a possible protective mechanism, we found that CAP expo-

sure induced systemic and pulmonary oxidative stress in male, but not female mice that was accompanied by a higher expression of antioxidant enzymes in the female lungs. Our results indicate that choosing an unhealthy diet or sleeping/eating pattern could increase the susceptibility to PM_{2.5}.

W 1128 Sex, Diet, and Micro/Nanoplastics: Enhancing Translational Fidelity in Toxicological Models

S. Phatak. University of New Mexico, Albuquerque, NM.

Micro- and nanoplastics (MNPs) are increasingly detected in human tissues and food systems, raising concerns about their long-term health impacts. Many plastic particles and additives are lipophilic, suggesting that dietary components, particularly fat and fiber, may influence MNP absorption, bioavailability, and physiological effects. These interactions are further complicated by sex-specific differences in dietary intake and metabolism. However, a critical gap remains in environmental toxicology: understanding how sex-specific dietary responses influence MNP toxicokinetics and outcomes. Sex differences play fundamental roles in shaping developmental biology, immune function, metabolism, and disease susceptibility. These differences, driven by hormonal signaling, immune responses, and energy metabolism, are likely to influence how MNPs are processed and impact physiological systems. In our study, we examined the long-term effects of chronic dietary MNP exposure (0.5–5 µm polystyrene) in mice from adolescence to adulthood. To ensure translational relevance, we used defined purified diets to eliminate confounding non-nutrient variables found in standard chow. Despite equivalent MNP intake across groups, we observed sexually dimorphic physiological responses. Single-cell transcriptomics revealed divergent immunometabolic profiles by sex, underscoring the interactive effects of diet and sex on MNP biodistribution and toxicity. Our methodological approach addresses limitations of conventional exposure models: gastric gavage induces acute stress and bolus dosing, while drinking water models suffer from inconsistent intake and particle sedimentation. By incorporating MNPs directly into a defined diet, we achieved chronic, low-dose exposure under physiologically relevant conditions, better simulating real-world dietary exposure. This study highlights the importance of integrating sex as a biological variable and controlling dietary context in environmental toxicology. These findings have broad implications for both experimental design and public health strategies aimed at mitigating plastic-associated risks. Moreover, our data suggest that targeted dietary manipulation may offer a practical approach to modulate MNP uptake and reduce their physiological impact.

W 1129 Modeling Interactions Between Diet and Xenobiotic Exposure for Translation to Human Health

B. Mickelson. Inotiv, Madison, WI. Sponsor: K. Gowdy

The interaction of diet and how this influences biological responses to xenobiotics is an emerging area in toxicological research. This is often examined in animal models with dietary supplement and/or development of diets that reflect human consumption of macro and micro nutrients. However, there are several experimental factors to consider when designing experiments to examine diet in animal models. This talk will cover the following topics to increase rigor and reproducibility in this emerging area of toxicology including 1) what is the appropriate 'control diet' for an experiment; 2) what are the dietary needs are for the model and how will manipulating them will change the health of the rodent; and 3) how to test different dietary patterns/ingredients in rodents to model human dietary intake given known species differences. This multidisciplinary talk will provide researchers with information and considerations for designing dietary experiments so they can make the best possible diet decisions for toxicological models.

W 1130 Science Simplified Through Graphics

A. Bernstein. Rutgers, The State University of New Jersey, Piscataway, NJ.

In today's fast-paced digital world, the ability to communicate toxicological science visually is more important than ever. This interactive Workshop will equip participants with the tools and strategies to transform complex toxicology data into engaging, accurate, and accessible visual content. Through hands-on training, attendees will learn the fundamentals of effective graphic design, how to create impactful infographics, and best practices for developing graphical abstracts tailored for publication, social media, and public engagement. Whether you are explaining chemical risk assessments, mechanisms of toxicity, or environmental exposure data, visual storytelling can enhance comprehension and broaden the reach of your science. Participants will explore key design principles—including color, layout, hierarchy, and typography—and receive guidance on selecting the right format and graphics for different audiences and platforms. Examples from publications, social media, and community outreach materials will be used to highlight effective practices and common pitfalls. By the end of the session, participants will have drafted their own visual piece and gained practical insights into tools like Canva, BioRender, NIH BioArt, and PowerPoint. This Workshop is ideal for toxicologists at all career stages

who want to improve their science communication through compelling visuals that inform, educate, and inspire. No prior design experience is necessary. Bring a laptop to fully immerse in this hands-on training.

W 1131 Essentials First: Define What You Are Communicating

A. Bernstein. Rutgers, The State University of New Jersey, Piscataway, NJ.

This opening activity sets the stage for the workshop by helping participants clarify the core message they want to communicate and define their target audience. After a brief introduction, each participant will identify one key aspect of their work they wish to convey visually and specify the intended audience. Participants will then have five minutes to work independently before regrouping to share and discuss their ideas with peers at the table. The session will conclude with a recall exercise designed to demonstrate the limited extent to which scientists can effectively convey content through visuals in a short period of time, reinforcing the necessity of concise and intentional communication.

W 1132 Align Your Message with Audience Interests

A. Tukker. Purdue University, West Lafayette, IN.

Effective communication is a two-way exchange that happens with an audience, not to an audience. In this session, participants will explore how to set audience-specific communication goals that align both with the scientist's intended message and the audience's interests or needs. Following a brief introduction by the moderator, participants will further refine their target audience and define clear goals for what they hope to communicate. The session will also highlight compelling examples that demonstrate how content can be strategically tailored to resonate with different groups.

W 1133 Visual Storytelling Through Tailored and Compelling Graphics

L. Aleksunes¹, and A. Jennings². ¹Rutgers, The State University of New Jersey, Piscataway, NJ; and ²Consultant, Bloomfield, NJ.

Building on audience-specific goals, this session guides participants in refining their content into clear, focused messages suitable for visual communication. A foundational overview of graphic design principles will be provided, including color theory, font choice, text alignment, effective use of imagery, and accessibility considerations. Participants will also learn how different communication platforms—such as social media, academic posters, and public-facing brochures—have unique features that influence graphic design decisions. This session will equip attendees with the tools to create visually compelling and platform-appropriate materials that enhance audience engagement. Andi Jennings is an artist and graphic designer with over two decades of experience in branding, marketing, and digital and social storytelling. Andi believes that data, content, and design work in harmony, and her projects translate complex data into compelling visual stories.

W 1134 Building Your Graphic from Concept to Creation

A. Torres-Berrios¹, and L. Aleksunes². ¹Michigan State University, East Lansing, MI; and ²Rutgers, The State University of New Jersey, Piscataway, NJ.

The final portion of the workshop will be fully hands-on and iterative. Participants will have dedicated time to begin designing their graphic using a platform of their choice (e.g., Canva, BioRender, PowerPoint, etc.), applying the principles and goals developed throughout the workshop. Small groups will then share their drafts and offer constructive feedback to one another. The remaining time will be used for participants to revise and refine their designs based on this peer input. A selection of graphics will be submitted in real-time to the moderators and showcased to the full group for broader feedback and discussion.

W 1135 The Quality Awakens: New Frontiers in the Appraisal of In Vitro Mechanistic Study Quality/Reliability

A. Wang. NIEHS, Research Triangle Park, NC.

Mechanistic data from epidemiological, animal *in vivo*, and various *in vitro* studies have traditionally been a part of the information used in hazard and risk assessments. To reach a scientifically sound decision, assessors prioritize high-quality data over poorer-quality data, especially when conflicting results are reported. Compared to well-developed study quality appraisal approaches for epidemiological and animal *in vivo* studies, appraisal for *in vitro* studies has a shorter history and is less often deployed in risk assessment. Several groups in the US and Europe are developing

tools and approaches to advance specifically the *in vitro* study quality and reliability appraisal. This session is designed for scientists conducting *in vitro* studies and/or using *in vitro* data results, including risk assessors and systematic review practitioners, to be aware of the concept, approach, and tools of *in vitro* study quality appraisal and keep abreast of recent innovations and directions of future development. Five speakers will present several examples of *in vitro* study appraisal in ways that fit for their respective assessment purposes, innovations in the tool and approaches of *in vitro* study quality and reliability evaluation, reporting templates and considerations to increase the regulatory value of your *in vitro* data, and a novel framework to choose a suitable *in vitro* study appraisal tool.

W 1136 Bridging Biology and Risk: How US EPA Program Offices Apply In Vitro Data to Modernize Chemical Evaluations

I. Druwe. US EPA, Research Triangle Park, NC.

The US Environmental Protection Agency (US EPA) has increasingly incorporated *in vitro* studies into chemical risk evaluations and or assessments to enhance mechanistic understanding, support biological plausibility and hazard identification, and inform-dose response characterization. Across EPA program offices- including the Office of Chemical and Pollution Prevention's (OCSPP) Office of Pollution Prevention and Toxics (OPPT) and Office of Pesticide Programs (OPP), the evaluation and application of *in vitro* data reflect evolving scientific methodologies and statutory frameworks. *In vitro* assay data, in particular that derived from high throughput screening assays (e.g. ToxCast) and other new alternative methodologies (NAMs), are being used to prioritize chemicals, refine points of departure, and evaluate modes of action. Integration practices of *in vitro* and mechanistic data vary across EPA program offices due to differences in regulatory mandates and risk assessment paradigms. But there is a growing emphasis on data quality, biological relevance, and translational validity to *in vivo* endpoints. Case studies from recent risk evaluations demonstrate how *in vitro* data can be used alongside traditional toxicological evidence. This presentation will highlight current practices, scientific advancements, and critical challenges- such as assay validation, interpretation of potency metrics, and incorporation of *in vitro* assays into dose-response analyses- that EPA risk assessors face in the incorporation of *in vitro* studies for human health risk assessments. *Disclaimer: The views expressed are those of the authors and do not necessarily represent the views or policies of the US EPA.*

W 1137 The SciRAP Tools: Facilitating Integration of Mechanistic In Vitro Data in Chemical Assessments and Supporting the Use of NAMs

A. Beronius. Karolinska Institutet, Stockholm, Sweden. Sponsor: A. Wang

The Science in Risk Assessment and Policy (SciRAP) platform (www.scirap.org) is an openly accessible online resource offering tools to evaluate the reliability and relevance of non-standard (eco)toxicity, including *in vitro* studies, and epidemiological data. These tools support evidence appraisal and Weight of Evidence assessments across various contexts, including chemical hazard and risk assessments, mode of action analysis, and the development of Adverse Outcome Pathways (AOPs). A core objective of SciRAP is to promote the use of academic research data in regulatory chemical assessments. The platform also aims to facilitate the integration of data from New Approach Methodologies (NAMs)—many of which are not yet validated or standardized—into chemical hazard and risk evaluations. SciRAP's tools, including the CRED criteria (Criteria for Reporting and Evaluating ecotoxicity Data), are increasingly adopted by researchers and regulators and are cited in EU regulatory guidance documents for chemical assessments. This presentation focuses on the SciRAP *in vitro* tool, which offers general criteria for the transparent and structured evaluation of *in vitro* data. These criteria are designed to be adaptable and fit-for-purpose across different regulatory contexts. Ongoing work includes the development of customized versions of the tool to optimize evaluation of data from specific assay types, such as receptor transactivation assays. Work is also ongoing to develop a family of SciRAP AI agents that automates the SciRAP evaluations and enables evaluation of large numbers of datasets at the same time. We will introduce the SciRAP *in vitro* tool, highlight current developments, and present examples of its application in various settings. Particular emphasis will be placed on how tools like SciRAP can support the regulatory use of NAMs. Additionally, we will discuss SciRAP's role in the education and training of future toxicologists and risk assessors.

W 1138 Enhancing the Regulatory Value of In Vitro Mechanistic Data Through Internationally Harmonized Reporting Templates

I. Langezaal. European Commission Joint Research Center, Lombardy, Italy. Sponsor: A. Wang

Internationally approved templates for the reporting of mechanistic information facilitate the exchange of data between organisations and their re-use for various purposes. Two such templates relevant for the reporting of *in vitro* results for chemical hazard assessment have been adopted by the Organisation for Economic Cooperation and Development (OECD). The first one, the OECD Harmonised

Template (OHT) 201, is for the reporting of mechanistic information obtained from *in vitro* or *in chemico* methods. For all adopted OECD *in vitro* test guidelines, OHT 201 features pre-compiled pick lists for easy selection of standardised terms. OHT 201 has been embedded into IUCLID 6, a major software tool for submitting data on chemical substances to (regulatory) authorities (e.g., REACH) and for recording, storing and exchanging chemical data in general. Reporting elements flagged in SciRAP (see Talk 2) and the elements of the OECD guidance on Good *In Vitro* Method Practice (GIVIMP) were included in OHT 201. Also, a bridge was created between real-life OHT 201 chemical data and the chemical-agnostic Key Event descriptions in the AOP-Wiki: Both can be tagged with the same "process, object, action" triplet of ontology terms, which can ultimately lead to a much more obvious linkage between mechanistic knowledge (AOP-Wiki) and experimental observation (OHT 201). Recently developed OHT-R template is for the reporting of *in vitro* data published in the scientific literature, as recommended by the OECD guidance document on the generation, reporting and use of research data for regulatory assessments. While based on OHT 201, OHT-R has limited use of free-text fields, to ensure consistent reporting of detailed information. The OHT-R will help researchers, funders, editors, publishers, and reviewers to understand the level of detail required to maximise the regulatory value of reported data. When implemented in software tools (e.g., IUCLID) and following recommended data reporting standards, sharing and re-using of research data for a wide range of (regulatory) purposes will become straightforward. The more OHT-R can be completed with information, the more useful the data will be for regulatory decision making. With additional guidance, a regulator should be able to assess the reliability of the data for inclusion in weight of evidence approaches in regulatory decision making.

W 1139 Realistic Workflow to Critically Assess Mechanistic and *In Vitro* Study Quality with the OHAT Approach in Considering NAMs Data in Chemical Risk Assessment

A. Rooney. NIEHS, Research Triangle Park, NC.

The OHAT approach is an established framework for assessing human, animal, and mechanistic evidence on potential health effects from environmental chemicals. OHAT and other systematic review methods increase the rigor, reproducibility, and transparency in the risk assessment process from the literature search, through selecting, critically assessing, and then synthesizing evidence. Critical appraisal of individual studies in terms of internal validity or risk of bias is a key step to assure that the conclusions are based on the most reliable data and that uncertainties in the evidence base are reflected. Increasingly we are faced with datasets that have a greater number and proportion of *in vitro* and mechanistic studies. This presentation will use an evaluation of immunotoxicity associated with exposure to perfluorooctanoic acid (PFOA) to illustrate how mechanistic and NAMs data should be considered throughout the systematic review process starting with problem formulation. A tiered approach for assessing mechanistic data with the OHAT tool for assessing risk of bias will be presented such that resources are focused on studies that are likely to inform the conclusions. The manual workflow used in the 2016 National Toxicology Program (NTP) assessment of PFOA immunotoxicity will be contrasted with recent workflow advances that incorporate automation with human-in-the-loop user verification. The advantages and challenges of incorporating artificial intelligence (AI) in study quality assessment will also be presented in terms of traditional machine learning (ML) and natural language processing (NLP) workflow enhancements as well as the more flexible and more powerful large language models (LLM) based methods.

W 1140 How to Select a Fit-for-Purpose Critical Appraisal Tool: Using the FEAT Principles

P. Whaley. Lancaster University, Leuchars, United Kingdom.

Critical appraisal is a key component of systematic review, chemical risk assessment, AOP development, and many other toxicology research contexts. We just heard a few out of dozens of published tools for appraising study quality in different regulatory and scientific contexts. The problem is, these many tools are designed for different tasks, with varying levels of rigour in their development and quality constructs as their target. The tools also differ in their validity for a given task, transparency levels in their use, and suitability of results for summarising study quality for a particular use. This creates a minefield for their prospective users. Of dozens of tools that could be used for a given purpose, how does one determine which tool is the best fit? If no tool is perfect, how does one decide what modifications need to be made to the nearest-fitting tool for the needed job that is needed? The purpose of this presentation is to solve these problems for the listener, by providing them with a simple and memorable framework for assessing study appraisal tools. The framework is FEAT, which stands for Focus (the appraisal concepts targeted by an instrument), Extensiveness (the comprehensiveness with which the instrument covers those concepts), Application (the validity with which the results of using the instrument can be applied in the research context), and Transparency (the explainability of judgments made when using the instrument). This talk will explain to participants how to apply FEAT to structure their thinking about critical appraisal tools, helping them transparently screen and modify potential tools to select the most fit for purpose

tool. Broad and easily memorisable, FEAT is an assessment framework designed to be "carried in the head, not in the pocket". FEAT helps researchers apply their critical appraisal skills and articulate the appraisal requirements of their research context, particularly if FEAT is applied in team discussions. Importantly, the lessons learned and principles presented in FEAT can be applied in any appraisal context, from peer-review to risk assessment to grant proposals. Already in use in environmental sciences, and part of editorial policy for at least two toxicology journals, FEAT stands to support toxicologists in a vital part of the scientific process.

IS 1141 Incorporating Toxicology Principles Essential to Establishing Plausibility of Environmental Epidemiology Studies

J. Doherty. Independent Toxicologist, Oakton, VA.

Environmental epidemiology studies (EES) frequently report potential chemical hazards that are incorporated into the risk characterization of chemicals with serious scientific, economic, and social consequences. Owing to these consequences, independent and well-qualified scientists should critically review EES to ensure the relevance of the reported adverse outcomes. The toxicology community has a public health responsibility to be intricately involved in the review of EES. A working principle for this session is that a report of an adverse outcome is also a report of a toxic response of clinical and public health relevance. Therefore, this session raises the issue that toxicologists should implement processes to ensure appropriate peer/expert review and engage with epidemiologists who will consider the needs of toxicologists in interpreting epidemiological data. This session aims to stimulate toxicologists to develop standard criteria for EES that can be applied to formulate a plausibility statement based on principles of toxicology. The plausibility statement would characterize whether or not the reported adverse outcome from EES is sufficient to support clinical relevance and, therefore, regulatory action. The toxicology community recognizes and appreciates that EES are inherently difficult to conduct. It is also recognized that because of their inherent complexity, EES cannot have the more rigid Good Laboratory Practices, Quality Assurance, and reporting standards associated with animal studies. Currently, most toxicologists are trained to judge animal studies, and few are trained to evaluate EES. This results in EES often being accepted essentially at their face value. In addition to the current situation, there is growing interest in reducing animal toxicity testing as the basis for safety evaluation with *in vitro* and computer modeling. Should these approaches eventually replace laboratory animal testing, there is reason to expect that the frequency of EES will increase further to challenge the safety of chemicals. Thus, standardizing criteria based on toxicology principles and means to develop a plausibility statement is one way to prepare toxicologists to address the significance of EES reports of adverse outcomes. This session will have representatives from the epidemiology and toxicology communities presenting their approaches to better mutual interaction. Suggestions for other means to involve toxicologists in the critical review of EES will be welcome.

IS 1142 Toxicology Meets Public Policy: Lessons Learned from NAMs Advocacy in the United States

G. Hilton. PETA Science Consortium International e.V., Stuttgart, Germany.

The traditional roles of scientists have predominantly revolved around research, product development, and teaching. Careers in advocacy and government affairs are relatively uncommon in the sciences. While some scientists have the opportunity to bridge sectors, merging research with advocacy, activism, and lobbying, few have experience in this domain. Changing policies affecting the scientific landscape have sparked a growing interest within the scientific community to understand their potential role in advocacy. Given the interest in advocacy, scientists are well-positioned to learn from key governmental developments like advocacy efforts supporting the US Food and Drug Administration (FDA) Innovative Science and Technology Approaches for New Drugs (ISTAND) program and other related policy actions. Decades of advancements in technologies have spurred scientists and policymakers to increasingly consider how predictive toxicological methods can be better integrated into laws, policies, and practices. For example, PFAS is used in many consumer products, but little is known about their exposure and related toxicity—this is a classic case of where predictive toxicological methods can be enforced by policymakers to ensure safe products are screened faster before being manufactured to come onto the market. With a growing need for scientists to communicate with lawmakers, this Informational Session aims to provide a foundational overview of how stakeholders can engage with lawmakers and decision-makers to advance effective science policies. Speakers will provide examples of how scientists are creating positive change for toxicology, with a focus on new approach methodologies (NAMs) advocacy in the US Congress and regulatory agencies.

RI 1143 Revisiting the DDT Dump Site off Southern California: Oceanographic Survey, Ecological Impacts, and Aquatic Toxicity

C. Moore. San Diego Zoo Wildlife Alliance, San Diego, CA.

Beginning in 2011, scientists from the University of California Santa Barbara uncovered several unknown dumpsites of the legacy contaminant DDT in the San Pedro Basin off the coast of Los Angeles. In 2021, an oceanographic survey led by Scripps Institution of Oceanography surveyed more than 35,000 acres of seafloor and found tens of thousands of waste barrels in varying states of decay lining the region. A 2022 SOT Annual Meeting Regional Interest Session invited these scientists, as well as biomonitoring and human health researchers, to provide their early research on the scope and impacts of this dumpsite. Since then, the California Sea Grant program and then-Senator Diane Feinstein's office secured support to sponsor research programs to investigate this persistent challenge. This session will feature up-to-date information about the dumpsite range and contents, monitoring in avian and marine wildlife, and toxicological assessment. First, the session will provide a historical review of this issue and provide an update about the dumpsite with spatial and chemical information from recent oceanographic surveys. The next presenter will then speak on biomonitoring projects involving wildlife and conservation groups around Southern California, quantifying DDT and its co-occurring metabolites and potential by-products (referred to as DDT+). The last speaker will discuss with an aquatic toxicology study comparing each DDT+ species, including mechanistic data yielding clusters of DDT+ species with similar modes of action. This session will conclude with a 25-minute moderated panel discussion and Q&A with the speakers to address audience questions and discuss future plans related to research and action.

RI 1144 Ongoing Ocean Pollution from Legacy Offshore Disposal of DDT Waste: What's Actually Down There?

D. Valentine. University of California Santa Barbara, Santa Barbara, CA. Sponsor: C. Moore

Ocean disposal of petrochemical waste was a common practice in the mid 20th century, particularly near industrial centers. The coastal ocean off Los Angeles, California is a prime example, with numerous waste streams disposed to deep water (900m) basins located close to the coast. This presentation will consider the offshore disposal of manufacturing wastes associated with synthesis of the pesticide DDT. Combining results of a sediment sampling campaign for chlorinated chemicals and metagenome-assembled genomes with analysis of historical records, this presentation will explore the spatial and temporal patterns of DDT waste disposal as well as transport and fate processes that distribute DDT wastes through the region. By defining a regional footprint of DDT waste contamination of more than 1000 square kilometers this work also explores target areas of potential ongoing exposure. Furthermore, this presentation will touch on the relationship of DDT waste with other observed contaminants and processes, and the current state of *in-situ* biodegradation.

RI 1145 Defining Biomagnified DDT+ Chemical Profiles and Investigating the Health Impacts on Sentinel Wildlife Species and Humans

N. Dodder. San Diego State University, San Diego, CA. Sponsor: C. Moore

During its production, DDT waste was discharged via a marine outfall to the Palos Verdes Shelf (PVS) near Los Angeles. Accordingly, the historical narrative and environmental monitoring focused on the PVS as the primary source of DDT to the regional environment. Although offshore dumping industrial waste was legal at the time, this alternate disposal route was largely dismissed until sedimentary DDT waste was (re)discovered further offshore in the San Pedro Basin in 2019. At approximately the same time, nontargeted analysis (NTA) based on comprehensive two-dimensional gas chromatography coupled to time-of-flight mass spectrometry (GC×GC/TOF-MS) of regional marine mammal blubber identified not only the typically monitored DDT compounds (DDX) but also a suite of 45 DDT related compounds (DDT+). It was hypothesized the DDT+ profile reflects the persistent and transformed waste contaminants and is unique to the region. The average concentration of total DDX was 180 ug/g lipid mass, the highest known cetacean concentration in the world. Additionally, regional biological impacts were found to be associated with present-day DDT levels. A preliminary association of DDT+ with endocrine disruption was observed in cetaceans. A large-scale epidemiology study of California sea lions found an association between contaminant body burden (including DDX) and the occurrence of urogenital cancer. A reproductive decline due to eggshell thinning in endangered California condors was associated with coastal scavenging of marine mammal carcasses and subsequent exposure to DDX. DDX compounds were observed to activate estrogen receptors of the California condor, thus mechanistically linking exposure to condor reproduction impacts. At this point (ca. 2022), there was evidence of relatively high levels DDX in the southern California ecosystem, and a unique and chemically complex mixture of additional related compounds and structurally unidentified halogenated organic contaminants. There was evidence of biological impacts, but also a lack of contaminant monitoring data in historically

endangered or impacted species. Therefore, to systematically assess southern California wildlife and human exposure to DDT+ and address data gaps, the objective of our study was to measure current levels, temporal trends, the geographic distribution, and the association of DDT+ with biological outcomes.

RI 1146 A "Deeper Dive" into DDT+: Comparative Responses to DDT+ Chemical Species *In Vitro* and in Zebrafish

K. Sant. Michigan State University, East Lansing, MI.

DDT is a legacy pesticide with many existing environmental and biomonitoring programs, the recent research conducted in Southern California has demonstrated the persistence of many lesser-studied DDT metabolites and related products (DDT+) in marine environmental and coastal biota. For many of these DDT+ compounds, almost no toxicity information was yet available or was highly limited. During this presentation, we will build upon the research presented by Drs. Valentine and Dodder, but present our novel findings related to broader DDT+ toxicity. We will present *in vitro* research comparing cytotoxicity and estrogen receptor activity of DDT+ compounds, followed by aquatic toxicology research in zebrafish investigating impacts in developmental success, transcriptomics, and behavior. We will present data that suggest that the DDT byproducts tris(4-chlorophenyl)-methane and -methanol may be of particular interest for ecotoxicological and human health research due to conserved toxicity with DDT and similar bioaccumulation patterns. Likewise, estrogen receptor agonism is moderately conserved across humans and California condors, and there are clear differences in estrogen receptor activity between DDT+ species. Transcriptomics for exposed zebrafish embryos reveal distinct clusters of DDT+ compounds based on molecular response, and p,p'-DDT, -DDE, and -DDD have unique responses compared to the other DDT+ compounds assessed. Overall, we categorize these contaminants into groups of higher or lower priority for future investigation, mitigation efforts, and conservation.

S 1147 Current Nonclinical Approaches in Characterizing Local Tolerability with Long-Acting Injectable Therapies

S. Kulkarni. Gilead Sciences Inc., Foster City, CA.

Injection-site reactions (ISRs) are one of the most common adverse events, occurring in up to 40% of patients receiving injectable therapeutics. This Symposium is one of the first sessions at the SOT Annual Meeting to explore the current status of nonclinical characterization of ISRs with a focus on small molecule, depot-forming therapeutics or long-acting injectables (LAIs, long-acting anti-psychotics, antivirals, etc.) when administered via subcutaneous (SC) or intramuscular (IM) routes and their impact on drug development with industry, academic, CRO, and regulatory experts. ISRs are local inflammatory reactions originating around the injection site that manifest as discomfort, pain erythema, induration, and itching and, in some cases, more severely as ulceration or necrosis. While relatively mild ISRs could be acceptable, they are a cause for suboptimal patient experience and generally not desirable. On the other hand, higher-severity ISRs pose a significant challenge for patient compliance and commercial viability, hence requiring characterization and derisking early in drug development. The current practices in nonclinical species selection, study design and endpoint consideration for ISR evaluation will be presented. Histopathology assessment of ISRs and the impact of route and species differences on local tolerability determination will also be discussed. Regulatory guidelines on evaluating local tolerability are not specific and likely do not take into account the newer, long-acting type formulations for therapeutics intended for less frequent administration. A regulatory perspective on local tolerability and sponsor-generated ISR data in support of a clinical plan will be presented in this session. Furthermore, published literature indicates low confidence in the predictive capacity of severity of nonclinical ISRs to the clinic, and available *in vitro* systems fall short on capturing the temporal immune and inflammatory dynamics at the injection site. Given the implications, ISR evaluation in animal models and derisking for clinical progression remain challenging. LAI case studies will highlight the impact of therapeutic-related factors on ISRs in animal models and their progression through clinical development. Overall, this Symposium will provide an update on the current status, challenges, and mitigation in the evaluation and characterization of ISRs.

S 1148 Study Design Considerations and in Life Evaluation for Nonclinical ISR Evaluation

J. Wendel. Labcorp Early Development Laboratories Inc., Greenfield, IN.

Non-clinical safety assessment studies are used to determine tolerability and toxicity of pharmaceuticals prior to use in a clinical setting. Non-clinical safety assessment studies are also used to assess different forms, formulations, dose routes, or patient populations of currently clinically available pharmaceuticals. Based on the intended purpose of the non-clinical safety assessment study, the study may require a different design and/or specialized endpoints. This talk will focus on pharmaceutical compounds with a clinical route of injection such as subcutaneous or intramuscular and considerations that should be taken into account during the study design

process to meet the intended study objective. The risks and rewards of including local tolerance endpoints on a systemic toxicology study or completing a focused local tolerance study will be discussed. Opportunities for reduction in animal usage by assessing multiple dose routes in one animal or utilizing animals as their own control will also be discussed. Following the presentation of study design considerations, this presentation will focus on the endpoints needed to determine local tolerance and the differences in endpoints depending on the route of administration. When and if it is necessary to add specialized dermal observations and how to minimize variability in potentially subjective endpoints, will also be discussed.

S 1149 Pathology Considerations for Evaluation of Injection Site Reactions: Animal Models, Sampling, and Histopathologic Evaluation

K. Nelson. Inotiv, Portage, MI. Sponsor: S. Kulkarni

Injectable therapies utilize subcutaneous (SC) and intramuscular (IM) administration routes for delivery, with depot formation. Often, the injection site reaction (ISR) may be one of the key elements in evaluating the response. Careful collection and sampling of the injection site facilitates the accurate assessment of the ISR by the pathologist. The ISR is the site of test material delivery, the site of greatest test material concentration, the most common site for histopathological findings, and the determinant for local tolerability. Typical histopathological findings include a spectrum of inflammation, hemorrhage, pseudocyst formation, edema, necrosis, fibrosis, and delivery material presence. These findings may vary according to a range of factors, including the animal model, particle size, vehicle characteristics, trauma associated with administration, and nature of the therapeutic agent. Evaluation of the injection site should encompass thorough sampling of the region, consistent and descriptive terminology for both macroscopic and microscopic observations, and consideration of the ISR in the context to the overall health status of the animal, particularly when determining tolerability.

S 1150 Nonclinical Regulatory Perspectives on Injection Site Reactions

J. Hawes Oliphant. US FDA/NCTR, Jefferson, AR.

Regulatory expectations for evaluation of injection site reactions in nonclinical studies supporting therapeutic development programs for injectable products will be reviewed. Considerations and challenges associated with adverse ISR findings in nonclinical studies and translation to clinical relevance will be discussed, particularly in how they may potentially impact overall nonclinical risk assessments. Case study examples will be provided.

S 1151 The Development and Associated Challenges of Long-Acting Injectable Formulations

E. Pierson. Merck & Co., Rahway, NJ. Sponsor: S. Kulkarni

Long-acting injectable (LAI) formulations can provide several advantages over the more traditional oral formulation as drug product opportunities. LAI formulations can achieve sustained drug release for extended periods of time, which results in less frequent dosing requirements leading to higher patient adherence and more optimal therapeutic outcomes. This talk will provide an industry perspective on the development and associated challenges of long-acting injectable formulations, including considerations of the Active Pharmaceutical Ingredient, optimization of the formulation, biopharmaceutical properties and characterization of LAIs through *in vitro*, *in vivo* and *in silico* approaches.

S 1152 Nonclinical-to-Clinical Translation of Injection Site Reactions

D. Zane. Gilead Sciences Inc., Foster City, CA.

The translation of observed nonclinical injection site reactions (ISRs) to the clinic has been a challenge for all types of therapeutics. From all the available literature, there is poor interspecies concordance with respect to ISRs. In addition, nonclinical studies have been shown to overpredict or underpredict the potential for ISRs in humans. While some nonclinical studies have been useful in predicting that ISRs may occur with parenteral products, the magnitude of effect remains poorly correlated. Regardless of the material, inflammation is the most common response to a foreign material in the subcutis. This presentation will discuss an overview on the nonclinical strategy in the development of long acting injectables which will include considerations to general study design of ISR studies (also known as local tolerability studies) to support entry into the clinic, discussion of species selection, case example of nonclinical-to-clinical translation and lessons learned.

S 1153 It's Complicated: The Messy Relationship Between Environmental Exposures and Metabolic Health

J. Beier. University of Pittsburgh, Pittsburgh, PA.

Environmental pollutants significantly impact the development, progression, and outcomes of metabolic disorders with the liver serving as a primary target organ. Recent epidemiological and experimental evidence has firmly established associations between various environmental exposures and metabolic dysfunction-associated steatotic liver disease (MASLD), obesity, and related metabolic disorders. This Symposium will explore cutting-edge research on the complex relationships between environmental chemicals and metabolic health, with particular emphasis on hepatic outcomes and mechanisms. The liver plays a central role in xenobiotic metabolism and intermediary metabolism, making it uniquely vulnerable to toxic insult. Emerging research has identified several classes of environmental chemicals as metabolism-disrupting chemicals (MDCs) that can promote alterations in liver lipid metabolism, energy homeostasis, and insulin sensitivity. These include per- and polyfluoroalkyl substances (PFAS), persistent organic pollutants like polychlorinated biphenyls (PCBs), plasticizers, pesticides, and air pollutants. New epidemiological evidence demonstrates robust associations between these exposures and liver disease severity, metabolic dysregulation, and obesity across diverse populations. This Symposium will highlight recent advances in our understanding of exposure-related metabolic toxicity. Presenters will discuss innovative research applying multi-omics technologies, exposomics approaches, and novel biomarkers to identify chemical effects on liver pathology and metabolic health. Critical discussion will focus on sex-specific effects, developmental origins of exposure-related metabolic diseases, and gene-environment interactions that modify individual susceptibility. Emerging research on the hepatic effects of exposure mixtures that reflect real-world scenarios will be presented alongside mechanistic investigations elucidating molecular pathways of toxicity, including nuclear receptor signaling, oxidative stress, mitochondrial dysfunction, and inflammatory processes. The Symposium will conclude with translational perspectives on implementing environmental health science in clinical practice, exploring new approaches for exposure assessment, patient screening, and intervention strategies. By bringing together diverse expertise spanning environmental health sciences, hepatology, and metabolism research, this session will provide critical insights into the role of environmental exposures in metabolic health and disease, with implications for toxicological risk assessment, clinical practice, and public health policy.

S 1154 Proteomic Markers of Gut Dysfunction and Mortality in Alcohol-Associated Hepatitis

B. Schnabl. University of California San Diego, San Diego, CA. Sponsor: J. Beier

Patients with alcohol-associated hepatitis (AH) face a high risk of mortality, largely due to alcohol's damaging effects on the liver and its ability to disrupt gut health. Alcohol damages the intestinal barrier, facilitates microbial translocation to the liver and contributes to chronic liver inflammation and progression of liver disease. To better understand intestinal changes and identify potential mediators of gut barrier dysfunction, we conducted a study analyzing fecal proteins from individuals across three groups: healthy controls, patients with alcohol use disorder (AUD), and those with AH. Using Tandem Mass Tag (TMT) proteomics, we examined fecal samples from two large multicenter cohorts and identified distinct differences in the proteomic profiles of each group. These differences followed a clear pattern that aligned with disease progression. Notably, proteins associated with neutrophil granules became increasingly abundant as disease severity worsened. Among these proteins, myeloperoxidase (MPO), a key enzyme found in neutrophil granules, was strongly correlated with both disease severity and the likelihood of death within 60 days. Furthermore, fecal levels of cathepsin B, a secreted lysosomal protease, and activity progressively increased in patients with AUD and AH compared with controls and were associated with higher 90-day and 180-day mortality in patients with AH in the exploratory and validation cohort. Immunofluorescence analysis in patients with AUD revealed that cathepsin B is upregulated and predominantly expressed in macrophages in the intestine. Cathepsin B proteolytically cleaves occludin in enzymatic assays, and its inhibition prevented occludin degradation and barrier disruption in intestinal organoids and epithelial monolayers. These findings highlight intestinal neutrophils and cathepsin B as mediators of gut barrier dysfunction and therapeutic target in alcohol-associated liver disease.

S 1155 High-Throughput Chemical Exposomics: Understanding Body Burden of Environmental Chemicals

D. Jones. Emory University, Atlanta, GA.

Environmental disease often develops and progresses over decades. Unfortunately, cost and throughput have limited human toxicology studies to a relatively small number of the thousands of potentially harmful environmental chemicals to which humans are exposed. To address this problem, we developed a scalable workflow for gas chromatography-high resolution mass spectrometry analyses of human samples with capability to measure hundreds to thousands of chemicals in single analyses. We now have introduced software to rapidly identify and quantify envi-

ronmental chemicals relative to pooled reference materials with known concentrations of thousands of chemicals. The methods have been applied to serum samples from human cohorts to study environmental chemical contributions to breast cancer, prostate cancer, Alzheimer's disease, Parkinson's disease and idiopathic pulmonary fibrosis, as well as to thyroid cancer, non-alcoholic fatty liver disease, and hyperparathyroidism. Results show up to 600 environmental chemicals within individual samples, including POPs, PAHs, pesticides, commercial chemicals, food additives and personal use products. Integration with metabolomics, phenotype and disease measures enables mechanistic investigation of individual chemicals as well as complex chemical mixtures.

S 1156 How Sex, Dose, and Diet Shape Liver Responses to POPs

B. Wahlang. University of Louisville, Louisville, KY.

Polychlorinated biphenyls (PCBs), dioxins and organochlorine pesticides, the original "dirty dozen", are well-associated with steatotic liver disease and metabolic disruption. However, epidemiological studies investigating links between levels of these legacy persistent organic pollutants (POPs) and liver/metabolic disease outcomes were concentrated mostly on chemical and agricultural workers who were mostly men. Experimental and toxicological studies have also largely been carried out predominantly on male rodent models as they were considered less messy. Critical knowledge gaps exist in the context of pathogenesis and disease progression, and more importantly mechanisms driving toxicity outcomes pertaining to POPs and women's liver and metabolic health. There is also emerging evidence that exposures to these POPs, often dictated by socio-economic status, is accompanied by poor nutritional status and comorbidities such as obesity. This presentation will focus on how exposures to mixtures of these legacy POPs, tailored to simulate current human exposure patterns, in conjunction with hypercaloric diets, can lead to sex-specific liver and metabolic toxicity. Notably, the presentation will emphasize on the significance of environmentally relevant doses, and how distinct mode-of action(s) including xenobiotic receptor activation and altered estrogen signaling modulate sex-chemical-diet interactions to consequently impact liver disease outcomes.

S 1157 From Bench to Community-Based Interventions: Translational Insights into PFAS and MASLD Pathogenesis

L. Chatzi. University of Southern California, Los Angeles, CA. Sponsor: J. Beier

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental contaminants that accumulate in the liver and are increasingly recognized as modifiable risk factors for metabolic dysfunction-associated steatotic liver disease (MASLD). This translational research framework integrates findings from human population studies and mechanistic *in vitro* models to illuminate how distinct PFAS compounds contribute to MASLD pathogenesis and inform targeted intervention strategies. In adolescents with severe obesity, elevated plasma concentrations of perfluoroheptanoic acid (PFHpA) were significantly associated with increased MASLD risk, severity of steatosis, and fibrosis. Multi-omics analyses revealed PFHpA-induced disruption of lipid metabolism, oxidative stress, and immune pathways. In parallel, advanced single-cell transcriptomics of 3D human liver spheroids exposed to PFHpA, PFOA, PFOS, PFHxS, or PFNA uncovered compound- and sex-specific mechanisms of hepatic injury. PFOA and PFHpA promoted lipid accumulation via upregulation of *de novo* lipogenesis and PPARα signaling, while PFNA and PFOS triggered oncogenic and immunosuppressive pathways. Notably, PFNA-exposed hepatocytes displayed strong cancer-like transcriptional signatures. Integrating omics data across platforms identified PFAS-related proteomic signatures predictive of MASLD risk, offering potential biomarkers for early detection. Collectively, our findings bridge molecular insights from the bench with population-level observations, advancing precision prevention strategies and informing community-based interventions to reduce PFAS-related liver disease burden.

S 1158 From Mechanisms to Medicine: Translating the Science of Metabolism Disruption into Clinical Practice

R. Sargis. University of Illinois at Chicago, Chicago, IL. Sponsor: J. Beier

The burgeoning metabolic disease pandemic has laid bare our failure to address its underlying drivers. While genetic predisposition coupled with excess energy intake and insufficient energy expenditure are undoubted drivers of metabolic dysfunction, these factors alone fail to explain the magnitude and rapidity with which metabolic health has deteriorated in the U.S. and globally. As such, other factors are likely at play and need to be addressed. Indeed, the last two decades have witnessed the emergence of robust data linking exposure to environmental toxicants to metabolic dysfunction. Our own cell-based, animal, and population-based studies corroborate the general literature that implicates exposure to a variety of environmental toxicants in the worsening of metabolic health. Furthermore, data indicate that many exposures, analyzed as single chemicals or mixtures, promote reinforcing cardiometabolic derangements that likely synergize to augment the risk of cardiovascular disease, the leading cause of mortality. Despite the strength of data across the

evidentiary spectrum, clinical medicine neglects the contribution of environmental exposures to metabolic disease risk. Our analyses of clinical practice guidelines confirms that the metabolic threat posed by environmental toxicants are largely, if not entirely, neglected in clinical medicine, a factor that impairs scientific progress, the development of public policy, and patient care. While policy interventions are critical for addressing these emerging health threats and promoting health equity, it is critical that the knowledge of environmental metabolism-disrupting chemicals leave the laboratories and enter the medical mainstream. Herein we discuss how our current environmental science can be applied to improve metabolic disease care.

S 1159 AHR-Mediated Dose Dependent Spatial and Temporal Metabolic Disruption in TCDD-Elicited Hepatotoxicity

T. Zacharewski. Michigan State University, East Lansing, MI.

2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD) induces dose-dependent hepatotoxicity and the progression of simple, reversible steatosis to steatohepatitis with fibrosis in C57BL/6J mice. The integration of computationally identified putative dioxin response elements (pDREs) with ChIPseq, bulk RNAseq, snRNAseq, spatial transcriptomic and metabolomics datasets as well as complementary histopathology in wild-type and a hepatocyte-specific, inducible aryl hydrocarbon receptor (AHR) null model has identified the dose dependent disruption of a number of metabolic pathways following the persistent of the AHR activation by TCDD. This includes (i) the ablation of circadian regulated carbohydrate, lipid and amino acid metabolism, (ii) the functional organization of metabolism across the liver lobule, and (iii) the accumulation of toxic intermediates such as secondary bile acids, acrylyl-CoA, ammonia and dicarboxylic acids. Persistent AHR activation by TCDD also elicited changes in the levels of acetyl-CoA, beta-hydroxybutyrate, ammonia and glutathione. This resulted in alterations in the levels of post-translation modification by acetylation, beta-hydroxybutylation, carbamylation and S-glutathionylation, respectively. These changes not only compromised cellular bioenergetics and antioxidant defenses but also altered the levels of intracellular messengers such as hydrogen sulfide and cobalamin. Overall, our results suggests that the hepatotoxicity of TCDD and related compounds goes beyond changes in gene expression and likely is due to the cumulative burden of metabolic disruption resulting from persistent AHR activation by TCDD and related compounds.

W 1160 Integrating In Vitro Data and PBK Modeling for Exposure-Led Risk Assessment

N. Kramer. Wageningen University, Wageningen, Netherlands.

Exposure-Led risk assessment uses estimates of human exposure as a primary driver to evaluate health risks, determine testing needs, refine hazard information, and support regulatory decisions. In this context, the integration of new approach methodology (NAM)-derived *in vitro* data with physiologically based kinetic (PBK) modeling is increasingly relevant. Together, these approaches provide a practical and mechanistic means to increase human relevance, reduce reliance on animal testing, and support more transparent and predictive exposure assessments. When combined through *in vitro-in vivo* extrapolation (IVIVE), these approaches help link *in vitro* bioactivity data with internal and external exposure estimates in humans. They can be applied in reverse dosimetry, deriving external doses corresponding to *in vitro* effect levels, and forward dosimetry, predicting tissue concentrations from expected exposures to compare with *in vitro* bioactivity data. Because IVIVE-PBK approaches are based on mechanistic understanding of human biology, they allow refinement of traditional risk assessments by accounting for biological and population variability. This session will emphasize both scientific and regulatory perspectives on implementing IVIVE-PBK in real-world contexts, with speakers from Europe and North America representing academia and industry. Case studies will draw on recent initiatives such as the European Food Safety Authority (EFSA) ADME4NGRA project, the ONTOX project, VHP4Safety, and the Partnership for the Assessment of Risks from Chemicals (PARC). Applications will span environmental chemicals, consumer products, nanomaterials, and sensitive endpoints, including developmental and reproductive toxicity (DART). The session will explore how *in vitro*-derived parameters, such as metabolic clearance, protein binding, and transporter activity, can be used to parameterize PBK models. Both reverse and forward dosimetry applications will be covered, with a focus on deriving external doses aligned with *in vitro* effect concentrations and comparing predicted internal concentrations with thresholds of biological activity. The session will also address the use of virtual populations and probabilistic modeling to characterize interindividual variability and inform regulatory decision-making. Finally, we will review current best practices for documenting model assumptions, selecting and sourcing input parameters, and communicating uncertainty, with reference to international guidance. Audience engagement will be encouraged to discuss challenges, evolving best practices, and strategies for ensuring transparency, reproducibility, and regulatory relevance in exposure-led risk assessment.

W 1161 Using *In Silico* Modeling to Support *In Vitro* ADME Parameterization of Physiologically Based Kinetic Modeling

N. Kramer. Wageningen University, Wageningen, Netherlands.

Next generation risk assessment (NGRA) encourages the use of *in silico* and *in vitro* tools as opposed to *in vivo* kinetic studies to parameterize physiologically based kinetic (PBK) models for quantitative *in vitro-in vivo* extrapolation (QIVIVE). In this study, we examine the applicability domains of *in vitro*-based absorption, distribution, metabolism, excretion (ADME) assays parameterizing PBK models for NGRA. It draws on experience from four ongoing European research projects: (1) the European Food Safety Authority (EFSA) ADME4NGRA project, (2) the EU Horizon 2020 ONTOX project, (3) the Dutch National Research Organization Virtual Human Project (VHP4Safety), (4) the European Partnership for the Assessment of Risks from Chemicals (PARC). The study describes how *in vitro* distribution kinetic modeling can explain and extend the chemical applicability domain of *in vitro* ADME assays, including rat and human stem cell based intestinal models for assessing the role of extrahepatic metabolism in absorption, new methods for determining plasma protein binding, human hepatic models of increasing complexity, from microsomes to microphysiological systems, for assessing hepatic clearance, and human proximal tubule models for describing transporter mediated excretion. The relevance of model outputs, such as internal dose metrics for comparing with *in vitro* bioactivity thresholds, will be discussed alongside uncertainties in assay extrapolation. Regulatory considerations, including how these model outputs can inform exposure-led risk assessment decisions, will also be addressed. This talk will emphasize practical strategies for incorporating these approaches into exposure-led regulatory decisions.

W 1162 Advancing NGRA for Developmental Neurotoxicity and Developmental and Reproductive Toxicity: Integrating *In Vitro* and *In Silico* Strategies

M. Moreau. ESQlabs GmbH, Durham, NC.

Developmental and reproductive toxicity (DART) evaluations are increasingly relying on New Approach Methodology (NAM) and IVIVE-PBK models to interpret effects without *in vivo* testing. This presentation will focus on how gestational kinetic models contribute to the interpretation of developmental and reproductive toxicity (DART)-related NAM data, particularly during pregnancy. Here, PBK models must consider dynamic physiological changes during gestation, including placental function and fetal development. Current maternal-fetal modeling platforms and methodologies for parameterizing placental chemical transfer will be presented, along with the existing knowledge gaps. To demonstrate the practical application of these models, case studies using quantitative *in vitro* to *in vivo* extrapolation (QIVIVE) from developmental neurotoxicity (DNT) research will be discussed, comparing approaches that can be used in tiered risk assessments and evaluating their respective strengths and limitations. We will also discuss model uncertainties and opportunities to enhance regulatory confidence through transparent parameterization and variability analysis using virtual populations. This presentation directly supports the session themes by addressing complex endpoints, NAM integration, and decision-relevant model outputs.

W 1163 Integrating *In Vitro* Data and *In Silico* Predictions to Develop and Apply PBK Models to Support Risk Assessments of Chemicals and Nanoparticles

Z. Lin. University of Florida, Gainesville, FL.

Integrating *in vitro* experimentation and *in silico* modeling is an important approach for the 21st century toxicity testing paradigm for chemicals and nanoparticles. While many studies have successfully applied *in vitro* data and *in silico* predictions to build PBK models for small molecular drugs and environmental chemicals, very few studies have been able to build PBK models for nanoparticles solely based on *in vitro* and *in silico* data. This presentation will discuss the similarities and differences in building PBK models for small molecular chemicals and nanoparticles. Recent studies will be presented to illustrate how *in vitro* dissolution, uptake, and retention data can be used to parameterize PBK models and predict internal concentrations in humans *in vitro*. In addition, the presentation will introduce how to apply PBK models to support toxicity and risk assessments of chemicals and nanoparticles by predicting human equivalent doses and risk ranking based on *in vitro* data. We will also address uncertainties in nanoparticle modeling and discuss how PBK outputs inform exposure limits in the absence of *in vivo* data, in connection with regulatory expectations for NAMs and risk-based decisions.

W 1164 Building Confidence in Bottom-Up PBK Model Development for NGRA Without Support of *In Vivo* Data

A. Punt. Unilever, Arnhem, Netherlands. Sponsor: N. Kramer

Bottom-up physiologically based kinetic (PBK) models use *in vitro* and *in silico* data to estimate internal chemical concentrations in humans. Evaluating PBK models typically requires *in vivo* data, but such data are often unavailable. This presentation will describe how confidence in PBK predictions can be achieved without *in vivo* data, through analog-based performance assessment, parameter sensitivity analysis, and software comparisons. We will illustrate how predicted plasma concentrations from bottom-up models are compared to *in vitro* thresholds to support point-of-departure derivation in regulatory submissions. Methods to transparently document assumptions, address uncertainty, and support model credibility will be discussed. This presentation supports the session themes of model transparency, reproducibility, and practical application of IVIVE-PBK in regulatory risk assessment. The results show that bottom-up PBK models can provide protective plasma concentration predictions for next generation risk evaluations (NGRA).

W 1165 Toxic Insights Unlocked: Leveraging Machine Learning and Advanced Image Analysis to Transform the Science of Toxicology

A. Green. Sciome LLC, Research Triangle Park, NC.

Advancements in imaging technologies and machine learning algorithms have revolutionized chemical safety assessment. Traditional methods, like manual evaluation of cellular assays or histological slides, are insufficient for addressing the growing influx of environmental and pharmaceutical compounds requiring examination. Three-Dimensional cell culture models and early developmental stage model organisms, such as zebrafish embryos, yield more physiologically relevant data but present new challenges with data complexity and throughput. To bridge this gap, the community has adopted scalable, automated procedures driven by bespoke deep-learning architectures and cloud-native infrastructures. In this session, attendees will discover how the latest imaging and computational advances are transforming chemical safety assessment into a faster, more reliable, and more predictive science. The session will explore how automated image-analysis workflows can turn thousands of raw images, whether whole organisms or cell cultures, into clear, quantitative readouts, overcoming long-standing challenges of data volume and human bias. Attendees will see how these approaches unlock subtle biological responses to chemical exposures at unprecedented scale, helping both academic researchers and industry practitioners generate high-quality data with confidence. The session also will highlight how integrated experimental platforms, 3D tissue models to high-content live-cell assays, are being bridged to traditional toxicology endpoints, speeding regulatory acceptance and strengthening mechanistic insights. Attendees will learn why packaging each step of the analysis into portable, end-to-end workflows is critical for reproducibility and collaboration across labs. Finally, the session will share general strategies for building robust analysis pipelines that stand up to real-world variability in staining, lighting, and sample preparation. Whether you're focused on environmental monitoring, drug safety, or regulatory science, this session will leave you equipped with the practical vision and inspiration to harness these innovations for your research programs.

W 1166 Advanced Scalable Screening of Phenotypic Responses to Chemicals

L. Truong. Oregon State University, Corvallis, OR.

This presentation will delve into our latest advancements in the scalable screening of phenotypic responses to chemicals using early life stage zebrafish models. We will discuss our cutting-edge techniques that enhance throughput and sensitivity in detecting potential toxicants, crucial for environmental and pharmaceutical safety assessments. We will discuss the state of scalable screening and automated imaging and analysis technologies that increase the efficiency and precision of phenotypic assays. We will discuss how data from phenotypic screenings are integrated and analyzed using advanced computational methods using new case studies. This presentation is intended for researchers, practitioners, and policymakers in toxicology, pharmacology, environmental sciences, and related fields. It will also benefit regulatory agencies and industry scientists interested in the latest methods for safety assessment. We hope to illustrate the practical applications of these techniques in real-world chemical assessments and to foster collaboration and discussion on improving chemical safety evaluations through advanced scientific techniques.

W 1167 Imaging of Microphysiological Systems for Toxicologic Pathology

S. Ferguson. NIEHS, Research Triangle Park, NC.

The needs of drug and environmental chemical safety research have inspired an array of new approach methods (NAMs) that mechanistically inform our understanding of chemical-biological interactions. However, most NAMs, to date, have limited

capacity to integrate biological response pathways to feed forward into recognizable toxicologic pathologies. Significant progress has been made with various types of microphysiological systems (MPS) that emulate tissue-like cellular architectures, hallmarks of tissue functionality, and human responses to drug and environmental chemical exposures. Surprisingly, MPS have had limited adoption for regulatory use, a consequence of historical approaches that rely on toxicologic pathology (e.g., clinical pathology, histopathology) in animal models and human clinical studies for decision-making and MPS developer's limited understanding of the needs of toxicologic pathology. To bridge these translational gaps, cellular imaging of MPS, in tandem with clinical pathology biomarkers and mechanistic assay systems, has the potential to serve as a 'Rosetta Stone' to relate these disparate fields and facilitate regulatory adoption of NAM-based approaches. Furthermore, due to their enhanced longevity and fidelity to model hallmarks of tissue functionality, MPS platforms hold the potential to model sub-chronic toxicity and disease. In this presentation, we describe case studies for the successful development and application of MPS to model human liver and kidney (i.e., proximal tubule) toxicity in response to drug and environmental chemical exposures that leverage imaging-based assay approaches. These include examples with exposures to PFAS, botanicals, and drug substances that reveal phenotypic changes consistent with hepatocellular injury, hepatic steatosis, cholestasis, and nephrotoxicity. In combination with biomarker and mechanistic data, imaging-based approaches with MPS using longer-term exposures hold the potential to serve as translational threads for the prediction of human health effects that collectively sew a growing quilt of drug and environmental chemical solutions for adoption in next-generation risk assessments.

W 1168 Automated Image Analysis Pipelines for High-Throughput Toxicological Screening

A. Tandon. Sciome LLC, Research Triangle Park, NC. Sponsor: A. Green

Advances in computational image analysis are changing toxicological screening by enabling automated, high-throughput measurement of morphological traits across multiple biological models. In this presentation we discuss customized deep learning pipelines for image analysis and segmentation of whole organism assays, histopathology slides, and cellular images to increase repeatability and efficiency in screening procedures. In our approach, we developed and deployed automated imaging and analysis pipelines for various assay formats, including 3D spheroid cultures, whole organism zebrafish embryos, high-resolution histopathology slides, and cell-based *in vitro* assays. We will discuss the deployment of a 3D U-Net convolutional neural network to analyze confocal z-stack images of liver spheroids inside a fully parallelized framework. Followed by the creation of a multi-view CNN system for checking early life stage zebrafish using dorsal and lateral projections, allowing for a combined method to identify more than twenty morphological features and segment essential organs with minimal user involvement. Lastly, we will present a computer vision approach for the assessment of cellular monolayers and tissue sections, incorporating focused loss algorithms and considerable data augmentation to address class imbalance and staining variability. This presentation concludes by discussing the benefits of containerizing each analysis pipeline to automatically orchestrate image preprocessing, inference, and post-analysis metric extraction to significantly increase throughput and reproducibility across screening campaigns.

S 1169 Understanding the GRAS Loophole: History, Science, and Legal Challenges

B. Mahadevan. Brincor Associates LLC, Corvallis, OR.

Recent discussions have centered on the potential for closing the generally recognized as safe (GRAS) loophole for food ingredient approval and strengthening US FDA oversight of food ingredients, leading to governmentally recognized as safe. The Human and Health Services Secretary has directed the US FDA to explore eliminating the self-GRAS pathway. This change could lead to premarket approval for food additives, potentially impacting the availability of some currently used ingredients and delaying the entry of future ingredients. It will create more work for the US FDA and increase costs for food manufacturers. Is rule-making to enforce US FDA-notified GRAS as mandatory possible? Potential legal hurdles and challenges will be illustrated. The history of GRAS, its current status, and related controversies will be discussed. Self-GRAS pros include streamlined approval, faster innovations, focus on established safety, and the role of qualified experts, while self-GRAS cons potentially include weakened oversight, lack of resources, potential for harm, lack of transparency, conflict of interest, and public health concern. These points must be considered and discussed before changing the current GRAS regulation. In recent months, the food regulatory landscape has been intensely scrutinized, with particular focus on the mechanisms and policies governing food ingredient approvals. This scrutiny has been sparked by growing public and scientific concern over the adequacy of current oversight practices.

S 1170 Mechanisms of Persistent Neurotoxicity: Changes Seen Throughout the Lifespan

D. Kendricks. NIEHS, Research Triangle Park, NC.

Early life exposures to many environmental contaminants may induce changes in nervous system development and function. Many such compounds induce neurobehavioral and physiological disruptions that arise shortly after exposure but are absent years after exposure has ended. However, there are many others that induce permanent changes in nervous system function that result in persistent, observable detriments throughout the lifespan, well into aging. These persisting effects are of paramount importance due to implications in neurodevelopmental disease onset, elevated risk of later-life disease manifestation, and heightened risk of neurodegenerative disease. Metals, pesticides, flame retardants, and many others remain a common risk in human populations throughout the world and have varied impacts on nervous system development and degeneration. However, current observations of the effects of these compounds have drifted away from investigating those mechanisms that persist throughout the lifespan. The goals of this Symposium are to shed fresh light onto the importance of understanding and considering long-term consequences of exposures and to provide further evidence of mechanisms associated with persistent effects seen following developmental exposure. In this Symposium, speakers will provide a framework that highlights essential considerations in models assessing long-term impacts of exposures and provide various examples of different models used to assess potential mechanisms underlying persistent neurotoxic effects. These discussions will include frameworks for understanding neurobehavioral outcomes linked to persistent neurotoxicity, biological variables to be considered, and examples of persistent neurotoxicity linked to exposure to heavy metals such as MeHg or ambient ultrafine particulate matter. Given the essential interaction between the time course of exposure and manifestation of neurotoxic effect, this Symposium will provide discussions highlighting exposures across various developmental timepoints. The speakers include experts from academia and government. The Symposium will begin with an introduction that will set the framework for understanding the importance of assessing risk of persistent neurotoxicity and current approaches for understanding potential mechanisms. The first speaker will provide a framework of the importance of understanding long-term disease risk associated with early life exposures. The talk will provide an overview of the importance of modeling behavioral outcomes resulting from early life exposure to showcase the importance of behavioral phenotype as an essential endpoint in the etiology of persistent disease. The second speaker will further elaborate on essential considerations in models addressing early life exposures. The talk will provide focus on incidence of neurodevelopmental disease risk and implications of sex as a biological variable. The third speaker will provide a discussion of potential mechanisms of persistent neurotoxicity associated with developmental exposure to the heavy metal methylmercury. The talk will address the relationship between chronic methylmercury neurotoxicity and the persistent decline in a dopamine-related behavioral phenotype using *Caenorhabditis elegans*. The final speaker will close out by discussing the persistence of behavioral effects resulting from developmental exposure to concentrated ambient ultrafine particulate matter and the potential relationships between these effects and altered levels of brain neurotransmitters in mice. The Symposium will conclude with a Q&A with all speakers to provide additional information and discussion on the importance of persistent effects of exposure. Together, this Symposium will provide valuable insights into the potential mechanisms of persistent neurotoxicity resulting from exposure to various environmental toxicants, which may advance the development of more effective prevention and intervention strategies to attenuate later-life disease risk.

S 1171 Long-Term Alterations in Behavior Resulting from Early Developmental Toxicant Exposure

E. Levin. Duke University, Durham, NC.

Toxicant exposure during the process of brain development can cause long-term alterations in neurobehavioral function that are expressed throughout the rest of life. In a great many studies, with a variety of toxicants including heavy metals, pesticides, marine toxins, flame retardants and polyfluorinated compounds, across species from zebrafish to rats to monkeys, we and others have found that developmental toxicant exposure causes long-term behavioral changes in sensorimotor function, emotional response and cognition. Several overarching conclusions can be drawn from these studies. Even relatively brief or low-level toxicant exposure during brain development can cause long-term behavioral alterations. Long-term effects are not necessarily predicted by short-term effects. Cognitive impairment from developmental toxicant exposure can emerge during older adulthood. Typical sex differences in behavior, particularly with locomotor activity and cognitive function, have been found to be diminished or reversed by developmental neurotoxicity. Therapeutic treatments can counter the imitation of developmental neurobehavioral toxicity or attenuate the expression of its behavioral consequences later in life. There is a plethora of interacting factors that play key roles in determining whether developmental toxicant exposure causes long-term neurobehavioral changes. Translational animal models can provide the complexity of an evolved integrated organism to test the long-term consequences of developmental neurotoxic exposure on neurobehavioral function. Species with shorter life courses can provide a look ahead at potential risks that may develop over the many decades of the human life span. The long-term func-

tional behavioral effects of developmental neurotoxicity can be a starting point to track back the interacting mechanisms that give rise to the impairment, meeting the forward mechanistic studies beginning with incipient effects to increase our understanding of the more complete causative series of events that result in long-term neurobehavioral dysfunction resulting from developmental toxicant exposure.

S 1172 The Timing Makes the Poison: Critical Windows, Chemical Exposures, and Neurotoxicity Across Brain Development and Maturation

H. Patisaul. NIEHS, Research Triangle Park, NC.

Heightened attention on the precipitous rise in the prevalence of multiple neurodevelopmental disorders (NDDs), such as autism spectrum disorder (ASD), has renewed interest in environmental factors as potential contributors, and how to better screen for developmental neurotoxicity (DNT). While most of the work seeking to understand how chemical exposures may contribute to NDD risk has focused on prenatal or early life exposure, significant aspects of human brain development occur long after birth and continue into early adulthood. Accounting for these windows is poised to significantly enhance the capacity to identify neurotoxicants and their modes of action. The post-natal brain has windows of rapid change and maturation currently not considered in animal or non-animal testing platforms. Those myriad processes include brain sexual differentiation, synaptic refinement, myelination, and neuroendocrine system maturation. Additionally, although all mental health disorders, including ASD, have a sex bias, many studies and research efforts, including emerging NAM platforms, still largely fail to incorporate sex as a biological variable let alone age, endocrine influence, or cellular or genetic diversity. Finally, although ASD and other NDDs share many socioemotional deficits, including sociality, the neuroendocrine systems underlying those behaviors remain absent from testing platforms despite the availability of tools from the neurosciences that could do so. This presentation will provide an overview of brain critical periods across pre- and post-natal life, how those windows align with NDD risk, and the processes and systems undergoing maturation and refinement during those key periods along with the imperative to account for them in any DNT testing platform as well as sex differences.

S 1173 Latent Alterations in Swimming Behavior by Developmental Methylmercury Exposure Are Modulated by the Homolog of Tyrosine Hydroxylase in *Caenorhabditis elegans*

M. Aschner. Albert Einstein College of Medicine, Bronx, NY.

Silent neurotoxicity is defined as persistent change to the nervous system that does not manifest as overt toxicity unless unmasked by experimental or natural processes. Silent neurotoxicants are challenging for risk assessors, as the multifactorial experiments needed to reveal their effects are seldom conducted, and they are not addressed by current study guidelines. Previous studies have shown that developmental exposure to MeHg can damage brain functions, which may only become apparent after years or decades. However, the underlying mechanisms of the latent neurotoxicity associated with exposure to MeHg are not yet fully understood. Using *Caenorhabditis elegans* (*C. elegans*), we investigated the latent toxicity of developmental MeHg exposure. Synchronized L1 stage worms were exposed to MeHg (0, 0.05, 0.5, and 5 μ M) for 48 hours. We analyzed the swimming speeds of adult worms that had been exposed to MeHg during their early larval stages. Worms exposed to MeHg developmentally showed a significant decline in swimming speed at the adult stage on day 10, but not on day 1 or day 5, despite mercury levels in worms exposed to 0.05 or 0.5 μ M MeHg being below the quantification limit on day 10. Day 10 adult worms treated with MeHg exhibited a significant decrease in bending angle and bending frequency during swimming. Additionally, their reduced swimming speeds tended to increase during the 300-second swimming experiment. Dopamine signaling is known to regulate worms' swimming speed. Therefore, we assessed the swimming speed of worms with cat-2 (mammalian tyrosine hydroxylase homolog) mutation or dat-1 deletion on day 10 of adulthood. The cat-2 mutant worms did not show a decline in swimming speed, body bends, or bending angles during swimming on day 10. Analysis of the swimming speeds of worms with dat-1 deletion revealed that their speeds were further reduced after MeHg exposure. However, the effects of MeHg and dat-1 deletion were not synergistic, as the interaction between these parameters did not reach statistical significance. In summary, our results suggest that developmental MeHg exposure induced a latent reduction in swim speed that was less pronounced with deficient dopamine synthesis. These findings highlight the pivotal role of dopamine and its metabolism in the latent, and likely the persistent neurotoxic effects of MeHg.

S 1174 Persistence of Neurochemical and Behavioral Changes Following Developmental Exposures to Concentrated Ambient Ultrafine Particulate Matter Air Pollution in Mice

D. Cory-Slechta. University of Rochester Medical Center, Rochester, NY.

Air pollution (AP) exposures are associated with neurodevelopmental disorders and neurodegenerative diseases, raising the question as to whether neurotoxic effects of developmental exposures persist and contribute to subsequent vulnerability for neurodegenerative diseases. Our prior studies in mice show that developmental exposures (postnatal days 4-7 and 10-13) to inhaled ambient ultrafine particulate (UFP) matter produce behavioral deficits and brain neurotransmitter system alterations. Subsequent studies have examined the impact of developmental exposures to inhaled nanoparticulate iron oxide (alone (Fe) or with SO₂ (FeS)), the most prominent AP metal contaminant as a potential determinant of UFP effects at 3 time points post exposure. Fe is critical to brain growth and development, but also redox active. At PND14, marked changes in brain frontal cortex and striatal neurotransmitter systems were observed, particularly in response to FeS as compared to Fe only, in glutamatergic and dopaminergic systems that were of opposite directions by sex. By PND 357, it was found, as expected, that behavioral experience markedly altered baseline levels of neurotransmitters as well as transsulfuration markers. Corresponding changes did not occur in developmentally FeS-exposed males. In contrast, females showed persistent neurochemical effects of developmental exposures to Fe alone at PND 215, as well as increased homocysteine levels in frontal cortex and striatum. Behavioral experience markedly increased correlations across frontal cortical and striatal glutamatergic, dopaminergic and serotonergic systems in control brains at PND357 (FeS) or 215 (Fe), and these correlations were significantly attenuated by developmental exposures to FeS and Fe, particularly in males. Collectively, the findings indicate a persistence of air pollution-related neurotoxicity with the trajectory of adverse changes modified by behavioral experience.

R 1175 Do We Need a Number, a Pathway, or Both? Applying Transcriptomics for Chemical Hazard Assessment

J. Rogers. Merck & Co. Inc., West Point, PA.

Gene expression profiling has gained considerable traction across the toxicology community. Beyond the original promise of "mechanistic interpretation," transcriptomics data is increasingly used for chemical prioritization and early derisking and to support alternatives to traditional toxicity testing (such as grouping and read-across). Transcriptomics platforms have been shown to provide a health-protective point of departure for provisional risk assessments, and gene expression biomarkers have been validated for well-studied hazards such as genotoxicity, liver injury, and endocrine disruption. Expansion to other hazards and their related mechanisms of action could expand the utility of these data beyond quantitative point-of-departure estimation. These readouts, whether from *in vivo* or *in vitro* studies, are often integrated with other experimental data into multidimensional datasets, thus meeting the long-standing need for "phenotypic anchoring." As the volume, speed, and complexity of gene expression data continue to grow, it's time to critically assess their accuracy and define clear contexts for their use. This session aims to highlight practical applications of toxicogenomic data in regulatory science. Speakers will explore several interconnected themes: a review of current and emerging gene expression profiling and interpretation methods in toxicology; case studies applying toxicogenomic data toward hazard characterization in regulatory contexts; and strategies to make these data more interpretable and actionable for decision-makers. By highlighting recent developments from pharma, government, and academic sectors, this session will further build consensus for how transcriptomics can directly support informed decision-making in toxicology.

R 1176 Toward a New Paradigm: Can Mechanistic *In Vivo* Studies Replace Traditional DART Guideline Studies?

S. Mitchell-Ryan. HESI, Washington, DC.

Current regulatory frameworks rely heavily on a battery of animal-intensive OECD test guideline studies to assess reproductive and developmental toxicity for various sectors, like agrochemicals and industrial chemicals. However, there is increasing recognition that short-term studies *in vivo* that employ high-dimensional biological metrics derived from 'omics technologies (e.g., transcriptomics) can be used to derive a point of departure (POD) that is based on a concerted molecular change. It has been suggested that this molecular POD-based approach potentially offers a more efficient, health protective, and animal-sparing alternative to traditional guideline studies. This Roundtable will explore the feasibility of converging toward a single *in vivo* study design that encompasses all critical windows of susceptibility and captures key developmental and reproductive endpoints while leveraging molecular and mechanistic data to ensure human health protection. Experts will discuss how traditional developmental and reproductive toxicology (DART) studies (e.g., OECD 414, 421, 416, and 443) are currently used and will present emerging designs that integrate gene expression and new approach methods to enhance predictive power and generate health-protective POD values while reducing/refining animal use. Special

attention will be given to how these newer approaches compare to current methods, including whether they can identify responses across all sensitive life stages and detect potential developmental and reproductive toxicants that might otherwise be missed. Challenges in interpreting gene expression data will be discussed, along with the role of kinetic data, cross-sector needs, and region-specific regulatory expectations. A case study presentation will illustrate comparisons between 'omics PODs and apical outcomes and highlight some specific efforts to increase reproducibility and standardize 'omics analyses and applications. Through collaborative discussion with the audience, panelists will work toward defining what an optimal, protective, and streamlined study could look like—one that reduces animal use, spans regulatory sectors, and is grounded in established mechanistic science. By identifying scientific and regulatory gaps, this session will help chart a path toward innovative testing strategies that are both ethically and scientifically robust.

R 1177 Mice with a Mission: Optimal Use of Humanized Transgenic Mice as an "FDA Innovative Platform"

T. Papenfuss. StageBio, Frederick, MD.

Humanized transgenic mice (HuMs) are a tool with potential to replicate human-specific physiology and pathology and provide a translational *in vivo* model for drug development. The recent US FDA Roadmap to reducing animal testing in preclinical safety studies has recognized the utility of HuMs as an innovative platform for refining current animal requirements. With this in mind, thoughtful guidance as to the proper application of HuM models to current drug development paradigms, technical considerations for their use, and discussion on their strengths and weaknesses for human translatability in comparison to traditional animal models is necessary. In particular, there are no consistent approaches to the technical and translational considerations of different HuMs for various disease models or how immune and pathology study endpoints are incorporated or applied for study interpretation or human risk assessment. The goals of this workshop will be to (1) provide an overview of the technical and translational applications of various HuM models currently available, (2) outline key considerations in study design and selection of immunotoxicology and pathology endpoints in safety versus efficacy studies, and (3) describe the practical use and application of HuMs data within industry to inform on drug development. At the beginning of the Workshop, attendees will be introduced to the US FDA "Roadmap to Reducing Animal Testing in Preclinical Safety Studies" and the concept of how HuMs can serve as an innovative platform as a refined *in vivo* method (for transition). Brief points to consider on how to optimize the use, application, and translational considerations of HuMs for reducing animal testing will be introduced prior to the presentations by the speakers. Presentations will provide technical and translational considerations for HuM models and a contextual framework on how and when HuMs should be employed (and for what purposes) that will serve as a foundation for the roundtable discussion. The first speaker will begin the discussion on the technical and translational applications of various HuM models that are currently available, the use of HuMs, and expectations for the qualification of use in drug discovery/validation versus nonclinical safety and efficacy. The second speaker will present study design considerations, such as how to leverage HuM models and immune concepts to answer key scientific questions and the preferred study data endpoints (i.e., immune, pathology) for answering these questions. Reference to designing a study with the "end-in-mind" and the different considerations of how efficacy versus safety studies will be emphasized. The last speaker will discuss how data generated from HuM models are currently incorporated into drug development programs for human risk assessment and opportunities/challenges with HuM models versus traditional large animal models. Following the presentations, there will be a roundtable discussion among presenters and audience members on how to optimize the use of HuMs to refine current animal testing practices while ensuring preclinical safety studies maintain the highest quality of translational relevance.

EC 1178 Navigating Your Scientific Career: The Power of Transforming Networking into Mentoring

C. McGinnis. Center for Toxicology and Environmental Health, Little Rock, AR.

Most of us have had the opportunity to experience a mentoring relationship at least once in our scientific careers, typically in an academic setting or as an early career scientist. What can be more challenging is to find and build a mentoring relationship outside of traditional hierarchies, such as supervisors or collaborators. It is not uncommon to attend networking events where we have opportunities to connect with peers and like-minded people. Perhaps we are connecting with new contacts at Specialty Section or Regional Chapter events. But what happens when there is interest in expanding surface-level networking into a more formalized mentoring relationship? This session will equip attendees with practical tools to build meaningful mentoring relationships by exploring best practices, strategies for setting effective goals, and addressing the current needs of participants. This session explores scenarios and avenues to establish mentoring relationships for all career stages and will start by asking the attendees to reflect on a time they needed mentorship. This starting reflection will be facilitated by a poll where participants submit one-to-two-word examples of a scenario where they needed mentorship (i.e., tenure, career change). The session will proceed with the first speaker who will provide an over-

view of mentoring-related resources available through SOT. The second speaker will explore mentoring at different career stages and share experiences in fostering successful mentoring relationships. The third speaker will explore opportunities to build a mentoring relationship through SOT Special Interest Groups and Regional Chapters. The session will transition to a breakout-group (BOG) style of discussion that will enable audience participation by sharing their experiences in mentoring relationships across career levels. The BOG will be facilitated by members of the SOT Career Advancement, Mentoring, and Networking (CAMAN) Committee; the SOT Graduate Student Leadership Committee (GSLC); and the SOT Postdoctoral Assembly (PDA) of varying career levels to provide some context on how mentoring relationships may vary throughout one's career. Prompting questions and scenarios will be used to encourage attendees to consider best mentoring practice, how to effectively communicate the goals of the mentoring relationship, and how to develop a mutual learning dynamic. Questions will include "how do I identify the right mentors for me," "what works or does not work in maintaining a strong mentoring relationship," "how does mentoring evolve throughout different career stages," and "how do you establish clear objectives of a mentoring relationship?" Scenarios will be used to illustrate ways to initiate and clearly communicate the goals, duration, and responsibilities of the mentor and mentee. Scenarios will be career-dependent to help facilitate the formation of mentorship relationships at all career stages.

S 1179 In Vitro Testing for Skin Sensitization of Mixtures: Where Science Stands Today

S. Farahmand. The Honest Company Inc., Los Angeles, CA.

The assessment of skin sensitization potential in complex mixtures, such as cosmetic products, medical devices, and industrial formulations, presents unique scientific and regulatory challenges. Such an endeavor also provides an avenue for applying the established scientific framework of the adverse outcome pathway (AOP) to enhance risk assessment methodologies for products and devices (mixtures) that we encounter in daily life. Traditional *in vivo* methods and many NAMs were primarily developed for individual chemicals and often require adaptation for effective application to mixtures. This session explores recent advancements in nonanimal approaches tailored to address these challenges, supplemented by detailed case studies demonstrating their practical implementation in risk assessment frameworks. Presentations will showcase NAM approaches that evaluate the key events (KE) in the skin sensitization AOP and methods to derive potency for use in quantitative risk assessment. Reconstructed human epidermis models, such as those enabling surface-area-based dosing and realistic exposure scenarios, are particularly effective for poorly soluble and complex substances. Advances in genomics-based platforms and machine learning models will also be discussed, emphasizing their ability to predict sensitization potency and derive points of departure (PODs) that support quantitative risk assessment without animal or human confirmatory testing. Additionally, the session will address the integration of exposure-based waiving thresholds and dermal absorption models that account for formulation- and skin-specific parameters, further strengthening risk assessment frameworks. Case studies will highlight the application of these methods to finished cosmetic products and medical device extracts, including adaptations that enable both hazard identification (addressing several KE) and potency estimation. The presented methods and their use in risk assessment are the outcome of several years of collaboration between industry, academia, and government agencies. This session highlights the achievements of this endeavor and the practical use by experts in a variety of sectors as a tool used to ensure consumer safety. Attendees will gain (1) a comprehensive understanding of the scientific and regulatory challenges in evaluating skin sensitization of mixtures, with a focus on risk assessment; (2) insight into validated and emerging *in vitro* models suited for complex formulations; (3) practical examples of how NAMs can be applied in product development and regulatory submissions; (4) knowledge of potency prediction methods and how PODs can be derived without animal or human testing; and (5) an overview of how integrated strategies and modeling tools can enhance risk assessment accuracy for mixtures. Collectively, these efforts represent a significant step forward in the development and regulatory acceptance of NAMs for complex mixtures, offering scientifically robust and ethically sound alternatives to traditional testing.

S 1180 Advancements Toward a Mixture-Specific NAMs-Based Framework for Skin Sensitization Risk Assessment

D. Allen. International Collaboration on Cosmetics Safety, Durham, NC.

Existing sensitization testing methods, including traditional *in vivo* approaches as well as new approach methodologies (NAM), have primarily been developed for individual defined chemicals and may not always be fully compatible with the testing of mixtures. Due to differences in their composition and sample characteristics (e.g. form, physical and chemical properties) testing and resulting interpretation can be challenging. Therefore, there is a pressing need to evaluate and amend the existing NAMs-based risk assessment framework so that it considers better the specific characteristics of mixtures. This adapted framework should incorporate exposure-based waiving thresholds, optimized NAM applications, as well as effective integration of data, to enable more accurate and reliable skin sensitization risk assessment of

mixtures. This presentation will discuss ongoing efforts that involve NAM development and evaluation activities, to address these challenges to ensure the safe use of cosmetic products, meeting the growing demand for natural and sustainable options while prioritizing consumer safety that includes such complex mixtures. Attendees will learn about novel *in vitro* method development as well as evaluation and optimization efforts directed towards expanding an existing next generation risk assessment framework to incorporate these types of substances.

S 1181 Application of the EpiSensA for Skin Sensitization Assessment of Mixtures

A. Islas-Robles. Institute for In Vitro Sciences Inc., Gaithersburg, MD.

Keratinocyte activation, identified as Key Event 2 in the skin sensitization Adverse Outcome Pathway, is a critical biological step that can be evaluated using *in vitro* methods to support non-animal hazard identification. The Epidermal Sensitization Assay (EpiSensA, OECD TG 442D) is the first *in vitro* skin sensitization assay validated using three-dimensional reconstructed human epidermis (RhE), providing a biologically relevant model that closely resembles native human skin. This tissue architecture enables surface-area-based dosing and more physiologically realistic exposure scenarios, making it particularly well-suited for the assessment of complex mixtures. The EpiSensA measures gene expression markers associated with keratinocyte activation, delivering a mechanistic and human-relevant endpoint for identifying sensitizers. This presentation will highlight a literature-based analysis that examines the potential to expand the applicability domain of the EpiSensA across diverse chemical spaces, with a particular focus on complex and difficult-to-test mixtures. The EpiSensA was applied to three agrochemical formulations and two surfactant-based mixtures with available *in vivo* data (Mizumachi, 2020). Both surfactant mixtures were accurately classified as sensitizers, and the sensitization potential of the agrochemicals was correctly identified, although one was a false positive. Similarly, a study evaluating various medical device extracts found that EpiSensA successfully detected sensitization potential in devices previously classified as sensitizers through *in vivo* tests (Okamoto, 2024). Notably, positive responses were observed for the non-polar extract, aligning with animal test outcomes. These findings highlight the potential of the RhE-based model to identify skin sensitizers across diverse mixtures, including those with challenging characteristics for *in vitro* testing. Further research is still needed using larger datasets, including the evaluation of other mixture categories such as cosmetics, to better demonstrate the assay's practical utility, performance attributes, and regulatory potential within defined approaches and integrated testing strategies.

S 1182 Use of the SENS-IS Transcriptomic Reconstructed Epidermis Assay in the Skin Sensitization Testing of Mixtures

H. Groux. Immunosearch Labs SARL, Grasse, France. Sponsor: S. Farahmand

The assessment of skin sensitization potential in complex mixtures, such as cosmetic products and medical device extracts, presents distinct scientific and regulatory challenges. While validated *in vitro* methods have significantly advanced for individual substances, their application to mixtures requires careful consideration of formulation effects, irritancy, and potential chemical interactions. The SENS-IS assay, based on a transcriptomic approach using reconstructed human epidermis, offers a robust tool for addressing these complexities. A catch-up study supporting the use of a newly developed in-house 3D epidermis model is currently under evaluation by the OECD, further reinforcing the assay's relevance for regulatory use. Our published work (2019) demonstrated that SENS-IS can identify a variety of mixture-related effects, including vehicle-dependent modulation of sensitization potency, irritant-induced enhancement, additive or synergistic interactions at low concentrations, and positive responses in finished consumer products. Since then, the assay has been applied to a wide range of mixtures, supporting its applicability across different regulatory contexts. This presentation will focus on recent case studies involving cosmetic products, illustrating how formulation components can significantly influence the sensitization profile of active substances. To expand the assay's relevance, we are also evaluating a complementary full-thickness skin model that incorporates a dermal compartment. This system more closely mimics native skin architecture and offers new insights into mixture effects involving deeper skin layers. Together, the epidermal and full-thickness models enhance the utility of the SENS-IS assay in mixture testing, contributing valuable data for risk assessment frameworks. This work underscores the importance of advanced *in vitro* models in the ongoing transition toward non-animal testing strategies in regulatory toxicology.

S 1183 In Vitro Assessment of Complex Mixtures Using a Genomics and Machine Learning-Based Approach

T. Lindberg. SenzaGen AB, Lund, Sweden. Sponsor: S. Farahmand

Recent advances in New Approach Methodologies (NAMs) have led to *in vitro* methods that assess skin sensitization with predictive performance comparable to animal models, offering greater ethical and human relevance. However, testing complex

mixtures and finished formulations remains challenging due to solubility, compositional variability, and interference from non-sensitizing components. Even when technically compatible with validated assays, these substances often require protocol adaptations, and interpreting results can be difficult. GARD (Genomic Allergen Rapid Detection™) technology, combining gene expression profiling with machine learning, is one such NAM. Based on a dendritic cell-like line and included in OECD Test Guideline 442E (Key Event 3), GARDskin has demonstrated potential for evaluating mixtures. This presentation reviews the scientific principles, performance characteristics, and limitations of GARDskin in the context of mixture testing. Data from peer-reviewed studies and industry collaborations highlight its applicability to personal care products, finished formulations, UVCBs (Substances of Unknown or Variable Composition, Complex Reaction Products, or Biological Materials), and hydrophobic mixtures (Log P: 3.5). The GARDskin Dose-Response adaptation will also be discussed, showcasing its ability to predict human NESIL values and UN GHS/CLP subclassifications—key for regulatory risk assessment. Technical considerations, including solvent compatibility with both polar and non-polar substances, are addressed as they are critical for handling hydrophobic ingredients and complex medical device extracts. In summary, GARDskin provides a robust and adaptable *in vitro* solution for assessing skin sensitization hazard and potency in complex mixtures. These advances further support the regulatory relevance of NAMs as scientifically valid alternatives to animal testing.

S 1184 Replacing Human Testing with NAMs: Deriving Points of Departure for Quantitative Risk Assessment of Natural Complex Substances and Mixtures

I. Lee. Research Institute for Fragrance Materials, Woodcliff Lake, NJ.

Quantitative risk assessment (QRA) for dermal sensitization is critical in establishing safe use levels of sensitizing ingredients in consumer products. Traditionally, QRA relies on the No Expected Sensitization Induction Level (NESIL) as the point of departure (PoD), often determined through human testing via the Confirmation of No Induction in Humans (CNIH) repeat patch test. However, with the advancement of New Approach Methodologies (NAMs) and their integration into Next Generation Risk Assessment (NGRA) frameworks, industry is moving toward not only non-animal, but also non-human testing strategies for PoD derivation. Significant progress has been made in applying NAMs to discrete chemicals, but challenges remain in evaluating natural complex substances (NCS) and other mixtures due to their multi-constituent and variable nature. In the fragrance industry, many NCS contain known discrete components, enabling a component-based risk assessment approach. However, this strategy is not universally applicable, prompting exploration of NAM-based methods for direct PoD derivation. This presentation highlights the use of several quantitative potency-based NAMs, which may include Bayesian models like SARA and SARA-ICE, the GARDskin dose-response assay, and OECD *in vitro* regression models, to support risk assessment of NCS and mixtures. Within the NGRA framework, these methods allow for the derivation of a NAM-based PoD, which can be adjusted using uncertainty factors to estimate a predicted NESIL (pNESIL). This value is then used to calculate Acceptable Exposure Levels (AELs) for consumer products such as deodorants and bar soaps, which are compared against estimated Consumer Exposure Levels (CELs) to determine the margin of safety. Case studies will be presented to demonstrate how currently available NAMs can be effectively used in NGRA to assess NCS, offering a scientifically robust alternative to traditional animal and human testing for QRA.

S 1185 NAM In Vitro Assessment of Intestinal Metabolism to Inform PBK Modeling of Bioavailability and Systemic Exposure

J. Wambaugh. US EPA, Research Triangle Park, NC.

Next-Generation chemical risk assessment (NGRA) aims to replace and expand on traditional toxicity testing with new approach methodologies (NAMs). One central aspect in NGRA is the assessment of toxicokinetic properties to estimate the bioavailable concentration of the dosed compounds and/or potentially toxicologically relevant metabolites. This question is also relevant to address interspecies differences or route-to-route extrapolation. The development of NGRA framework needs a joint effort, and several projects are advancing this field like ASPIS (Animal-Free Safety Assessment of Chemicals), the EFSA ADME4NGRA and PARC (Partnership for the Assessment of Risks from Chemicals). This session will highlight recent advances from these projects to fill methodological, as well as knowledge, gaps. A current knowledge gap is generating data on intestinal pre-systemic metabolism and metabolite formation. Advanced models for the study of intestinal metabolism in primary human cells and organoids will be presented along with studies on metabolism by the intestinal microbiome. The kinetics need to be integrated with toxicodynamic evidence to allow the derivation of a point of departure for hazard and risk assessment. The ASPIS project cluster is developing a framework for NGRA, which is termed ASPA (Animal-Free Safety Algorithm).

S 1186 Advanced *In Vitro* Models for the Assessment of Intestinal Metabolism

P. Lundquist. Uppsala Universitet, Uppsala, Sweden. Sponsor: B. Islam

Newly developed *in vitro* NAM models for intestinal metabolism and permeability, such as primary human enterocytes and 3D-cultured human adult stem cell derived intestinal organoids will be presented and discussed in the context of absorption of orally ingested xenobiotics. The models show pronounced activity of phase I and II metabolizing enzymes, including CYP450:s, UGT:s and SULT:s. Metabolism measured in these system have been modeled by PBK yielding human exposure estimates in good agreement with human studies. Additionally, activity ADME relevant transporters could be demonstrated. Global proteomics are used for in depth assessment of protein expression in the *in vitro* models enabling comparison to *in vivo* human intestinal physiology and expression of ADME proteins. Isolated human enterocytes and 3D cultured intestinal organoids from the jejunum and colon were found to show proteins expression levels in good agreement with the human tissue of origin, in contrast to cell line derived models. These novel intestinal *in vitro* models show promise to generate human relevant data on intestinal metabolism of toxicants, drugs, and xenobiotics.

S 1187 Rat and Human Intestinal Organoid Models to Assess Species Differences in Intestinal Absorption of Chemicals

J. Wang. Wageningen University and Research, Wageningen, Netherlands.

Traditionally, rats are used in toxicokinetics and toxicology studies. However, species differences in the processes driving the absorption, distribution, metabolism and excretion (ADME). For example, there are marked differences in transporter and biotransformation enzymes in enterocytes that affect a chemical's bioavailability. Human *in vitro* cell models have been well established as a means to estimate gut permeability. However, a comparative rat cell model is currently lacking. This presentation we present a rat jejunum organoid-derived model. We evaluate human and rat jejunum organoid-derived monolayer models in comparison with the conventional Caco-2 cell monolayer model for studying xenobiotic metabolism and transport. Key focus areas include profiling the expression of metabolic and transporter genes, highlighting both species-specific differences between humans and rats, and model-specific differences between organoid-derived and Caco-2 cell-derived monolayers. Tacrolimus, a clinically relevant CYP3A5 and P-glycoprotein (P-gp) substrate, will be used as a case study to illustrate the impact of intestinal pre-systemic metabolism and transporter expression on overall toxicokinetic. The resulting data will be integrated into a physiologically based kinetic (PBK) model of tacrolimus to support quantitative *in vitro*-to-*in vivo* extrapolation (QIVIVE) for nephrotoxicity.

S 1188 Advances in Assessing Chemical Biotransformation by the Gut Microbiome and Its Incorporation into Physiologically Based Kinetic Models

G. Aichinger. ETH Zurich, Zurich, Switzerland. Sponsor: B. Wetmore

The gut microbiome is emerging as a key contributor to chemical metabolism. We optimized and harmonized strategies to assess chemical biotransformation kinetics in anaerobic fecal fermentations and to include respective parameters for facilitating microbiome-competent PBK modeling. The application of this methodology for predicting pharmaco-/toxicokinetics of selected chemicals revealed a highly individual impact of gut microbiota on chemical bioavailability and facilitated quantitative extrapolation from *in vitro* toxicity characterization of microbial metabolites to their *in vivo* bioactivity.

S 1189 Evaluating Contribution of Intestinal Toxicokinetic Features on Bioavailability Estimation

B. Wetmore. US EPA, Research Triangle Park, NC.

Bioavailability is an important factor in physiologically-based toxicokinetic (PBTK) models estimating internal dose following oral exposure. In higher-throughput models designed for new approach methodology (NAM) application, a minimum set of TK inputs may be considered, with other parameters set to conservative assumptions (for instance, no consideration of extrahepatic metabolism). Strategic identification of key modulators of intestinal bioavailability may assist by either identifying priorities in selecting promising NAM models or in identifying key model inputs that could be leveraged for more immediate application in generic PBTK models. This presentation will summarize findings from an experimental 11-chemical case study that employed *in vitro*-*in vivo* extrapolation (IVIVE) - PBTK modeling and a meta-analysis designed to evaluate the contribution cytochrome P450 (CYP) 3A4, the most abundant intestinal CYP isozyme, along with the role of other intestinal enzymes, transporters, and physicochemical properties in modulating bioavailability. Findings show that incorporating CYP3A4 metabolic contribution to estimate

intestinal metabolism aligns with *in vivo* derived oral bioavailability estimates and far outweighs the contribution of intestinal absorption or other metabolic or disposition pathways. These findings should prove informative as development of TK NAM experimental and computational modeling approaches evolve. *This abstract does not necessarily reflect the views of the US EPA.*

S 1190 Integration of *In Vitro* ADME Parameters and Biokinetics Data in PBPK Modeling and Chemical Risk Assessment

B. Islam. Certara UK Limited, Sheffield, United Kingdom.

One of the steps in chemical risk assessment is converting toxic concentrations into an external dose using physiologically-based kinetic (PBK) modelling. Developing a PBK model requires information on the absorption, distribution, metabolism and excretion (ADME) properties of the compound, which can be obtained through various *in silico* and *in vitro* methods. Within the European Union Horizon2020 project Riskhunt3R, state-of-the-art methods have been used to characterize ADME parameters of the compounds and incorporate them in a tiered assessment framework. These include intestinal absorption and metabolism assessment. The influence of these parameters on PBK modelling and their implications for chemical risk assessment were systematically evaluated. In addition, biokinetic modelling of the compounds in *in vitro* systems was performed to account for losses due to binding to plastic surfaces, as well as partitioning into air, cells, and media components. Integrating data from *in vitro* assay-derived points of departure, *in vitro* biokinetics, and PBK modelling represents a critical component of *in vitro* to *in vivo* extrapolation and supports more accurate and mechanistic chemical risk assessment.

S 1191 New Frontiers in Reproductive Toxicology: Emerging Contaminants and Novel Mechanisms of Toxicity

A. Veiga-Lopez. University of Illinois at Chicago, Chicago, IL.

Pregnancy represents a uniquely sensitive window in which environmental exposures can exert lasting effects on maternal and fetal health. While certain environmental contaminants are well-studied, many contaminants of emerging concern—such as novel industrial compounds, dietary toxicants, microplastics, and next-generation PFAS—remain data-poor despite widespread human exposure. These emerging contaminants may not exhibit overt toxicity at high doses but can interfere with the development of critical biological systems, leading to adverse reproductive and developmental outcomes. This Symposium brings together a multidisciplinary panel of scientists representing a diversity of career stages and expertise, including exposure science, reproductive toxicology, and molecular epidemiology, to highlight cutting-edge research on emerging contaminants and novel mechanisms of reproductive toxicity in the context of pregnancy. Studies presented will utilize multiple approaches, including longitudinal pregnancy cohorts, *in vivo* animal models, and mechanistic *in vitro* systems, providing translational insight across biological levels and exposure contexts. The session will dive into the methods used to prioritize and identify emerging contaminants, focusing on the innovative tools and screening platforms that are reshaping how we understand these risks. The session will explore how emerging contaminants are identified and prioritized by federal agencies, with a focus on the innovative tools and screening platforms reshaping our understanding of environmental risks. Chemical profiling techniques and high-throughput screening will be highlighted, demonstrating how advanced *in vitro* systems are being used to assess bioactivity and toxicity in new and emerging contaminants. Dietary mycotoxins will also be a focal point, with research detailing their impact on placental barrier integrity and fetal development, integrating both cohort data and mechanistic insights. Next, the session will examine the reproductive risks posed by next-generation PFAS, exploring challenges such as endpoint selection, mixture toxicity, and the long-term effects on fertility and pregnancy outcomes, with an emphasis on sex-specific effects. The growing concern around microplastics will be addressed through their effects on placental function and transport, revealing how exposure to microplastics may alter fetal health outcomes. Finally, research will delve into new mechanisms of toxicity for legacy chemicals including PBDEs, UV stabilizers, and dioxins, exploring how they interfere with key placental signaling pathways, such as the epidermal growth factor, and challenge long-standing assumptions about their relevance to maternal and developmental health. A 20-minute panel discussion will conclude the session, providing a platform for cross-disciplinary exchange on research priorities, regulatory needs, and strategies for protecting maternal-child health in the face of a changing chemical landscape.

S 1192 New Frontiers, Hidden Threats: Introducing Emerging Contaminants in Reproductive Health

A. Paquette. Seattle Children's Research Institute, Seattle, WA.

The session will begin with a brief introduction of how emerging contaminants are identified and prioritized by federal agencies.

S 1193 Leveraging In Vivo, In Vitro, and In Silico Approaches to Accelerate the Discovery of Novel Reproductive Toxicants

P. Allard. University of California Los Angeles, Los Angeles, CA.

The identification of environmental chemicals that impair reproduction is complex due to the intricacies of the reproductive process which spans multiple organ systems and developmental/life stages. Traditional testing methods are not scalable to screen the approximately 350,000 chemicals in use globally, highlighting the need to address the significant public health issue of infertility which affects about 1 in 6 people worldwide. We will describe an integrated strategy combining *in vitro* and *in silico* methods used to assess the reproductive toxicity of 133 physiologically-relevant chemicals. Following a primary high-throughput screen leveraging the tractability of *C. elegans*, we validated the hits by a secondary reproductive assay also in *C. elegans* focused on embryonic viability. In total, 13 chemicals were classified as reproductive toxicants with the top hits being Quaternary Ammonium Compounds (QACs), commonly used as disinfectants but with limited reproductive toxicity data. Further mining of the ToxCast data revealed no significant differences in the bioactivity or in the average potency (AC50) between the top and bottom chemicals. However, chemicals with greater biological activity (higher Z-scores) showed an over-representation of steroid hormone targets, suggesting potential reproductive toxicity mechanisms. The presentation will conclude by emphasizing the need to prioritize the assessment of QACs' impacts on reproduction.

S 1194 Emerging PFAS: Ultra-Short Chain and Polyether Carboxylate Compounds Display Similar Maternal, Fetal, and Neonatal Effects

J. Robinson. University of California San Francisco, San Francisco, CA.

Perfluorooctanoic acid (PFOA), a legacy per- and polyfluoroalkyl substance (PFAS), remains widespread in humans, including pregnant women, despite efforts to phase out its use. The placenta is a suspected target of PFAS toxicity; however, the pathways by which PFAS disrupt placental development and function remain poorly defined. Placental cytotrophoblasts (CTBs) are essential for implantation, uterine invasion, and vascular remodeling, and their dysfunction underlies common pregnancy complications. In culture, primary human villous CTBs differentiate into an invasive phenotype modeling the CTB-to-extravillous trophoblast (EVT) transition. Primary human CTBs were isolated from second-trimester placentas and exposed to sub-cytotoxic concentrations of PFOA (0.1-25µM) for 48h. Proteomic profiling using SWATH-mass spectrometry detected 3,240 proteins, of which 274 were differentially expressed following PFOA exposure. Pathway enrichment analyses revealed overrepresentation of proteins involved in immune defense, lipid metabolism, and amino acid biosynthesis. Integration of proteomic and transcriptomic datasets identified regulatory nodes linking PFOA exposure to altered immune signaling and placental functional pathways. Molecular docking and molecular dynamics simulations predicted direct interactions between PFOA and structurally related PFAS with peroxisome proliferator-activated receptors (PPARA/G) and immune transcriptional regulators (STAT and IRF family members). Benchmark concentration modeling indicated that proteomic alterations occur at concentrations overlapping reported human serum levels and those associated with placental toxicity in animal studies. These findings provide systems-level mechanistic evidence that PFOA perturbs placental metabolic and immune networks through interactions with key transcriptional regulators. Targeting of shared regulatory pathways by PFOA and select PFAS may represent a mechanistic basis for PFAS-induced placental dysfunction.

S 1195 From Popcorn to Placenta: How Mycoestrogens Impact Development

L. Aleksunes. Rutgers, The State University of New Jersey, Piscataway, NJ.

As global temperatures rise and humidity increases, concerns about hidden toxins from fungal contaminants in our diet are also growing. Warm, humid conditions promote the overgrowth of *Fusarium* fungus and the release of mycotoxins, including zearalenone, into a wide range of foodstuffs, including baby formula, grains, cereals, popcorn, pasta, and oatmeal. Structurally similar to 17β-estradiol, zearalenone and its metabolites interact with estrogen receptors and are classified as a 'mycoestrogen.' Mycoestrogens enter and cross the rodent and human placenta, although a fraction undergoes active efflux back to the maternal circulation by the BCRP/ABCG2 transporter. This presentation will cover the latest research regarding how mycoestrogens adversely impact pregnancies and offspring development by targeting the placenta. We have identified the Q141K variant in ABCG2 as an

important determinant of how mycoestrogens reduce fetoplacental ratios and birth weight in healthy pregnancies. Moreover, we will discuss how mycoestrogens disrupt placental steroidogenesis in a sex dependent manner. Mechanistic studies suggest that zearalenone and other mycotoxins alter trophoblast migration and other pathways, yielding novel clues to their potential impact on pregnancy complications such as preeclampsia. As the field advances, it will be essential to identify factors that diminish BCRP-mediated protection to safeguard vulnerable populations at higher risk of perinatal mycoestrogen toxicity.

S 1196 Micro- and Nanoplastic Exposures During Pregnancy: Effects on the Placenta

P. Stapleton. Rutgers, The State University of New Jersey, Piscataway, NJ.

Micro- and nanoplastic particles (MNP) have been identified as a novel and emerging contaminant. Their deposition in human placental tissue has been reliably detected, with temporal increase in the last 20 years. This causes concern for the influence that MNP exposure may have on placental development including trophoblast invasion of the spiral arteries, maternal/fetal surface area, and intraheam distance, ultimately influencing fetal health. Our laboratory has established a whole-body rodent inhalation model, using polyamide (e.g., nylon) MNP to assess exposure throughout pregnancy. Using this model, we have identified that MNP particles migrate from the mother's lung to the placenta, breach the placental barrier, deposit within fetal tissues, and culminate in reduced fetal growth. Morphometric analyses revealed impaired placental development and maturation at gestational day 12, 16, and 20, after exposure to MNP aerosols during pregnancy. These outcomes are evidenced by poor trophoblast invasion and reduced maternal/fetal surface areas limiting nutrient delivery and waste exchange. In this session, we will discuss the placenta as a target organ of concern for maternal MNP exposure. Particle deposition elicits physiologically relevant responses, which directly affect fetal health and the developmental onset of adult disease.

S 1197 The Epidermal Growth Factor Receptor Serves as a Cell Surface Sensor for Environmental Chemicals: Relevance for Reproductive Toxicity?

T. Haarmann-Stemann. IUF—Leibniz Research Institute for Environmental Medicine, Düsseldorf, Germany.

The epidermal growth factor receptor (EGFR) is a transmembrane receptor tyrosine kinase of utmost importance for proper embryonic development and tissue integrity. Humans born with a loss-of-function mutation in the EGFR gene have shortened life expectancy, and EGFR-deficient mice die early after birth due to epithelial immaturity and multiorgan failure. EGFR is activated upon binding of growth factors to its extracellular domain (ECD), resulting in receptor dimerization and activation of kinase activity, which ultimately regulates cellular processes, such as proliferation, differentiation and migration. We and others have shown that several environmental contaminants, including dibenzo-p-dioxins, polychlorinated biphenyls, phenolic benzotriazoles and others, can interfere with the growth factor-triggered activation of EGFR in human cells. Using *in silico* docking analyses, receptor internalization assays, immunoblotting and mutational amino acid exchange experiments, we have observed evidence of direct binding of these chemicals to the EGFR ECD, leading to displacement of bound growth factors and an inhibition of DNA synthesis and other downstream events. Since EGFR and its ligand EGF play a critical role in regulating placental and fetal growth, and epidemiologic studies suggest that exposure to EGFR-interacting chemicals correlate with changes in birth weight or gestational age at delivery, further in-depth investigation of this novel mode of action could help improve risk assessment.

S 1198 Take a Deep Breath ... Hold It! Rising Cardiopulmonary Toxicity and Regulatory Concerns of Nontobacco-Derived Nicotine and CBD Vaping Products

A. Noël. Louisiana State University, Baton Rouge, LA.

The recent emergence of new alternative nontobacco-derived vaping products, including synthetic nicotine, nicotine analogs, and cannabidiol (CBD), raises concerns as their use becomes more widespread, the health risks are largely unknown, and regulations of these substances being either nonexistent or evolving. In the United States, in 2023, more than 17 million adults used vaping products, which is in addition to youth vaping which represents ~1.6 million individuals. Further, within the adolescent population, among current e-cigarette users, 21.3% have previously vaped CBD. In the US, the vaping products market was valued at \$11.2 billion, and in 2024, the estimated market shares for freebase nicotine were 77%, nicotine salt 10%, synthetic nicotine 2.2%, and CBD/hemp 0.04%. While tobacco-derived nicotine vaping may present fewer health risks than smoking, vaping is not without its own potential harms, particularly with prolonged use and with regard to the bioactive molecule (nicotine, synthetic/analog nicotine, CBD) present in the e-liquid. E-cigarette aerosol

toxicity is driven by several factors primarily linked to the chemicals found in the aerosols, and these factors could potentially be subjected to regulation. These key factors include (1) nicotine forms (free base, salt, synthetic, analog) or CBD and their concentrations in the e-liquids, which affects addiction and cardiopulmonary toxicity—nicotine analogs, which are distinct, but have a chemically similar structure to nicotine, may lead to different health risks and potential adverse effects are understudied; (2) flavoring chemicals, including vanillin and benzaldehyde, sweeteners, and solvents, which can cause irritation, oxidative stress, and enhance the cardiopulmonary toxicity of the other components; and (3) heavy metals (e.g., chromium, lead, nickel, iron and copper), which can leach from the heating coils and metallic parts of the devices to the e-liquid and then transfer to the e-cigarette aerosol, which is inhaled into the lungs. These metals can cause both carcinogenic and noncarcinogenic effects. Overall, vaping toxicity is influenced by a combination of factors and chemicals with oxidative potential and can directly damage the cardiopulmonary system through mechanisms involving cytotoxicity, inflammation, and oxidative stress. The regulation of vaping products depends on the substance being vaped and the country or state. In the US, the US FDA regulates nicotine vaping products, including e-cigarettes, as tobacco products, whereas nicotine analogs are not under the purview of the US FDA. This represents a loophole for which no premarket authorization (PMTA) is required. While in the US, there is no limit on nicotine concentration for vaping products, Canada and the UK established a nicotine concentration limit of 20 mg/mL. This diverse landscape of regulation and the already-documented health effects underscore the importance of further research and regulation in the vaping and cannabis space. This Symposium will discuss how specific components of either the e-liquid or the e-cigarette aerosol (e.g., nicotine form, nicotine analogs, metals, CBD) impact cardiopulmonary toxicity and elaborate on why each of these factors is crucial when establishing a regulatory framework for vaping products. The first speaker will discuss pulmonary effects of nicotine chemical forms, analogs and synthetics, in comparison to known benchmarks associated with the impact of freebase nicotine on respiratory health using an *in vivo* model. The second speaker will present on the development of biomarkers of both exposure and cardiovascular harm of new vaping products containing nicotine analogs (6-methyl nicotine). This will be followed by a presentation on the impacts of 6-methyl nicotine, sweeteners and solvents on *in vitro* and *in vivo* toxicity, with a focus on margin of exposures and safety thresholds. The fourth speaker will discuss the presence of metals in e-cigarette aerosols and their blood levels found in e-cigarette users as well as their potential health effects. The last speaker will talk about another bioactive vaping molecule of concern, CBD, with regard to the pulmonary effects in the context of regulatory screening work. Overall, the toxicological research needs for new alternative nontobacco-derived nicotine vaping products requires a consolidated effort regarding standardization of testing methodologies and reporting of outcomes to inform the development of regulatory frameworks to protect public health. This engaging Symposium on a timely matter will highlight research on the cardiopulmonary health impacts of nontobacco-derived nicotine vaping products to help better understand the short- and long-term health effects of those emerging products and initiate a conversation on how these data could be incorporated into a regulatory framework.

S 1199 The Source of Nicotine Matters: Influence of the Source of Nicotine, Tobacco-Derived Versus Nontobacco-Derived, in Electronic Nicotine Delivery System Aerosols on Pulmonary Responses in Mice

A. Noël. Louisiana State University, Baton Rouge, LA.

Nicotine can be found in several chemical forms, including: unprotonated (free base) present in cigarettes and in first- to third-generation electronic nicotine delivery systems (ENDS); protonated (nicotine salt) found in fourth-generation ENDS; and non-tobacco derived nicotine (synthetic), racemic mixtures of S- and R-nicotine enantiomers or up to 99% 'purified' S-nicotine. Despite their identical physicochemical characteristics, each nicotine enantiomer has distinct toxicokinetic and toxicodynamic profiles, which may result in different biological responses. Thus, the advent of new ENDS products using both S- and R-nicotine raise serious public health concerns, given that little is known about the pulmonary health effects and toxicity of R-nicotine or of the racemic mixture in humans when present in ENDS aerosols alongside heated propylene glycol, glycerin, and flavoring chemicals. We used a well-characterized mouse model of inhalation exposures to establish the difference in pulmonary toxicity between ENDS aerosol containing either tobacco-derived free base nicotine or non-tobacco-derived synthetic nicotine. In male mice, following 4 weeks of exposure, lung function testing revealed a significant decrease in the minute volume of mice from both groups exposed to nicotine-containing ENDS aerosols compared to air controls suggesting that inhaling nicotine-containing ENDS aerosols alter lung function. At the molecular level, the ENDS aerosol containing free base nicotine dysregulated the expression of genes associated with biotransformation and oxidative stress responses, whereas synthetic nicotine only down-regulated the expression of Nqo1, although to a greater extent than free base nicotine. These results suggest that nicotine from both sources can influence the antioxidant response element signaling pathway, with synthetic nicotine inducing a stronger suppression. While we showed that the inhalation of ENDS aerosols containing either tobacco-derived or non-tobacco derived nicotine induced similar pulmonary responses, in terms of effects on lung function and inflammation, unique respiratory impacts of ENDS aerosols containing synthetic nicotine compared to those contain-

ing tobacco-derived nicotine were noted at the molecular level. Thus, the source of nicotine, in addition to its chemical form, are critical factors impacting molecular lung toxicity.

S 1200 Tracking Biomarkers of Exposure and Biomarkers of Cardiovascular Harm of a Novel Non-nicotine Analog

D. Conklin. University of Louisville, Louisville, KY.

A new synthetic nicotine analog, (S)-6-methylnicotine (2-methyl-5-[(2S)-1-methylpyrrolidin-2-yl]pyridine; 6MN; aka Metatine), is present in an Electronic Nicotine Delivery System (ENDS) called SPREE BAR with the intent to circumvent FDA regulatory authority on nicotine containing products. However, neither 6MN (Metatine) metabolism nor its toxicity has been published. We sought to develop biomarkers of exposure and biomarkers of cardiovascular harm to track both exposure to and potential injury of 6MN exposure. For this, mice were injected with Metatine or inhaled Spree Bar or PG:VG with 6MN, and urine collected over 24h. Two human E-cig users also vaped Spree Bar Blue Razz Ice and urine was collected 2 h post-exposure. Our method identified: 6-methylnicotine and eight metabolites: 6-methylnor-nicotine; 6-methylnorcotinine; 6-methylcotinine; 6-methylnicotine-1'-N-oxide; 6-methyl-3'-hydroxycotinine; 6-methylcotinine-N-oxide; 6-methylnicotine-N-glucuronide; and 6-methylcotinine-N-glucuronide. To evaluate the metabolic fate of MNIC following inhalation exposure, we measured urinary levels of MNIC-derived metabolites in mice exposed to aerosols either of PG:VG+6MN or of Spree Bar with 6MN and normalized LC-MS responses to creatinine for each metabolite. All nine metabolites were detected at elevated levels shortly after exposure (0-3h), with several remaining elevated at the later time point (3-21h). At the early time point, Spree Bar exposure resulted in nearly twice the metabolite levels observed in the PG:VG+6MN group, reaching concentrations comparable to those seen following the high dose injection. These results show that systemic exposure to 6MN via either injection or inhalation led to indistinguishable metabolism of 6MN. This supports that 6MN urinary metabolites are likely highly robust and useful biomarkers of real-world exposures to 6MN regardless of product consumed (e.g., oral or inhaled). Direct exposure to Spree Bar e-liquid significantly impaired aortic contraction and relaxation – an effect not replicated by 6MN, S-nicotine, not PG:VG suggesting another component of Spree Bar is highly toxic. Overall, we provide an analytical method useful for detecting biomarkers of 6MN exposure, and evidence that 6MN is toxic at high levels potentially achievable in users of SPREE BAR, which is currently an unregulated non-nicotine product.

S 1201 Behavioral and Toxicological Effects and Health Risk Assessment of 6-Methyl Nicotine, an Emerging Synthetic Nicotine Analog in E-cigarettes and Oral Pouches

S. Jabba. Duke University, Durham, NC. Sponsor: A. Noël

To evade federal and state regulations, manufacturers of electronic cigarettes and oral nicotine pouches recently introduced products in which nicotine is replaced by a chemical analogue, 6-methyl nicotine. Previous preclinical studies demonstrated that 6-methyl nicotine is more toxic than nicotine and binds to nicotinic receptors with higher potency. However, although 6-methyl nicotine products are freely available on the US market for consumption, the chemosensory and toxicological properties of 6-methyl nicotine remain unknown. Data will be presented from mouse behavioral experiments comparing the chemosensory aversive effects of 6-methyl nicotine and nicotine. These studies revealed that 6-methyl nicotine is more potent than nicotine in producing aversive behaviors, with younger adolescent mice showing heightened sensitivity. Choice drinking assays in mice revealed that sweeteners and the electronic cigarette solvent, glycerol, augmented preference and consumption of 6-methyl nicotine, more robustly than for nicotine. These effects were absent in mice deficient in the sweet taste receptor (Tas1r2^{-/-}). Toxicological and metabolic assays in oral mucosal and human airway cells and lung organoids demonstrated that 6-methyl nicotine is more toxic than nicotine. The impact of other product constituents, including flavors, sweeteners and solvent chemicals, on 6-methyl nicotine toxicity was also investigated. Resulting data were used to assess the acute human health risks from use of 6-methyl nicotine containing products, such as potential for convulsions and increase in heart rate. Exposure levels for 6-methyl nicotine from commercial product were several orders higher than the human acute reference dose (ARfD) accepted for heart rate increase and also significantly higher than the calculated safety threshold levels for producing convulsions. Together, 6-methyl nicotine has robust chemosensory effects that corroborate its higher potency compared to nicotine. Other product constituent such as sweeteners facilitate 6-methyl nicotine intake. Consumers using these products are exposed to 6MN levels that may exceed safety thresholds, potentially leading to toxicity and adverse health effects. Nicotine analogues should be urgently addressed by lawmakers and regulators, and FDA should be granted authority to regulate products containing them as tobacco products.

S 1202 Blood Metal Levels Differ by Electronic Cigarette Use Behaviors and Device Characteristics: Findings from the EMIT Study

A. Rule. Johns Hopkins Bloomberg School of Public Health, Baltimore, MD. Sponsor: A. Noël

Introduction: Electronic cigarettes (e-cigs) rapidly evolved from “MOD” devices mostly used by smokers as a risk reduction strategy to “POD” devices with higher nicotine content and marketed to young non-smokers. Metals, such as nickel and chromium, found in e-cig components, have been found in e-cig aerosols. We hypothesized that differences between device type and user behaviors impact metal exposure. **Goal:** Compare metal levels in blood of e-cig users and non-users and by e-cig use behaviors and device type. **Methods:** From 63 participants (18 MOD, 26 POD, and 31 non-users) we collected e-cig aerosol, blood, sociodemographic data, use behaviors, device characteristics. Blood and aerosol metals were analyzed by inductively coupled plasma - mass spectrometry. Chi-squared, ANOVA, and regression analyses were used to assess relationships between variables and groups. **Results:** Chromium (Cr) was higher in POD and MOD users compared to non-users ($p=0.016$). Nickel (Ni) was higher in MOD users compared to other groups ($p=0.003$). Zn was higher in PODs compared to MODs ($p=0.007$). Nicotine percentage was positively associated with Pb ($p=0.011$), and Zn ($p=0.028$). The amount of e-liquid consumed per week was positively associated with Ni (0.007). Using mint/menthol e-juice over fruit/candy flavors was positively associated with blood Zn ($p=0.028$). Earlier time to first vape in the morning was positively associated with Ni ($p=0.01$). The positive interaction between amount of e-juice per week and nicotine percentage was significant for Cd ($p=0.048$), Cr ($p=0.037$), and Sb ($p<0.001$). **Conclusions:** E-cig heating components, differences in power between devices, and different chemistry of flavorings within the e-juice help explain differences in metal exposures. Our results show that device type and behaviors determine exposure to metals and could indicate differential health risks for e-cig users given what we know about chronic, low-dose metal inhalation. This information can help inform potential interventions and public health strategies.

S 1203 Pulmonary Effects of CBD Vaping Products

M. Doyle-Eisele. Lovelace Biomedical, Albuquerque, NM.

Cannabidiol (CBD), a phytocannabinoid of increasing interest for its purported therapeutic effects, is primarily consumed via ingestion and inhalation. While the toxicology of orally administered CBD has been reported, little is known about the effects of CBD inhalation. Doses selected for these analyses allowed for evaluation of dose-response at concentrations >100-fold higher than typical human consumption levels. Rodent and canine inhalation studies, nose-only or face mask, resulted in dose-dependent inflammatory and necrotic responses in the nose. There were no histological findings in the extrapulmonary organs. Exposure-related clinical observations were related to respiratory distress and labored breathing that was recoverable in the large animal studies. Improved formulations, dry powders vs. aqueous solutions, have increased bioavailability of various forms of CBD opening new challenges within the drug development pathway. Complications associated with targeted delivery systems has created additional hurdles within the CBD market due to the physiochemical properties and formulations needed for the various routes of administration.

S 1204 Visionary Foresight: Pioneering Cell-Based Therapies

E. Budzynski. Akkeri, Deforest, WI.

Cell-Based therapies are rapidly transforming the treatment landscape for diseases with high, unmet medical needs, particularly within the realms of ocular disorders and neurodegenerative conditions. This Symposium will explore the nonclinical development, regulatory considerations, and translational challenges associated with bringing advanced cell therapies from bench to bedside. Presentations will highlight the strategic and scientific complexities of developing both autologous and allogeneic products, derived from embryonic stem cells or inducible stem cells. The session will emphasize regulatory expectations for toxicologic evaluations from first-in-human (FIH) to biologics license applications (BLA). Case studies spanning therapies for Parkinson's disease, ocular surface diseases, and geographic atrophy due to age-related macular degeneration (AMD) will provide real-world examples of how toxicology, biodistribution, tumorigenicity, and product characterization shape clinical readiness. The role of contract research organizations (CROs) in navigating preclinical development, as well as collaborative innovations across academia, industry, and regulatory sectors, will be discussed. By focusing on translational strategies and safety evaluations in relevant animal models, this session will equip attendees with a comprehensive view of the current landscape and future directions for cell therapy development in ophthalmology and beyond.

S 1205 Overview of Regulatory Requirements for Ocular and Neurological Cell Therapeutic Developments in Support of FIH and BLA

J. White. Blue Rock, Cambridge, MA. Sponsor: E. Budzynski

Cell therapy is an ever-changing field with innovative approaches that can lead to groundbreaking therapeutics to treat diseases with unmet medical needs. Owing to its rapidly evolving nature, there may be many program-to-program differences that can lead to numerous regulatory questions and ultimately challenges during the drug review process. This session will include an overview of the toxicology requirements for regulatory submissions from investigational new drug (IND) applications to biologics license application (BLA) submissions for stem cell therapy. This presentation will showcase a nonclinical case study highlighting the successful development trajectory of a therapeutic cell therapy product. Using an allogeneic stem cell therapy for the treatment of Parkinson's disease as a case example, we will explore its preclinical efficacy and safety data within the broader context of drug development.

S 1206 Enabling Breakthroughs in Ocular Disease: The Strategic Role of CROs in Cell Therapy Development

S. Kumar. Pharmaron, Carlsbad, CA. Sponsor: E. Budzynski

Cell-based therapies hold transformative potential for treating ocular diseases, offering innovative approaches for conditions that currently lack effective treatments. Their successful development, however, requires comprehensive and rigorous preclinical evaluation to ensure safety, efficacy, and alignment with regulatory expectations. Contract Research Organizations (CROs) play a pivotal role in supporting pharmaceutical and biotechnology sponsors throughout the nonclinical development pipeline. This presentation will highlight the strategic contributions of CROs in designing and executing ocular cell therapy studies that support safety and efficacy assessments—from early-stage planning through Investigational New Drug (IND)-enabling studies. Key focus areas include selecting appropriate and translational animal models, thorough characterization of the cell therapy product, precise surgical delivery techniques tailored for ocular administration, and advanced *in vivo* imaging modalities to monitor biodistribution, therapeutic effects and safety. The importance of adhering to Good Laboratory Practice (GLP) standards will also be discussed, as these are critical for ensuring data integrity, meeting regulatory requirements, and facilitating a smooth transition to first-in-human clinical trials.

S 1207 Toxicology Strategies and Challenges for Developing Subretinal Cell Therapeutics for Geographic Atrophy Treatment

R. Skalter. Cell Cure Neuroscience Ltd., Jerusalem, Israel. Sponsor: E. Budzynski

New treatment approaches are needed to address the retinal damage and vision loss associated with geographic atrophy (GA) secondary to dry age-related macular degeneration (AMD). Development of novel approaches, such as cell therapy, presents both advantages and challenges due to the unique aspects of ocular anatomy and physiology. OpRegen (RG6501), a clinical-stage allogenic pluripotent stem cell line-derived retinal pigment epithelium (RPE) cell therapy, is one example of such an approach. While a single subretinal administration of an RPE cell suspension offers the potential to reverse retinal damage and restore vision in patients with GA, toxicological strategies require chronic studies in relevant animal species to enable clinical transition. A case study of the completed comprehensive safety and toxicology evaluations to enable the first in-human study of OpRegen will be discussed.

S 1208 Developing an Autologous Cell Therapy for Age-Related Macular Degeneration

K. Bharti. National Eye Institute, Bethesda, MD. Sponsor: E. Budzynski

This presentation will provide an overview of a cell replacement autologous patch therapy for treating GA patients currently in clinical development testing. Patient induced pluripotent stem cells (iPSC) are differentiated into pure RPE cells and matured on a biodegradable polylactic co-glycolic acid (PLGA) scaffold. The presentation will cover the nonclinical safety evaluation strategy of the iPSC-RPE patch in a pig model of laser induced RPE ablation to support FIH studies. The Phase I/IIa trial for this work is currently ongoing at the National Eye Institute at NIH to test the safety and feasibility of an autologous iPSC-RPE patch in AMD patients with GA.

S 1209 Bridging Concept to Clinic: Preclinical Considerations for Stem Cell-Based Ocular Surface Repair

T. Ilmarinen. StemSight, Tampere, Finland. Sponsor: E. Budzynski

This session will focus on the nonclinical development of an allogenic iPSC-derived limbal stem cell therapy designed to treat severe ocular surface disorders, such as limbal stem cell deficiency or persistent epithelial defects. The preclinical toxicology strategy and general considerations to support FIH studies will be discussed. Key aspects addressed will include nonclinical strategy to support FIH, including demonstration of proof of concept, biodistribution, and tumorigenic and toxicologic potential in both rodent and large animal models. A key translational challenge was optimizing delivery to maintain cell viability and ensure engraftment across species. The program employed iterative testing *in vitro*, *ex vivo*, and *in vivo* systems, enabling refinement of the delivery method, dosing strategy, and potency assay selection. Iterative testing across *in vitro*, *ex vivo*, and *in vivo* platforms provided critical insights into product performance and safety, which in turn informed the design of FIH clinical trials and guided regulatory strategy.

W 1210 Cardiovascular Toxicity as a Globally Harmonized System Hazard Trait: The Evidence and the Path Forward

I. Rusyn. Texas A&M University, College Station, TX.

While cardiovascular disease is the leading cause of death worldwide and adverse cardiac effects are a top reason for the attrition of pharmaceuticals, the potential cardiovascular risks from environmental pollutants are not yet recognized as a stand-alone hazard trait. There is growing evidence that environmental chemicals pose a significant and often underrecognized threat to cardiovascular health. Both human and animal studies show that many industrial and environmental chemicals, such as heavy metals, solvents, and endocrine disruptors, can adversely affect the heart and blood vessels. These substances may induce oxidative stress, inflammation, and endothelial dysfunction, potentially leading to hypertension, arrhythmias, and heart failure. Despite these risks, current chemical safety assessments often overlook cardiovascular endpoints. This session will first review the evidence used to support the evaluation of the state-of-the-science for recognizing the cardiotoxicity of chemical substances under the OECD Working Party on Hazard Assessment. Next, key characteristics of cardiovascular toxicants and new approach methodologies (NAMs) that can provide experimental evidence for evaluating potential hazards will be presented. Finally, a framework will be discussed for integrating clinical, animal, and NAMs data to support decisions regarding potential cardiovascular toxicity.

W 1211 Evidence in Support of Classifying Cardiotoxicity as a GHS Hazard Trait

C. Tsitsimpikou. General Chemical State Laboratory of Greece, Athens, Greece. Sponsor: I. Rusyn

Human health hazards and related risks from chemicals are well regulated internationally. However, in many regulatory frameworks, cardiotoxicity is not recognized as a stand-alone hazard, nor are there harmonized criteria for classifying substances as cardiotoxic. To substantiate the concern of cardiotoxicity as an emerging hazard, a regulatory roadmap should be adopted. To support the development of this roadmap, an OECD working group was established with the following objectives: to define cardiotoxicity; describe established modes of action at the cellular and tissue levels; assess the ability of existing toxicity test methods to identify cardiotoxic hazards; validate the use of existing animal data by introducing acceptance criteria; and evaluate new regulatory approaches and novel methods (such as NAMs and omics technologies) for identifying cardiotoxicity. This presentation will describe the background evidence linking environmental exposures to cardiovascular health effects and provide an update on the recently endorsed OECD working group progress.

W 1212 Key Characteristics of Cardiovascular Toxicants: An Organizing Principle for Collection and Evaluation of the Hazard Data

M. Smith. University of California Berkeley, Berkeley, CA.

A group of experts representing different areas of mechanistic and regulatory toxicology developed 12 key characteristics (KCs) of cardiovascular toxicants to better identify and assess chemicals that may harm the heart and blood vessels. These KCs were established through expert consensus and organized by effects on the heart, blood vessels, or both. They include impairments in heart rhythm, contractility, vascular function, mitochondrial activity, and hormone signaling, as well as induction of inflammation, oxidative stress, and dyslipidemia. The KCs aim to improve understanding of cardiovascular toxicity and guide more systematic evidence maps from existing data as well as prospective testing of environmental chemicals and pharmaceuticals.

W 1213 From Assay to Dose: Integrating ToxCast Data with IVIVE and PBPK Modeling to Predict Cardiotoxicity of Environmental Chemicals

S. Krishna. Physicians Committee for Responsible Medicine, Durham, NC.

High-throughput screening (HTS) data from ToxC21/ToxCast offers a powerful, human-relevant platform for identifying environmental chemicals with cardiotoxic potential. In this study, we identified 314 HTS assays associated with molecular and cellular events relevant to six cardiovascular failure modes, covering 40 cardio-relevant targets. Using the Toxicological Priority Index (ToxPi) for visualization and ranking, 1,138 chemicals were prioritized for their potential to disrupt cardiovascular function. To enhance translational relevance, bioactive concentrations were converted to human equivalent administered doses (EADs) using *in vitro* to *in vivo* extrapolation (IVIVE) combined with physiologically based pharmacokinetic (PBPK) modeling. These EADs were compared against exposure predictions and *in vivo* points of departure from toxicological studies to refine hazard characterization. The integration of IVIVE and PBPK modeling revealed chemical classes—such as organotin, bisphenols, flame retardants, and pesticides—likely to induce cardiotoxic effects at human-relevant exposure levels. This multiscale approach supports the use of NAMs in cardiovascular risk assessment and identifies priority chemicals for further investigation.

W 1214 iPSC-Derived Cardiomyocytes and Endothelial Cells as Robust NAMs for Studies of Chemical Effects on Cardiovascular System

I. Rusyn. Texas A&M University, College Station, TX.

Human-induced pluripotent stem cell (iPSC)-derived organ-specific cells have rapidly become a key tool in biomedical research and preclinical safety testing. With respect to cardiovascular system both cardiomyocytes and endothelial cells are available from human iPSCs and have been used widely in studies with drugs and environmental chemicals. This presentation will highlight their use in assessing cardiovascular toxicity hazards, characterizing risk, and modeling population variability. These cell-based models improve the accuracy and efficiency of identifying cardiovascular toxicity from drugs and environmental chemicals. While promising, challenges remain, such as improving cell maturation and expanding their application to structural cardiotoxicity and effects on contractility, as well as broader risk assessment.

W 1215 Translating Pharmaceutical Cardiovascular Safety Frameworks to Environmental Hazard Assessment: Opportunities and Challenges

J. Valentin. UCB Biopharma SRL, Brussels, Belgium.

Pharmaceutical development has long invested in structured frameworks to identify, characterize, and mitigate cardiovascular (CV) safety risks across the product lifecycle. These efforts integrate mechanistic understanding, translational models, and evolving regulatory expectations to reduce attrition and protect patients. As environmental exposures increasingly emerge as contributors to cardiovascular disease, lessons from pharmaceutical CV safety can inform environmental hazard identification and risk assessment. This presentation will explore how principles such as weight-of-evidence integration, safety margin estimation, use of human-relevant biomarkers, and tiered testing strategies can be adapted to the environmental context. Particular attention will be given to challenges in modeling combinatorial exposures, translating findings from alternative methods (NAMs), and ensuring relevance to human disease pathogenesis. Bridging these domains offers a unique opportunity to advance cardiovascular risk assessment across sectors, enhance public health protection, and reduce reliance on animal testing.

R 1216 Does Toxicology Need a Reformation? A Debate About Scientific Integrity

C. Borgert. Applied Pharmacology and Toxicology Inc., Gainesville, FL.

Much has been written about scientific revolutions, but periodically, fields of human inquiry may need to ask whether reformation is more appropriate than revolution. Reformation implies a reaffirmation of the fundamental principles that have allowed the field to advance and to ask whether a field is losing integrity in its quest for novel ideas, fresh theories, and surprising discoveries. A few practitioners of toxicology and related fields have asked questions regarding the erosion of scientific integrity for more than a decade, but these warnings went largely unnoticed or were ridiculed. Recently, however, words such as “crisis” and “failure” have been used to describe the status of the life sciences, again begging the question whether toxicology needs a broad reformation toward fundamental scientific principles. For the past decade, the Society of Environmental Toxicology and Chemistry (SETAC) has attempted to address this void in annual sessions on issues of scientific integrity (SI). Those sessions have been highly attended and well supported by scientists with diverse and often countervailing viewpoints. In 2022, the SOT Ethical, Legal,

Forensic and Societal Issues (ELFSI) Specialty Section and the SOT Regulatory and Safety Evaluation Specialty Section (RSESS) partnered with the Institute for the Advancement of Food and Nutrition Sciences (IAFNS) to sponsor a series of three online webinars on SI issues, all of which were well-attended. This session on SI partners with and builds upon the SETAC sessions. The session will consist of three brief talks to outline the topic and provide context and will be followed by a substantive panel discussion that encourages audience participation in the form of questions, comments, and debate about whether toxicology needs a reformation. The session will begin with a general talk on what constitutes SI and why it is essential for toxicology if toxicology is to continue to advance as a discipline and provide benefit to society. Examples of the ill-consequences of science that lacked integrity will serve to illustrate the issue and importance to public and environmental health. The second talk will argue that toxicology needs a reformation, as evidenced by the broad range of topics that have been covered and debated during annual SETAC sessions. An organizer of those sessions will provide a collective perspective, including an example of how toxicology has lost public trust and how failing to address the erosion of SI in toxicology may negatively affect SOT as well as SETAC. A final talk will provide the opposite perspective and will argue that toxicology is a field that has maintained high integrity and should serve as an exemplar to other scientific specialties that contribute expertise in the arena of public and environmental health protection. The final talk will offer suggestions on how to best communicate the high integrity of toxicology and toxicologists to the public. The debate framed by these talks will kick-start an interactive panel discussion with audience participation.

IS 1217 **Guardians of Public Health: The State We Are In**

D. McCant. Texas Commission on Environmental Quality, Austin, TX.

State toxicologists play a vital role in applying scientific evidence to protect public health and the environment, especially since each state has a unique set of priorities and challenges. Given the current uncertainties related to federal regulatory agency organization and priorities, the work of state agencies is even more important for identifying solutions and developing state-of-the-science assessments protective of human and environmental health. This session will focus on the unique role of state toxicologists and how they apply toxicological principles, the risk assessment framework, and risk communication to help inform practical decision-making and guide state-specific services, policy, and regulatory actions. Speakers from several states with a range of perspectives will discuss their state's approach to current toxicological and risk assessment issues. Each speaker will discuss tips and lessons learned on communicating risks and health information to the public in their states. One common goal among the different states is to build trust and empower communities. The session will examine strategies employed to effectively communicate complex toxicological concepts and risk information to varied stakeholders—ranging from the general public and community groups to industry representatives and policymakers. The session will conclude with a panel discussion with invited guests from private industry, a federal agency, and selected presenters to engage in a dialogue around a set of preapproved questions and relevant issues currently shaping the field. They will share their insights on toxicology at the state level and their experiences with state regulations and recommendations.

EC 1218 **Earning Trust and Driving Impact: Lessons in Communicating Risk to Diverse Audiences Amid Widespread Science Skepticism**

C. McLoughlin. Enhesa, Schuyler, VA.

Growing public distrust in science has been fueled in large part by the rapid spread of information without corresponding access to the expertise needed for critical interpretation. As a result, confusion—and often concern—about the safety of everyday products and the environment has taken hold, despite robust research and regulatory efforts. Meanwhile, misleading buzzwords like “chemical-free” have taken root, with marketing increasingly shaping public perception in ways that sideline scientific understanding. At the same time, the broader value of research and scientific expertise has come under growing scrutiny. This makes the need for effective science communication more urgent than ever. Scientists and advocates must adopt creative, audience-centered approaches to build trust and cut through the noise. That means not just simplifying complex topics but also demonstrating their relevance to people's everyday lives. Tools like engaging storytelling, relatable examples, visual content, and the use of diverse media platforms can help make science more accessible and compelling. In this climate of skepticism, researchers and communicators must hone strategies for meaningful public engagement. By fostering deeper understanding and addressing common misconceptions, they play a critical role in connecting scientific insight with public awareness. The session will open with practical guidance on tailoring scientific messages to different audiences, from students to the general public. The speaker will highlight the importance of understanding audience needs, reducing jargon, and adjusting complexity to improve clarity and engagement. The second speaker will share their approach to making toxicology relatable, highlighting strategies for connecting with regulatory and policy relevant audiences. The third speaker will highlight best practices and opportunities for engaging with policymakers and contributing to informed regulatory discussions. The final speaker will reflect on how external experts most effectively assisted in decision-making, offering an inside view into successful scientist-regulator commu-

nication. Following the individual presentations, a panel discussion will bring the speakers together to compare perspectives, explore common challenges, and answer questions from attendees. This session aims to equip participants with practical insights and tools for clear, impactful communication. Drawing on the expertise of our panelists, attendees will explore a range of strategies to counter misinformation and promote science-based policies. Real-World examples and interactive discussions will reinforce the importance of clarity, relevance, and trust in public outreach. Together, these perspectives will provide attendees with a strong toolkit for engaging nonscientific audiences, contributing to policy conversations, and advocating for the value of research. Whether you're speaking to your local community, preparing for a US Capitol Hill visit, or responding to a public comment period, this session will help sharpen your message and maximize your impact.

S 1219 **Human Health Risk Assessments of Biopesticides: Evaluating Safety for Agricultural Use**

L. Zorrilla. Bayer Crop Science, Chesterfield, MO.

Global interest in biological-based products for agriculture is growing rapidly, including products based on micro-organisms. This is an expanding market globally worth \$12 billion with a 15% compound annual growth rate, and conservative estimates put this market worth \$27 billion by 2027. As such, regulatory agencies all over the world are now reviewing data packages for microbial-based pesticides. However, there are no globally harmonized guidelines for human safety assessments, and in some countries, no regulatory paradigm exists to evaluate potential hazard and risk from these types of products. While regulatory frameworks exist for evaluation of synthetic pesticides, the frameworks are not fit-for-purpose to use for microbials, and even less so for genetically modified micro-organisms. Human safety assessments for biopesticides should be focused on specific strategies suited to the unique characteristics of the test material and not on using irrelevant testing strategies validated for small molecules or proteins. Some of the areas to be considered to address areas of potential human safety concern for microbial biopesticides are: (1) is the natural substance a potential human pathogen or capable of causing infection; (2) does the natural substance have toxic or genotoxic properties; (3) does the natural substance have the capability to produce clinically relevant antibiotics or contain clinically relevant antibiotic resistance markers; and (4) what additional safety information is critical for modified micro-organisms, or is that scientifically irrelevant? In addition, considering all the validation efforts for new approach methodologies (NAMs) for chemicals, could those be tailored to suit microbials, which could potentially support eliminating animal testing requirements? Critical to these efforts is global harmonization of testing strategies to reduce the number of *in vivo* tests to accurately predict potential human risk for these types of products. This session will provide a short background on microbes and their recent uses in agriculture, perspectives on human health testing strategies and challenges from industry and regulators, updates from the Organisation for Economic Co-operation and Development (OECD) Expert Group on Biopesticides (EGBP), challenges with developing NAMs and some ongoing efforts to validate micro-organisms, and considerations for testing strategies for modified micro-organisms. The attendees should come away with a basic understanding of the current human health risk assessments for micro-organisms, updates on challenges from the regulatory and industry perspectives, and the state-of-the-science updates on ongoing projects, including the OECD working groups where all stakeholders are working to modernize and align the best scientific practices for regulatory purposes.

S 1220 **Setting the Stage for the Current Status of Human Health Risk Assessments for Biopesticides**

L. Zorrilla. Bayer Crop Science, Chesterfield, MO.

Requirements to register microbial pesticides in the United States were first established by the Environmental Protection Agency (EPA) in 1983, revised in 1996, and since then, have become the basis and only guidelines for the hazard identification and risk assessment of microbial pesticides globally. The EPA's Office of Prevention, Pesticides, and Toxic Substances (OPPTS) 885 series of guideline studies evaluates whether a microbe can cause infection, disease, or toxicity through various routes of administration. In addition, standard acute “6-pack” studies, which are required for registration of conventional pesticides, are also required for biopesticide formulations. These studies aid in categorizing hazard potential for label safety details and assure safe use of the product. Since the EPA guidelines were issued, many advances in new approach methodologies (NAMs) have been developed to reduce the need for animal testing. However, biopesticides have not been included in these validation efforts, and no updates based on the current state of the science have been made to date. This introduction will provide a short history and outlines the opportunities for fit-for purpose human health risk assessments for biopesticides.

C. Pestana. Federal University of Paraná, São Paulo, Brazil.

Microbial pesticides are generally regarded as less toxic alternatives to synthetic pesticides. However, like their chemical counterparts, microbial pesticides are subject to regulatory approval before marketing. In addition to the focus on the toxicity of traditional plant protection products, microbial pesticides should also be assessed for infectivity, pathogenicity, and the effects of potential metabolites. Therefore, toxicological endpoints should be adapted and harmonized to achieve adequate confidence levels, particularly in the context of reducing or eliminating animal testing. Whilst New Approach Methodologies (NAMs) may hold significant promise for assessing microbial toxicity, several limitations remain. The potential value of NAMs in overcoming such challenges in assessing the sensitization hazard of microbial pesticides has been discussed to inform proposals for NAM-based strategies. A deeper understanding of the sensitization processes could pave the way for the development of NAMs, thereby improving the assessment of microbial pesticides, one of the most challenging toxicological endpoints in this field. Among NAMs, *in silico* methodologies could be particularly valuable for screening and for guiding further investigations into the hazard potential of secondary metabolites. Case studies illustrating the challenges and opportunities of *in silico* assessment of low and high-molecular-weight secondary metabolites, with a particular focus on cyanobacterial metabolites, are discussed. While traditional *in silico* tools are suggested to be useful for screening, prioritization, and elucidating potential mechanisms of action of genotoxicity and carcinogenicity of small molecules, they are less effective for larger macromolecules, which may fall outside the applicability domain of many models and lack reliable physicochemical descriptors. To address these limitations, multiple *in silico* tools covering diverse toxicological endpoints were integrated into a weight-of-evidence (WoE) approach, combined with read-across approaches and NAM existing mechanistic data to evaluate tumor promotion effects of microcystins (cyanobacterial metabolites). By explicitly accounting for uncertainties in the outcomes, this integrated approach is proposed as a viable alternative for assessing large and complex molecules.

S 1222a **The EU Regulatory Framework on Pesticides: An Introduction to the New Endocrine-Disrupting Hazard and the Registration Challenges**

M. Sachana. OECD, Paris, France. Sponsor: L. Zorrilla (L. Zorrilla in italics)

Microbial pesticides are part of the most scientifically and regulatory challenging categories of biopesticides, yet they are considered valuable alternatives to conventional pesticides. Their application is increasingly encouraged within integrated pest management approaches or in isolation, and they are recognised as one of the important pillars of sustainable agriculture. Under the auspices of OECD, the Expert Group on BioPesticides (EGBP) has, since 1999, coordinated international efforts to advance and facilitate the registration of microbial pesticides by supporting governments and industry with guidance documents and test methods and by harmonising and modernising testing and risk assessment approaches across countries. This presentation will outline past outputs and current activities under the EGBP that address human health considerations in the risk assessment of microbial pesticides. These include published guidance, for example, on microbial contaminants and anti-microbial resistance, and consensus documents on microorganisms strains. The audience will also be informed about ongoing work to develop an internationally recognised OECD Test Guideline that covers toxicity, pathogenicity and infectivity for testing microbial pesticides, using as a base an existing USEPA test and an applicable risk assessment framework for microbial pesticides that applies problem formulation and pathways for human health-related protection goals and hazards. Findings from a recent international survey will be presented to shed light on challenges and solutions captured with the aim to inform existing projects and shape future EGBP activities. Survey results highlight challenges and potential solutions to improve *in vivo* exposure scenarios and interpretation of microbial clearance findings and data. Respondents expressed interest in applying weight of evidence approaches to risk assessment that integrate whole genome sequencing data, bioinformatics, existing scientific literature and alternative methods. In this respect, preliminary work explored the application of new approach methodologies (NAMs), such as *in vitro* OECD Test Guidelines. A new project is expected to start under the EGBP to develop guidance and adapt these NAMs that could potentially replace the standard acute "6-pack" studies, starting with *in vitro* eye irritation test methods and expanding to other endpoints such as skin and respiratory sensitization. Ultimately, the presentation will highlight the coordinated efforts under the OECD to reduce redundancy of testing and accelerate the availability of innovative biological pest control solutions in the market by promoting scientific and regulatory exchange, developing guidance and introducing tools to improve and increase efficiency and harmonization in regulatory decision making, while protecting human health.

S 1223 **Challenges with Developing NAMs for Microbes**

P. Marx-Stoelting, and K. Wend. Bundesinstitut für Risikobewertung (BfR), Berlin, Germany. Sponsor: L. Zorrilla

The current guidelines for testing microbial pesticides face several challenges, primarily because these products consist of living microorganisms, which require different consideration from chemical pesticides. Guidelines for chemical pesticides focus on toxicity, but microbial pesticides also assess infectivity, pathogenicity, and the effects of potential metabolites. Unfortunately, microbial research to identify these effects is lacking, which makes safety assessments complex. One issue is defining "clearance" in microbial toxicity studies. The clearance of microorganisms from the body or tissues is often undefined, leading to uncertainties in interpreting the results. Moreover, spore-forming microbes, which have slow clearance rates, add complexity. The current test methods also struggle with the variability in microbial growth under different conditions. For example, temperature thresholds that could potentially exclude infectivity studies are not well-established, making it hard to apply a standardized approach. Additionally, many test guidelines lack clear instructions on the use of positive or negative controls. Without guidance, interpretation of results can be delayed or compromised, hindering the registration of microbial pesticides. Another challenge is related to microbial dose concentrations. When Colony-Forming Units (CFU) concentrations in tests exceed those in actual formulations, adverse effects may be misinterpreted as pathogenic, making hazard assessments difficult. Additionally, discrepancies in physical properties of microbial test materials can complicate the accurate preparation of test substances. Regulatory submissions in the EU and US demand Good Laboratory Practice (GLP)-compliant studies, but early development studies may be non-GLP, raising questions about their reliability. There is also increasing interest in non-animal methods (NAMs) for microbial pesticide testing, and integrating these methods could address some challenges in safety assessments. The development of NAMs and the use of technologies like whole-genome sequencing could identify microbial hazards without relying on animals, thus advancing microbial pesticide regulation globally. Ultimately, harmonizing testing methods and leveraging new technologies is crucial for ensuring the safe use of microbial pesticides while adhering to modern regulatory standards.

S 1224 **The Ever-Evolving World of Microbes: The Current State of Microbial Taxonomy, Genome Evolutionary Dynamics, and the Impact on Future Microbials Risk Assessment**

K. Karberg. Bayer Crop Science, Chesterfield, MO. Sponsor: L. Zorrilla

Risk assessment frameworks for plant agricultural biotechnology products have been in place for decades, focused on the evaluation of living biotechnology products created through genetic engineering. These products contain genetic material from outside the breeder's gene pool, which is often from different taxa or represents "novel combinations of genetic material". These products are typically considered to be "genetically modified" (GM) organisms in regulatory jurisdictions. However, in the microbial world, particularly among Bacteria and Archaea, the rapid expansion of genome sequence databases shows that natural microbial innovation primarily occurs through the natural exchange of genetic material from various sources, even from different taxa. This means that many microbes can be considered naturally occurring GM organisms. This raises the question of whether labeling a microbe as GM is always scientifically relevant for risk assessment. In most regulatory frameworks, being classified as GM significantly impacts the registration path, especially for microbes intended for environmental release. A more effective and science-based regulatory approach would assess the actual functions of a microbe rather than relying on the uncertain classification of its genetic material. This would benefit regulators, developers, and society by promoting the use of microbial technologies for agricultural use. The current state of microbial taxonomy, knowledge on genome evolutionary dynamics, and the relevance of this knowledge to regulation of agricultural biologicals intended for environmental release will be presented.

S 1225 **Advancing Skin and Respiratory Sensitization NAMs for Microbial-Based Pesticides**

A. Forreryd. SenzaGen AB, Lund, Sweden.

Microbial-based pesticides are a type of biopesticide that utilize living microorganisms, such as bacteria, fungi, viruses, or protozoa, to control agricultural pests. These agents act through mechanisms like infection, parasitism, or toxin production, offering high target specificity and minimum ecological disruption. They are increasingly adopted as sustainable alternatives to conventional chemical pesticides in integrated pest management. However, the human health risk assessment of microbial pesticides presents challenges and current safety evaluations lack globally harmonized guidelines. Allergenicity is one of the key health risk concerns, particularly in occupational settings when microbial spores or components may be inhaled or come into contact with the skin of workers. This presentation will introduce the GARD® technology, a genomics and machine learning-based New Approach Methodology (NAM) and explore its potential to support the human health risk assessment of microbial-based pesticides for the endpoints skin and respiratory sensitization.

GARD@skin, included in OECD Test Guideline 442E for skin sensitization testing, has demonstrated broad applicability across diverse chemical groups and can currently be tested with microbial pesticides. GARD@air, the first commercially available *in vitro* assay for respiratory sensitization, provides a novel solution for identifying and ruling out potential respiratory sensitizers in candidate substances, supporting safer product development and occupational health risk management. Recent scientific data from research and industrial collaborations showcase how GARD@skin and GARD@air address current challenges in skin and respiratory assessment, including: (1) Testing of “difficult-to-test” samples; (2) Skin sensitization potency assessment, including UN GHS/CLP subclassification and the prediction of safe dose levels or Point of Departure for Quantitative Risk Assessments; and (3) Respiratory sensitization assessment of chemicals and proteins. This presentation will explore the potential applicability of GARD@skin and GARD@air to microbial-based pesticides, addressing current knowledge gaps and future directions in non-animal safety testing for this emerging class of products.

S 1226 Mechanism of Metal Neurotoxicity in the Era of ‘Omics

A. Bowman. Purdue University, West Lafayette, IN.

Metals such as lead (Pb), iron (Fe), manganese (Mn), mercury (Hg), arsenic (As), and cadmium (Cd) have long been recognized for their toxicity in humans, with significant implications for neurological health. Exposure to these metals, whether through environmental sources, occupational hazards, or contaminated food and water, has been linked to various neurodegenerative and cognitive disorders, including Alzheimer's disease, Parkinson's disease, and developmental impairments in children. Heavy metals exert their neurotoxic effects through multiple mechanisms. They can disrupt neuronal function by generating oxidative stress, impairing mitochondrial activity, and inducing neuroinflammation. Metal ions interact with cellular structures, leading to alterations in enzyme activities, protein misfolding, and disruption of calcium signaling. Furthermore, these metals can interfere with neurotransmitter systems, which play a critical role in brain function and behavior. Despite advancements, there are still many uncertainties surrounding the mechanisms of neurotoxicity induced by these metals. Additionally, the interplay between genetic susceptibility and environmental factors complicates the identification of at-risk populations. Continued research into metal neurotoxicity is essential for developing preventive strategies, improving diagnostic methods, and informing public health policies to mitigate these risks and safeguard neurological health. This session will focus on the latest advancements in understanding the mechanisms of metal neurotoxicity, particularly through the lens of ‘omics technologies, such as epitranscriptomics, proteomics, metabolomics, multi-omics, and single-cell transcriptomics. With the growing prevalence of metal exposure and its associated neurotoxic effects, there is an urgent need to explore the molecular pathways and biological systems that are disrupted by metals. ‘Omics approaches offer a powerful tool set for uncovering these mechanisms and providing new insights into the cellular and molecular basis of neurotoxicity, enabling the development of novel diagnostic biomarkers and therapeutic strategies. Key objectives of the session are (1) to explore how ‘omics technologies are providing deeper insights into the molecular pathways of metal-induced neurotoxicity; (2) to discuss the mechanistic understanding of metal toxicity in the context of gene-environment interactions, epitranscriptomics, and their influence on neurodevelopmental and neurodegenerative diseases; (3) to evaluate the role of specific molecular networks, including oxidative stress, neuroinflammation, and mitochondrial dysfunction, in the pathophysiology of metal neurotoxicity; and (4) to assess the potential of ‘omics-derived biomarkers for early detection of metal exposure and neurotoxicity and their application in public health initiatives. This session is designed for researchers, clinicians, and public health professionals with an interest in toxicology, neurology, environmental health, and ‘omics technologies. It will also be of value to those focused on disease mechanisms, biomarker discovery, and novel therapeutic approaches. Participants will gain a deeper understanding of the molecular and cellular mechanisms underlying metal neurotoxicity, enhanced by the application of ‘omics technologies. By bringing together leading diverse experts in the field, the session will foster collaboration and stimulate future research aimed at mitigating the effects of metal exposure on neurological health. Additionally, it will highlight the potential for personalized medicine approaches in managing metal-induced neurological disorders.

S 1227 Multi-omics Tool Development for Exposure Signature Discovery and Regulatory Pathways Leading to Adverse Outcomes

R. Spurbeck. Battelle, Columbus, OH. Sponsor: S. Sarkar

The epigenome is a complex system of regulatory mechanisms which respond to exposures such as diet, chemicals, infections, stress, and other environment factors causing changes to the person's biology that can impact their health. The epigenome includes DNA methylation, histone modifications, chromatin accessibility, regulatory RNAs and transcription. Through study of integrated epigenetic signatures encompassing the whole epigenome, we can determine affected biological systems in response to different occupational and environmental exposures and develop diagnostic assays to identify individuals who have been impacted by these exposures. Furthermore, as some epigenetic modifications can be reversed, epigenetic signatures identified could become targets for therapeutics to treat harmful effects of

exposure. Here, the development of two tools for better understanding toxic exposures and regulatory pathways which lead to adverse outcomes will be described. First, the Epigenetic Signature Discovery Algorithm (ESDA), a computational model to identify diagnostic exposure signatures will be discussed. Second, we will describe the use of a platform which combines a microphysiological system with single-cell RNAseq and ATACseq, methylation, and hydroxymethylation sequencing. These tools combine into an end-to-end system to discover human exposure signatures and adverse outcome regulatory pathways which can enable therapeutic and diagnostic development.

S 1228 Multi-omics Identify Novel Molecular Networks in Metal-Induced Epitranscriptomic Dysregulation Underlying Chronic Neuroinflammation

A. Kanthasamy. University of Georgia, Athens, GA.

Astrocytes and microglia respond dynamically to environmental neurotoxic chemicals to protect and support neuronal health. When exposed to neurotoxins, glial cells undergo changes in their morphology and function, becoming reactive glia. While this reactive response aims to limit damage and maintain homeostasis, chronic activation of astrocytes and microglia leads to uncontrolled inflammatory responses and contributes to various neurodegenerative conditions. Nevertheless, the precise molecular networks that regulate the pro-inflammatory state of these guardian cells under chronic neurotoxic conditions remain enigmatic. Emerging epitranscriptomic research reveals that N6-methyladenosine (m6A), the most abundant RNA modification in eukaryotic cells, plays a crucial role in regulating pro-inflammatory mediators including cytokine and chemokine production. However, how these m6A mRNA modifications regulate glia-driven chronic neuroinflammation in metal neurotoxicity is completely unknown. This presentation will highlight the power and versatility of multiple multi-omic approaches such as RIP-seq and m6A-seq in identifying epitranscriptomic networks associated with chronic neuroinflammation during neurotoxicant exposures in glial cells. Specifically, our studies reveal manganese exposure selectively downregulates the m6A reader protein YTHDF2 to activate the SEK1-JNK-CJun signaling network, which serves as a molecular switch to sustain a proinflammatory state in astroglia. Results from our other studies highlight how manganese can upregulate and mislocalize the m6A mRNA reader protein METTL3 in microglia to induce a neuroinflammatory response. Collectively, multi-omic technologies are integral to deciphering cell- and stimulus-specific molecular events underlying chronic neuroinflammation associated with environmentally linked neurodegenerative diseases such as Parkinson's and Alzheimer's diseases. *Supported by NIH grant ES R0103624.*

S 1229 Single-Cell RNA-Sequencing Enables Sensitive Detection of a Persistent Neurotoxic State

A. Bowman. Purdue University, West Lafayette, IN.

Methylmercury (MeHg) is a neurotoxin that indiscriminately disrupts multiple homeostatic pathways. Its neurotoxic outcomes include latent effects that persist long after exposure has subsided. We report on experiments to test the hypothesis that persistent effects of MeHg are self-perpetuating via interdependent relationships of key biological pathways that sustain and regulate neurological function. We developed a human induced pluripotent stem cell (hiPSC) model of differentiating cortical glutamatergic (GLUergic) neurons to assess persistent MeHg-induced neurotoxicity. Cultures were exposed continuously for ~6 or ~12 days during developmental stages to *in vivo* relevant MeHg concentrations (0.1 and 1 μ M). Following exposure, cortical GLU neuronal differentiation was continued till cultures reached mature stages. At day 40, 150 and 280 of differentiation cells were assessed for persistent effects using single cell RNA sequencing (scRNAseq). MeHg exposure during development resulted in a robust pattern of differentially expressed genes that play key roles in functional and biological pathways indicating a persistent toxic effect. Persistently impacted pathways include signaling pathways required for healthy aging, neurotransmission and metabolic/energetic homeostasis; and functional correlates of these changes have been observed. We will present ongoing studies aimed at identifying the basis of these persistent changes long-after exposure has ceased and MeHg is absent from the model system. Our data demonstrate that scRNAseq can detect persistent effects of developmental exposures to MeHg, that these effects can be reproduced by proteomic approaches, and that persistence manifests as an altered -omic and functional state that differs across distinct cell identities in hiPSC-derived cortical cultures. *Supported by NIH R01 ES007331.*

S 1230 Using New Approach Methods and Multi-omics to Study Metal Toxicity Mechanistically

S. Sarkar. University of Rochester Medical Center, Rochester, NY.

Epidemiological studies have implicated the critical role of environmental factors in driving neurodegeneration in various diseases like Parkinson's (PD), Alzheimer's disease (AD), and others. Manganese (Mn) overexposure has been linked to the development of a neurodegenerative disorder similar to PD called Manganism. Further, Mn has also been shown to induce aggregation of α -synuclein, a PARK gene, demonstrating the potential role of Mn exposure in sporadic PD. We took a bottom-up approach and performed untargeted high-resolution mass spectrometry proteomics and metabolomics on the brains of flies exposed to Mn. Pathway enrichment analysis on the multi-omics dataset identified peroxisomes as a key altered pathway in Mn toxicity. Peroxisomal markers were downregulated *in vivo* and *in vitro*, further confirming the importance of this organelle in Mn-toxicity. We identified peroxisomal biogenesis and contact peroxisomal transport as key regulators using a fly model. We further used a pharmacological drug to enhance peroxisomal biogenesis and demonstrated that the drug was able to rescue Mn-induced toxicity in patient-derived iPSC-derived midbrain culture. The peroxisomal biogenesis drug also improved mitochondrial health, suggesting a crosstalk between peroxisomes and mitochondria. High-resolution live cell microscopy revealed that Mn reduced the physical contact between peroxisome and mitochondria by downregulating the tethering protein Mitofusin (Mfn). Finally, the lipidomic analysis identified carnitines, a key lipid involved in the peroxisomal transport of lipids, to be upregulated in Mn-exposed flies. Previous studies in human patients suggested that stearate treatment can reduce acylcarnitine levels. In humans and flies, the stearate level can be regulated by Elovl7, a fatty acid elongase. Interestingly, Elovl7 is also a PD risk factor. Our preliminary data further suggested that increasing stearate through diet or genetically by regulating Elovl7 reduced Mn-induced toxicity and mitochondrial dysfunction. In summary, we demonstrated that the Peroxisomal biogenesis and reduced membrane contact sites between the peroxisome and mitochondria (PerMit) regulated Mn-induced neurotoxicity.

S 1231 Leveraging High-Resolution Mass Spectrometry to Decipher Molecular Mechanisms of Metal-Induced Toxicity

Y. Lai. Columbia University, New York, NY.

Metal exposure remains a significant public health concern, with both essential and non-essential heavy metals and/or metalloids contributing to a range of toxicological outcomes across organ systems. While the mechanistic understanding of metal-induced toxicity has advanced, the complexity of downstream biochemical alterations remains poorly characterized, requiring more sophisticated analytical assays and/or approaches that confer high sensitivity, coverage, and precision. High-resolution mass spectrometry (HRMS) has emerged as a transformative tool in toxicology, enabling the untargeted detection and *de novo* structural annotation of hundreds of thousands of endogenous and exogenous molecules within biological matrices. This study/proposal highlights the development and application of HRMS-based approaches in elucidating the molecular fingerprints associated with metal exposure, particularly heavy metals such as cadmium, arsenic, manganese, and lead. By integrating HRMS with advanced bioinformatics and exposomics frameworks, researchers can trace metal-induced perturbations on a much broader scale across metabolic, lipidomic, and xenobiotic pathways with high flexibility. HRMS also allows for discovering reactive metal species, altered redox metabolites, and metal-binding biomolecules that critically mediate toxicity. In cellular and animal models, longitudinally, time-resolved HRMS analyses provide insight into early biomarkers of exposure and injury, while in human cohort studies, non-targeted profiling supports exposure-wide association studies (ExWAS) for chronic metal burden. Together, these applications demonstrate how HRMS enables a systems-level view of metal toxicity, uncovering key pathways and molecular signatures that traditional approaches likely overlook. Future directions include coupling HRMS into spatial omics (i.e., metabolomics/lipidomics/exposomics MS imaging), ion mobility, and machine learning to further unravel the dynamic interplay between metal exposures and biological responses across wide-ranging toxicological and etiologic contexts.

S 1232 Metal Toxicity Meets Stem Cell Innovation: Early Stage Scientists Forging New Frontiers in Environmental Health

S. Medina. University of New Mexico, Albuquerque, NM.

Metals accumulate in the environment and are commonly found in soil, water, and living organisms, as well as in everyday consumer products. Many metals, including arsenic, mercury, cadmium, and lead, are toxic even at low exposure levels and have been linked to developmental disorders, increased cancer risk, neurological damage, and organ failure. Understanding the toxicological effects of metals on human health remains a critical scientific challenge. In recent years, stem cell-based models, particularly those utilizing human-induced pluripotent stem cells (hiPSCs), have become powerful tools for toxicological research. These systems allow modeling of specific human cell types at various developmental stages and can capture

donor-specific genetic variability, supporting personalized risk assessment. This session highlights early career scientists who are using innovative stem cell technologies to investigate how metals affect human health across multiple organ systems. The session will begin with an overview of stem cell-based platforms for toxicity testing, followed by presentations examining (1) persistent neurotoxic outcomes of developmental methylmercury and lead exposure in hiPSC-derived cortical neurons; (2) mechanisms of arsenic-induced hematotoxicity in primary mouse and human hematopoietic stem and progenitor cells; (3) chamber-specific impacts of lead exposure on calcium dynamics in iPSC-derived atrial and ventricular cardiomyocytes; (4) transcriptomic and functional disruption of intestinal epithelial differentiation caused by uranium-bearing particulate dust in human colonic organoids; and (5) cell-type and tissue-specific responses to chronic arsenic exposure using heterogeneous primary epithelial cultures derived from human ovarian and fallopian tube tissues. The session will conclude with a moderated panel discussion and audience Q&A designed to synthesize key insights, explore cross-cutting themes, and stimulate dialogue across disciplines. This session will provide a valuable platform for early career scientists to showcase their research and expertise, while also fostering meaningful interaction with established investigators to encourage feedback, mentorship, and potential collaborations. Collectively, these presentations and discussions will highlight the expanding role of stem cell models in metals toxicology and their potential to advance mechanistic insight and improve human health outcomes.

S 1233 Introduction to Stem Cell-Based Models for Toxicity Testing

S. Medina. University of New Mexico, Albuquerque, NM.

This talk will present a brief introduction to the use of stem cell models for toxicity testing and recent advances in these stem-cell based *in vitro* models, topics which will be further elaborated by subsequent speakers in the session.

S 1234 Developmental Methylmercury or Lead Exposure of hiPSC-Derived Cortical Cultures Induces a Similar Persistently Altered State

M. Strom, and A. Tukker. Purdue University, West Lafayette, IN.

It is becoming increasingly apparent that neurodegenerative diseases (NDs) are not just diseases of aging. The Developmental Origins of Health and Disease theory hypothesizes that early life exposure to environmental toxicants can create long-term lasting effects that can increase vulnerability for later-life chronic diseases. Here we investigate the hypothesis that developmental exposure to heavy metals can establish a persistently altered neurotoxic state early in life that can render an individual more susceptible to NDs in later life. Developmental exposure to heavy metals was modeled using human-induced pluripotent stem cell (hiPSC)-derived cortical glutamatergic neuronal cultures. Developing cultures were exposed for six days to 0.1-100nM methylmercury (MeHg) or 0.3-300nM of lead (Pb). 100+ days after the exposure was removed, microelectrode array (MEA) and Seahorse XF technology were used to assess persistent changes in spontaneous neuronal activity and cellular bioenergetics. Electrophysiological analysis revealed that developmental exposure to MeHg or Pb persistently alters neuronal network patterns in a similar manner. Notably, cultures exposed to lower concentrations of MeHg (0.1, 1nM) and Pb (0.3, 3nM) have an increase in overall neuronal activity compared to control cultures, whereas exposure to higher concentrations (10, 100nM and 30, 300nM, respectively) decrease overall activity. To understand the underlying molecular changes that cause these persistently altered network patterns, single-cell RNA sequencing was performed. Transcriptomic analysis revealed that pathways relating to NDs and oxidative phosphorylation are significantly altered, which led us to investigate changes in ATP production. Cultures exposed to lower concentrations of MeHg and Pb increase in overall ATP production, whereas cultures exposed to higher concentrations have decreased ATP production. We conclude that early developmental exposure to MeHg and Pb neurotoxic agents create a similar persistently altered state that affects major metabolic pathways involved in cellular health, aging, and neurodegeneration, rendering individuals more vulnerable to development of NDs. We plan to use hiPSC lines derived siblings with and without ND-related impairments to further explore gene x environment interactions in early life exposure and later life risk for NDs.

S 1235 Defining Mechanisms of Arsenic-Induced Hematotoxicity Using Mouse and Human Hematopoietic Stem and Progenitor Cell Models

L. Heine. University of New Mexico, Albuquerque, NM.

Hematopoietic stem and progenitor cells (HSPCs) are essential for maintaining blood system homeostasis by generating all mature blood cell lineages. Disruption of HSPC function can impair lineage specification and red blood cell differentiation, contributing to the development of anemia and other blood disorders. Our work over

the past several years has focused on characterizing how chronic environmental exposures to arsenic perturb HSPC fate decisions and transcriptional regulation. Using both primary mouse and human CD34+ bone marrow-derived HSPCs, we have demonstrated that inorganic arsenic (arsenite, AsIII) disrupts early erythropoiesis by targeting zinc finger transcription factors critical for erythroid lineage commitment, including GATA-1. Building upon these findings, we are now investigating how arsenic biotransformation influences hematotoxicity, with a particular focus on the methylated AsIII metabolite, monomethylarsonous acid (MMAIII). Together, these studies define novel mechanisms by which arsenic and its metabolites interfere with hematopoietic differentiation pathways, impair red blood cell development, and increase anemia risk in exposed populations.

S 1236 Chamber-Specific Impacts of Lead Exposure on Calcium Dynamics in Human iPSC-Derived Cardiomyocytes

I. Melis. University of Michigan Medical School, Ann Arbor, MI.

Lead (Pb) is a widespread environmental toxicant linked to increased cardiovascular risk, yet its direct effects on cardiomyocyte function remain incompletely understood. In this study, we investigated the chamber-specific impacts of Pb on calcium dynamics in human-induced pluripotent stem cell-derived atrial (aCMs) and ventricular cardiomyocytes (vCMs), focusing on dose- and time-dependent effects. Atrial and ventricular cardiomyocytes were differentiated from iPSCs using published small molecule-based protocols and purified to over 98% purity. Cells were exposed to environmentally relevant Pb concentrations in acute and sub-chronic models, and calcium dynamics, including beat frequency, calcium transient amplitude, and conduction velocity, were assessed using high-resolution optical mapping. Baseline measurements revealed that aCMs exhibited significantly higher beat frequency and conduction velocity, while vCMs displayed greater calcium transient amplitude. Pb exposure induced dose-dependent effects, with aCMs showing increases in calcium transient amplitude and upstroke slope at 500 μ M Pb, while vCMs experienced significant reductions in these parameters. Time-course analysis at 5 μ M Pb revealed dynamic, chamber-specific responses: baseline fluorescence in aCMs decreased after 1–12 hours of exposure but normalized by 72 hours, while vCMs showed an initial increase that returned to baseline by 6 hours. Calcium transient amplitude in aCMs peaked at 3 hours and remained elevated at 72 hours, whereas vCMs exhibited sustained decreases. Preliminary RNA sequencing analyses of these time-series samples revealed that the number of differentially expressed genes (DEGs) decreased over time, consistent with the temporal patterns observed in the calcium imaging data. These transcriptomic findings support the functional results and provide insight into the molecular mechanisms driving Pb-induced cardiac effects. Together, these results highlight the importance of chamber identity in toxicant susceptibility and lay the groundwork for identifying targets to mitigate Pb-related cardiovascular risks.

S 1237 Heavy Metal-Laden Particulate Dust Disrupts Intestinal Epithelial Differentiation in Human Colonic Organoids

J. In. University of New Mexico, Albuquerque, NM.

Over 160,000 abandoned mine waste sites are concentrated in the western United States and continue to degrade the environment with elevated heavy metals penetrating the surrounding sediment and groundwater. The sedimentary dust and water located near abandoned uranium mine (AUM) sites often exceeds the maximum contamination level for uranium (U, EPA max level 30 μ g/L). Chronic exposure to environmental toxins and heavy metals has been linked to intestinal inflammation, increased susceptibility to pathogen-induced diseases, and higher incidences of colorectal cancer, all of which have been steadily increasing in prevalence for the past 40 years. The negative effects of heavy metals on the intestinal microbiota, barrier permeability, and inhibition of intestinal epithelial healing have been described; however, transcriptomic changes within the intestinal epithelial cells are largely unknown. Thus, our goals are to characterize U-bearing dust (UBD) as an environmental toxicant that damages the intestinal epithelia and determine the molecular changes that develop as a response to this injury. We have previously characterized human intestinal organoids (HIOs) under homeostasis and pathogen infected conditions, to establish HIOs as a relevant intestinal pathophysiological model. Particularly in the secretory lineage of intestinal epithelial cells, there is divergence between human and rodent digestive physiology. Using HIOs, we seek to understand how UBD directly affects the stem and proliferative cells within the intestinal deep crypt and leads to transcriptional changes in the mucus-producing goblet cells and hormone-producing enteroendocrine cells. Understanding the mechanistic changes within the epithelia will help us understand if these changes have peripheral impact from the gut.

S 1238 Modeling Chronic Arsenic Exposure in Heterogeneous Human Primary Cultures: Insights into Cell-Type Specific and Tissue-Specific Mechanisms of Toxicity

D. Azzam. Florida International University, Miami, FL.

Understanding the long-term effects of environmental toxicants like arsenic requires model systems that reflect the cellular diversity of human tissues. In our study, we utilize primary human cultures—specifically OCE1 and FNE1—derived from the ovarian surface and fallopian tube epithelium of the same donor. These cultures comprise heterogeneous populations, including epithelial, immune and stem/progenitor cells, and offer a unique human-relevant platform to examine how chronic arsenic exposure impacts distinct cell types within a shared microenvironment. Our findings demonstrate that prolonged exposure to environmentally relevant levels of arsenic lead to significant cellular, molecular, and morphological alterations. These include the emergence of giant and/or multinucleated cells exhibiting phagocytic activity, DNA damage associated with nuclear remodeling, upregulation of cancer stem cell markers and activation of the NF- κ B inflammatory signaling pathway. These responses suggest coordinated cellular adaptations to chronic stress that may contribute to malignant transformation. By employing primary heterogeneous cultures, this model provides new insight into cell-type specific and ovarian-specific mechanisms underlying metal-induced toxicity.

S 1239 Toward Sex-Differences Research in Toxicology: New Approach Methodologies for Assessing Sex as a Biological Variable

K. Sullivan. Institute for In Vitro Sciences Inc., Gaithersburg, MD.

There is arguably no other attribute that has a greater impact on mammalian phenotype, physiology, and disease than sex. Diseases with well-established environmental etiology, such as cardiovascular diseases, liver diseases, neurodegenerative diseases, diabetes, and cancer, exhibit marked sexual dimorphism, suggesting that sex-dependent effects of environmental toxicants may underlie some of the observed differences in disease pathogenesis between males and females. Sex-specific effects have been reported for a wide array of environmental exposures, such as heavy metals, per- and polyfluoroalkyl substances, air pollution, and plastics. Despite these findings, the molecular mechanisms underlying sex differences in the context of environmental exposures are poorly understood. This is in part because until recently, females have been systematically underrepresented in both clinical and basic science studies. Likewise, sex chromosome complement in cell culture studies has largely been ignored. In studies where both sexes are included, sex-based analyses of the data are often lacking. Improvements in assessing sex differences have been made since the National Institutes of Health “Considering Sex as a Biological Variable” mandate in 2016, but challenges and opportunities remain. Concerns and misconceptions persist about cost and increased experimental variability when both sexes are included, as well as historic beliefs that males and females differ only in their reproductive biology. An additional hurdle has been a lack of appropriate models and methods to address sex differences. Recently, the biomedical sciences community has made strides in this regard with the development of new approach methodologies (NAMs) that specifically address sex as a biological variable. Additionally, in 2025, the US Food and Drug Administration released updated guidance on evaluating sex differences in clinical investigations, highlighting, among other considerations, the importance of collecting pharmacokinetics data. A more robust consideration of sex differences using NAMs in the preclinical stage could help facilitate better clinical study planning. This Symposium provides an up-to-date discussion of the current understanding of the impact of sex differences on disease etiology. Presentations will highlight the ongoing challenges and opportunities presented by sex-inclusive research and examine some of the recent new approach methodologies currently being explored to assess sex differences in toxicology studies. Physiologically based kinetic models can become more relevant to female toxicologic responses by considering incorporation of female-specific ADME parameters and anatomic compartments. Liver spheroids can be developed to reflect sex- and species-related response diversity, which is especially relevant for pharmaceutical efficacy and toxicity testing. Induced pluripotent stem cell-derived cardiomyocytes from male and female donors provide an opportunity to understand the sex-impacted response potential and mechanisms after PFAS exposure. A panel and audience discussion will explore research needs and challenges to addressing sex differences in toxicology, especially in the context of apparent defunding of initiatives focused on women. Discussions will also consider identification of priorities for further model development, current and future regulatory initiatives or frameworks across regions and sectors, and practical solutions with the greatest potential for impact on consumer and patient protection.

S 1240 Incorporating Sex as a Biological Variable into Basic and Clinical Research Studies

J. Regensteiner. University of Colorado Anschutz, Aurora, CO. Sponsor: *L. Svoboda*

Sex is one of the most fundamental differentiators of human beings. Sex differences, widely present in risk factors and diseases, need to be identified and understood so that women and men are treated optimally with regards to health. However, these

differences are not well understood at this point in time. For example, among individuals with type 2 diabetes (T2D), cardiovascular disease (CVD) is the leading cause of morbidity and mortality and accounts for >75% of hospitalizations and >50% of all deaths. Although nondiabetic women have fewer cardiovascular events than nondiabetic men of the same age, this advantage appears to be lost in the context of T2D. In addition, women with diabetes experience significantly greater morbidity and mortality than men from CVD. One cause of this may be abnormal cardiac and vascular function which are more pronounced in women than men with T2D. We found that peak exercise capacity (highly correlated with cardiovascular mortality) was reduced in men with diabetes and even more so in women with diabetes compared to nondiabetic counterparts, potentially related to cardiac and skeletal muscle abnormalities which became evident, in premenopausal women and age similar men with uncomplicated T2D. However, the reasons for these sex differences are not well understood and need to be better understood so that both women and men receive optimal care for their diabetes. These data provide a human-relevant lens to launch our discussions on the overarching need to reflect biological differences across the preclinical and clinical model development continuum.

S 1241 Induced Pluripotent Stem Cell-Derived Cardiomyocytes as a Model for Examining Sex-Specific Cardiotoxic Effects of Developmental PFAS Exposures

L. Svoboda, T. Ishikawa, C. Clark, A. Tapaswi, A. Monteiro Da Rocha, E. Jimenez-Vazquez, D. Jones, and J. Colacino. University of Michigan, Ann Arbor, MI.

Sex and environmental exposures play critical roles in the etiology of cardiovascular diseases (CVDs), but how these factors interact, and underlying molecular mechanisms, are unclear. Perfluoroalkyl substances (PFAS) are a family of man-made chemicals that resist degradation and bioaccumulate, resulting in ubiquitous human exposure. PFAS exposures are linked to several CVDs, but sex-specific effects of developmental exposures on the human heart are unclear. In this study, we utilized human-induced pluripotent stem cell-derived cardiomyocytes (iPSC-CM) from 2 donors (1 male and 1 female) to investigate the effects of PFAS exposure on CM differentiation, transcriptome, and function. iPSCs were exposed to perfluorooctanoic acid (PFOA), a ubiquitous legacy PFAS (0, 0.5, 5, and 50 μ M) for 3 days. Viability and pluripotency were measured using live cell imaging and qRT-PCR for expression of OCT4, SOX2, and NANOG. iPSCs were then differentiated into ventricular CMs in the continued presence or absence of PFOA using an established small molecules protocol, followed by CM purification and maturation for 10 days in PFOA free conditions. CM differentiation efficiency was assessed using flow cytometry and staining for cardiac troponin T (cTnT). Calcium dynamics and voltage were assessed in CM using optical mapping. IKr, IK1, ICa channel currents were measured using patch clamping. PFOA had no significant effect on viability or pluripotency of iPSCs from either donor. Exposure of the male-derived iPSCs to 5 μ M PFOA resulted in fewer cTnT positive cells, suggesting reduced differentiation efficiency. Optical mapping studies in iPSC-CM showed that PFOA significantly altered several parameters (beat frequency, conduction velocity, action potential duration, IKr currents $p < 0.05$) in both cell lines, with effects that differed by dose and donor. PFOA altered pathways related to lipids and lipoproteins in the female line, and calcium ion regulation and heart morphogenesis in the male line. A key objective is to understand effects of chromosomal sex on PFAS cardiotoxicity, and ongoing studies are being conducted in iPSCs from additional donors. These results underscore the need for further investigation into the sex-specific developmental effects of these chemicals on the heart, and highlight the utility of iPSC-CM for this purpose.

S 1242 Species and Sex-Specific Liver Microtissues: A Set of Micro-physiological Systems to Assess Translational Hepatotoxicity in Drug Development

M. Nag, M. Vittoria Colombo, F. Wenz, L. Fäs, A. Pawlowska, and B. Filippi. InSphero AG, Schlieren, Switzerland. Sponsor: K. Sullivan

The hepatotoxic effects of certain drugs differ significantly between humans and animals due to species-specific biological mechanisms. Interestingly, expanding on that theme, there are certain classes of drugs that differ in the way they are metabolized in biological females versus biological males, thereby, possibly flagging different risks. Species and sex specific liver microtissues can accurately recapitulate these differences, providing reliable preclinical toxicity assessments. Liver microtissues were developed from parenchymal and non-parenchymal cells isolated from *Macaca fascicularis* (Cynomolgus monkey), *Canis familiaris* (Beagle dog), *Rattus norvegicus* (Sprague Dawley rat), and humans. The microtissues were exposed to two FDA-approved drugs—fialuridine and chlorpromazine—and evaluated for cytotoxicity and transcriptomic responses. Cytotoxicity assays showed fialuridine was significantly more toxic to human liver microtissues compared to animal counterparts. Chlorpromazine, with no known species-specific hepatotoxicity, exhibited comparable cytotoxicity levels across all tested species. This is in agreement with clinical data. No differential hepatotoxicity *in vivo* has been reported for chlorpromazine. Transcriptomic analyses revealed a distinct response to fialuridine exposure in human liver microtissues, including significant alterations in genes associated with DNA damage response pathways. Multiple gene sets, encompassing genes acting

in the DNA damage response cascade, are specifically upregulated in human liver microtissues treated with low concentrations of fialuridine. These findings demonstrate that species-specific liver microtissues effectively capture critical differences in drug-induced hepatotoxicity. Following the same experimental rationale, we decided to test a rank ordered list of twenty drugs from the FDA's DILIRank database that were hypothesized to have differential effects in males versus females. These drugs will be tested for hepatotoxicity at both the level of the individual donor as well as with pooled donors. We expect that the differences that we see at the functional and transcriptomics levels will give us more insight into the differential mechanisms involved in hepatotoxicity and lay the foundation for employing this approach in other areas of toxicology and safety pharmacology.

S 1243 Advancing Female-Specific PBK Modeling: From Sex-Specific Organs to Whole-Body Pharmacokinetics

S. Fischer-Holzhausen. ESQlabs, Oslo, Norway. Sponsor: K. Sullivan

Biological differences between males and females extend well beyond the reproductive organs and their endocrine regulation. Sex dimorphism is described across human biology including anatomy, metabolism, the cardiovascular and respiratory system, as well as physiological processes such as immune function. Consequently, biological sex can affect how chemicals are absorbed, distributed, metabolized, and excreted by the body and thus plays a key role in determining potential risks. Physiologically based kinetic (PBK) and Quantitative systems modeling are established approaches that can incorporate sex differences in their model structure and parametrization. Historically, however, PBK model models have been developed using male reference physiology, often overlooking sex-specific anatomical and physiological differences. Our work addresses this gap by developing and validating female-tailored models. Leveraging the open-source modeling ecosystem provided by Open Systems Pharmacology, we are developing model extensions to address female-specific challenges in drug and chemical development. One such advancement is the extension of PBK models to include the female reproductive tract (FRT) – a structure usually neglected in standard PBK models. For the FRT extension module, four tissue compartments (cervix, vagina, endometrium, and myometrium) and two fluid compartments (uterine and cervicovaginal fluid) were informed using publicly available data. We validated the model for levonorgestrel and metronidazole for different routes of exposure (e.g. oral and vaginal route) by comparing predictions to clinical data, using goodness-of-fit plots and pharmacokinetic parameters. With minor parameter adjustments most model predictions fall within the 2-fold deviation. By predicting FRT tissues and plasma concentration for several routes of exposure, this extension addresses a gap to enable female-specific decision-making. Looking ahead, integrating PBK models with detailed endocrine regulatory networks represents a promising avenue for advancing a comprehensive women's health modeling platform covering female-specific anatomical structures and beyond, to physiological and metabolic differences throughout the body. Such integrative approaches will support model-informed decision-making in drug development and chemical safety assessment.

W 1244 Endocrine Disruption Safety Assessment Approaches for Cosmetics

K. Fussell. Wella Company, Darmstadt, Germany.

Disruption of endocrine system homeostasis is a toxicological hazard, one which is under increasing regulatory scrutiny. Within the context of the EU Regulation for Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) and the US Endocrine Disruptor Screening Project, substances are systematically evaluated for endocrine disruption (ED) against three criteria: an endocrine mode of action, adverse effects in intact organisms or (sub)populations, and a biologically plausible link between the mode of action and the observed effect. This evaluation currently demands the use of animal models for determination of the second criterion of adversity. For cosmetic ingredients, which are managed in the US and EU within the regulatory contexts of REACH, the EU Cosmetics Directive, the US Modernization of Cosmetics Regulation Act, and the US Toxic Substances Control Act, such data generated after the EU 2013 ban on animal testing cannot be used to assess their safety; yet, *in vivo* data generated prior to the ban do not fully address these ED regulatory requirements. In this context, the incorporation of results generated with new alternative methods into an integrated safety assessment has become imperative for cosmetics. Next-Generation risk assessments (NGRAs) are a means to integrate historical *in vivo* findings and novel *in silico* and *in vitro* data into a single, transparent risk profile. The resulting weight of evidence (WOE) evaluation provides a comprehensive assurance of human safety, leveraging data from the new alternative methods to plug current data gaps without the use of new animal studies—in effect modernizing older data beyond their historical limitations. This is particularly critical for thyroid disruption, which under previous guidelines was only detectable as altered thyroid gland histopathology. This Workshop aims to address the scientific suitability of NGRA-based approaches to the safety assessment of cosmetic ingredients with potential endocrine activities. Importantly, perspectives of both regulators and regulated industries will be evenly represented, including both EU and US regulatory contexts and geographies. These diverse speakers will explore the application

of NAMs data to address real-world concerns due to data gaps. Several practical state-of-the-art NGRA cases involving potential thyroid-disrupting substances and their WOE for human safety decision-making will be discussed. The first presenter, as a subject-matter expert at several EU regulatory authorities, will use 4-methylbenzylidene camphor to discuss the EU regulatory body perspective, highlighting some current issues with NGRA acceptance and proposing some next steps. The second speaker, representing an EU-corporate perspective, will cover an assessment approach suitable for the EU regulatory environment, which uses toxicokinetic data to bridge between *in vitro* thyroid peroxidase measures and findings from 90-day rat exposures conducted under previous OECD 408 guidelines. The third presenter is a member of a US regulatory authority and will address potential thyroid disruption during the critical fetal development window using a first trimester maternal-fetal high-throughput *in vitro* to *in vivo* extrapolation model to simulate thyroid active exposures from ToxCast activities. The final industry speaker from a US-based, consumer-products multinational will present a NGRA for the use of fluoride in oral health products, taking into account its alleged thyroid-disruption potential. Following each presentation, time permitting, the audience will have the opportunity to ask one or two brief questions. Lastly, the four speakers will join a dedicated panel discussion session in which additional questions from the floor will be addressed to allow deeper engagement with the speakers, as well as a structured dialogue using polling, both to be moderated by the session Chair.

W 1245 NGRA for Cosmetics Use: What Next Steps Are Needed

N. Cabaton. INRAE Toxalim, Toulouse, France. Sponsor: K. Fussell

Next generation risk assessment for cosmetic product ingredients represents a major advancement in the European Union's regulatory approach. Faced with health security challenges and increasing transparency demands, the EU aims to integrate alternative methods to animal testing, such as *in silico* models and *in vitro* tests. However, several challenges have to be met, such as the scientific and regulatory validation of these new approaches which remains a long and complex process. International standard harmonization poses a significant obstacle to the implementation of these new methods. To overcome these challenges, the EU could strengthen collaboration between researchers, regulators and industry professionals to accelerate the validation and acceptance of alternative methods. A case study describing the risk assessment of 4-methylbenzylidene camphor will serve as an example to highlight the gaps that need to be filled, particularly for extrapolations to humans from *in vitro* or *in silico* test results, often focusing on a single organ or tissue for which existing models are not yet sufficiently efficient and does not always reflect what happens in a more integrated model.

W 1246 Hazard Assessment of Endocrine-Disruption Potential Using New Alternative Methods: Use of Toxicokinetic Data to Bridge Endocrine Activity, Endocrine Disruption, and Human Health Risk

K. Fussell. Wella Company, Darmstadt, Germany.

Endocrine Disruption (ED) is a toxicological hazard defined by three criteria, only one of which can currently be assessed using new alternative methods (NAMs). The others currently require the use of animal models to meet regulatory requirements. In an effort to avoid additional animal testing we introduce an integrated hazard assessment using NAMs-generated toxicokinetic and endocrine data. For this purpose, we determined the metabolic stabilities of the hair dyes resorcinol (Res), p-aminophenol (PAP) and 3-amino-2,6-dimethylphenol (AdMP) in by human skin keratinocytes and liver hepatocytes with identification of all significant metabolites. In addition, intrinsic hepatic clearance and fraction unbound in plasma were modeled using the ToxCast HHTK package for R and used to calculate the volume of distribution and the steady-state plasma concentration, i.e. the systemically available levels of each substance. QSAR modeling was then applied to predict the potential of Res, PAP, AdMP or their metabolites for (anti-)estrogenic, anti-androgenic, thyroid- or steroidogenic activities. Thyroid peroxidase (TPO) inhibition was identified as the main effect of concern. The relevant metabolites were then synthesized and tested for TPO inhibition activity using the *in vitro* tyrosine iodination assay. Although inhibition was observed in the sensitive assay, our data indicate that the systemically available levels of Res, PAP, AdMP and their metabolites do not inhibit TPO. This is supported by the results of 13-week OECD 408 studies in rats demonstrating a lack of thyroid effects, as well as a general lack of such findings in modern pharmacovigilance and cosmetovigilance reports. Together these findings indicate no relevant hazard from cosmetic use of Res, PAP and AdMP and suggest the validity of our NAMs-based safety assessment for the determination of ED for regulatory purposes.

W 1247 Interpretation of Thyroid-Relevant Bioactivity Data for Comparison to *In Vivo* Exposures: A Prioritization Approach for Putative Chemical Inhibitors of *In Vitro* Deiodinase Activity

K. Paul Friedman. UL Research Institutes, Research Triangle Park, NC.

Many ToxCast assay endpoints can be mapped to molecular initiating events (MIEs) within the thyroid adverse outcome pathway (AOP) network, but a framework for interpretation of thyroid-relevant bioactivity data across MIEs has been lacking. Using ToxCast data on the inhibition of deiodinase (DIO) enzymes, which convert thyroid hormones between active and inactive forms, substances most likely to inhibit DIO enzymes were identified. Data from 4 relevant cell-free *in vitro* assays for chemicals in multi-concentration screening were filtered to identify chemicals that demonstrated inhibition for each DIO enzyme less likely to be confounded by assay interference, refining the list of putatively active chemicals from 523 to 135. *In vitro* bioactivity data were then used to estimate administered equivalent doses (AEDs) using a novel high throughput toxicokinetic (HTTK) model for *in vitro* to *in vivo* extrapolation (IVIVE) of dose. To understand thyroid-disrupting activity in an appropriate dose context, we extended an existing human maternal-fetal HTTK model to allow for simulations involving the first trimester of pregnancy. For many chemicals, simulations of fetal tissue concentrations produced lower AED estimates than using modeled maternal plasma concentrations alone, at least partially due to conservative assumptions in our HTTK model of complete gestation. This extensible approach for MIE groups of thyroid-related bioactivity data from ToxCast may inform further screening or analyses for potential adverse outcomes during pregnancy and development. *This abstract does not reflect US EPA policy.*

W 1248 Application of Next-Generation Risk Assessment to Better Understand ED Risk: Bringing Fluoride into Focus

A. Mudd. Procter & Gamble, Cincinnati, OH.

Cited as one of the ten greatest public health interventions of the 20th century, fluoride has left an indelible mark for its role in both reducing dental cavities but also improving general oral health of adults and children since the inception of US water fluoridation. However, fluoride has come under recent scrutiny regarding concerns over potential neurodevelopmental and endocrine-related toxicities. Several reviews have been conducted by authoritative bodies such as the NTP and EFSA, who concluded with moderate/reasonable confidence that higher levels of fluoride exposure (ie those above the upper limit in drinking water of 1.5 mg/L) are associated with modest decrements in IQ in children. EFSA also determined that adverse effects on the CNS, including neurobehavior or thyroid homeostasis, are unlikely to occur in children at exposures below those associated with dental fluorosis, making this a protective critical effect to utilize in risk assessment for this population. Thyroid homeostasis is of importance, as this is hypothesized to be associated with the epidemiological observations on IQ. A key outcome of these reviews is the level of uncertainty regarding whether these modest findings are biologically plausible. To address this outage and better understand if fluoride exerts direct biological activity on molecular and cellular targets related to the EATS modalities, an NGRA approach consisting of receptor binding assays of thyroid and other hormone related targets, H295R Steroidogenesis, and Sodium-Iodide Symporter (NIS) assays were carried out using exposures at and well in excess to those in the general public. Results showed that at levels well in excess of typical exposures, fluoride did not alter hormone levels in the steroidogenesis assay or bind to classical targets such as aromatase, steroid 5 alpha-reductase, estrogen or androgen receptors. Additionally, no alterations in iodide uptake via the sodium-iodide symporter or binding to thyroid-related targets such as the thyroid receptor or thyroid peroxidase were observed, and binding with other related targets, including but not limited to glucocorticoid and constitutive androstane receptors, were also not observed. The negative results from this series of experiments provide key insights into the absence of effects on the studied targets well in excess of typical exposure scenarios.

W 1249 Optimizing Chemical Risk Assessment for Medical Device Biological Safety: Challenges, Progress, and Collaborative Opportunities

X. Dai. Abbott Laboratories, Saint Paul, MN.

To ensure the biological safety of medical devices, manufacturers comply with international standards (ISO 10993). Use of the ISO 10993 series of standards enables more consistent evaluation of devices and helps drive harmonization of safety requirements for global regulatory submissions. With ISO 10993-17:2023 recognition by the US FDA and ongoing work tackling analytical chemistry issues associated with implementation of ISO 10993-18, regulatory demands have significantly increased. Despite significant progress to develop and update consistent and effective methods, unique challenges remain on how to determine potential toxicological risks for chemicals released from devices during clinical exposure. Inherent complexities of medical device material composition and manufacturing processes place unique hurdles in the path to advance and harmonize regulatory acceptance of biological safety risk without compromising a rigorous evaluation of accumulated safety

evidence. Currently, regulatory submission strategies rely on general methodologies defined in ISO 10993 with regulatory emphasis on being “most protective.” This approach potentially results in overestimated chemical safety risks, which can delay patient access or require unnecessary implementation of safety controls. A technical gap to address an unmet regulatory need represents an opportunity for well-defined approaches that determine potential chemical harms from clinical exposure to patients and are applicable for medical device chemical hazard and risk assessment. Multidisciplinary collaboration is critical to determine more relevant analytical conditions to human exposure and to generate exposure data specific to the intended clinical-use condition for the ultimate purpose of protecting patients from potential chemical harm when treating conditions with medical devices. In this session, experts from regulatory, industry, and nongovernmental organizations will come together to discuss the need, challenges, progress, and opportunities for a consensus perspective on optimizing and gaining confidence in chemical risk assessment approaches to improve confidence in medical device biological safety. The first presentation will discuss the current state-of-art chemical characterization studies from scientific, regulatory, and international standards perspectives. Key analytical opportunities affecting data quality will be addressed, including simulating solvents, analytical evaluation threshold (AET), uncertainty factor (UF), quantification by non-targeted screening (NTS), etc. Finally, suggestions for improving chemical characterization studies without compromising data quality will be proposed to stimulate discussion and collaboration among scientists, regulators, and standards. The second presentation will provide an industry perspective and present case studies related to device extractables and leachables that aim to capture practical applications, while discussing current technical limitations and challenges, such as the considerations of specific and appropriate chemical characterization conditions and parameters. The third presentation will highlight the implementation of new ISO 10993-1 and ISO 10993-17 standards to facilitate risk-based framework for biocompatibility assessments, focusing on the toxicological risk assessment of medical devices to address clinically relevant toxicological risks in addition to lessons learned following the release of the revised standard. The fourth presentation will focus on reviewing recent advancement in computational power to predict human exposure and pharmacokinetic parameters of nanomaterials. This review will draw from academic research and explore potential practical applications for the biological safety evaluation of medical devices that contain or are composed of nanomaterials. The fifth presentation will share advancements in regulatory science tools developed by US FDA CDRH Office of Science and Engineering Laboratories with a goal to provide clinically relevant, yet still conservative, chemical patient exposure estimates using a physics-based transport model for polymeric systems. It further explores the application of this extraction model to current ISO 10993-18 standard updates. Attendees will be invited to a short Q&A and panel discussion to learn more perspectives on the evolving nature and how to further expand state-of-the-art approaches and to delve into collaborative engaging activities to advance further scientific development of innovative approaches to assure the safety of medical device. The Workshop serves well for those who desire advanced knowledge and learning in the field of medical device and combination products.

W 1250 Can Chemical Characterization Studies of Medical Devices Be Streamlined Without Affecting Their Safety Assessment Through Toxicological Risk Evaluation?

J. Li. Chemical Characterization Solutions LLC, Woodbury, MN. Sponsor: X. Dai

The toxicological risk assessment for medical devices, as outlined in ISO 10993-17, heavily depends on the precision and accuracy of chemical characterization results conducted in line with ISO 10993-18, especially in terms of quantification and identification. Despite the implementation of ISO 10993-18:2020 five years ago, the standard has not fully achieved its intended outcomes due to various scientific challenges. Consequently, there is considerable variability among many contract research organizations (CROs), and the accuracy of data regarding both exposure levels and chemical identities within the same laboratories can remain uncertain. This presentation is intended to cover the following topics: 1) A comprehensive overview of the essential role that chemical characterization plays within regulatory frameworks for the approval and market entry of medical devices; 2) Current chemical characterization: scientific, regulatory, and ISO standards perspectives; 3) Summary of key complexities in chemical characterization of medical devices; 4) Discussion on scientific opportunities in chemical characterization. The presentation will contain comprehensive information and data, making it suitable for toxicologists, chemists, and professionals involved in the biological evaluation of medical device safety. It also aims to encourage dialogue and cooperation among regulators, scientists, and standards bodies.

W 1251 Practical Consideration with Case Studies on Clinically Relevant Patient Exposure via Targeted Chemical Analysis and Simulated-Use Extraction

S. Zhang. Abbott Laboratories, Little Canada, MN.

Chemical characterization per ISO10993-18 to provide critical patient chemical exposure data for the risk assessment assure the biological safety evaluation of toxicological effects for medical devices. For long-term implantable devices, exhaustive extractions are recommended to produce a worst-case patient exposure. When any exhaustive extractable potentially presents a toxicological risk, a more physiological relevant chemical characterization study is necessary to understand the patient exposure clinically, i.e. a leachables study under simulated use conditions. However, due to the complexity of medical device contact nature, the extraction condition to simulate the clinical use of the device, and the correlation of extractables release under exhaustive and simulated use conditions are not well understood. This presentation will provide practical considerations with a case study on the extractables release kinetics of a cardiovascular device incorporating complex materials and manufacturing processes. The extractables released from exhaustive extraction solvents and the commonly recognized blood simulating solvent will be compared and the toxicological impact in light of the clinical use conditions of the device will be discussed. In additional, evaluation of solvent systems to simulate the blood contact of various polymeric materials used in implantable medical devices will be discussed.

W 1252 Navigating ISO 10993-17 and 10993-1: Evolving Standards, Practical Insights, and Regulatory Impacts

X. Dai. Abbott Laboratories, St. Paul, MN.

Recent updates to ISO 10993-1 emphasize a more dynamic, risk-based framework for biological safety assessments. Many of the proposed changes to Part 1, including expanded biological effects for various device categories, are recommended to address by chemical characterization and toxicological risk assessment (TRA). ISO 10993-17 revision in September 2023, retitled Toxicological Risk Assessment of Medical Device Constituents, reflects a shift toward a more systematic approach to evaluate toxicological risks. This includes new concepts to offer practical tools for streamlining TRAs and strengthening weight-of-evidence evaluations, particularly for devices undergoing exhaustive extractions (e.g., long term implantable devices). This presentation will explore the application of these tools, their integration into broader biological safety evaluations, and their role within the overall risk management framework. As these methodologies are adopted, limitations and uncertainties have emerged. For example, how should these tools be applied to devices used in young pediatric patients? What approaches are appropriate for constituents with suspected carcinogens? When should simulated-use extraction studies be initiated to reliably estimate maximum total quantity for patient exposure? These challenges will be discussed alongside scenarios where caution is warranted and regulatory feedback that may influence future applications of ISO 10993 standards. Attendees will gain insights into the evolving landscape of biological safety risk assessment, practical strategies for implementing new TRA tools, and lessons learned from applications.

W 1253 Technical Advancements in Computational Technologies to Support Biological Safety Risk Assessment of Nanomaterials

T. Puzyn. Uniwersytetu Gdański, Gdansk, Poland. Sponsor: X. Dai

The biological safety evaluation of medical devices made of nanoparticles presents unique challenges due to distinct physicochemical characteristics of nanomaterial, such as chemical compositions and physical properties, which are critical to toxicities. Nanomaterials in medical devices can be present as free or embedded nanomaterials, potentially releasing into the body, posing significant toxicological risks. The existing knowledge gap regarding the mechanistic information on toxicity potency of nanomaterials necessitates thorough data assessment using advanced methodologies for risk evaluation to ensure regulatory decision making and patient safety. Recent advancements in computational power, big data informatics, artificial intelligence assisted analysis, and machine learning models have significantly enhanced the integration of mechanistic data on chemical and physical properties with biological information. These technologies better predict toxicity parameters for nanoparticles. Especially aggregating extensive ongoing research and case studies from academia provides further insights into the continuous development of international ISO standard for medical device safety.

W 1254 Incorporating New Approach Methods into Regulatory Science Tools for Toxicological Risk Assessment of Medical Device Leachables

D. Saylor. US FDA/CDRH, Silver Spring, MD. Sponsor: X. Dai

Toxicological risk assessment (TRA) is a common tool used to address toxicological concerns associated with chemicals that can leach from medical device materials. TRA currently relies primarily on *in vitro* extraction testing to estimate the potential for patient exposure, but the clinical relevance of the test results is often ambiguous. Regulatory science tools incorporating New Approach Methods (NAMs) are being developed to improve the current TRA paradigm. We have developed physics-based mass transport models that can be used to supplement or in lieu of *in vitro* testing to provide more clinically relevant exposure estimates of medical device leachables. Moreover, we have created web-based applications, collectively known as Chemical RISK calculators (CHRIS), to facilitate the use of these models by the medical device community. This presentation will provide an overview of the mass transport models for both *in vivo* exposure estimation and *in vitro* extractables testing. Further, we will describe efforts to conservatively establish system specific model parameters and validate the model predictions. The potential benefits and limitations will be discussed, along with ongoing efforts to expand the applicability and improve the clinical relevance of the model predictions. Additionally, this session will highlight how these advancements may help to reduce reliance on animal testing and enhance the use of *in vitro*, *in silico*, and *in chemico* methods, thereby promoting more ethical, rapid, and accurate safety assessments.

W 1255 Toxic Air, Targeted Care: Innovations in Inhalation Injury and Intervention Through Early Career Perspectives

B. Baird. University of New Mexico, Albuquerque, NM.

The American Lung Association reports that nearly half of Americans live in areas with unhealthy air, and western states dominate the list of most polluted US cities. This session brings together a diverse array of studies that collectively deepen our understanding of how inhaled environmental pollutants—ranging from nanoparticles and ozone to woodsmoke—disrupt physiological systems and contribute to disease. Despite differing pollutants and experimental models, a central theme emerges: air pollution induces complex, multi-organ inflammatory responses that are profoundly shaped by biological context, including sex, metabolic health, diet, and neuroendocrine signaling. Across all six presentations, lipid mediators and immune signaling surface as key drivers of pollutant-induced pathology. Several talks highlight the role of lipid-derived molecules—such as prostaglandins, resolvins, and cholesterol derivatives—in either exacerbating or resolving inflammation, depending on the exposure and physiological background. Equally prominent is the recognition that underlying conditions like metabolic syndrome, dietary composition, and circulating hormones critically influence both the magnitude and duration of pollutant effects. A recurring mechanistic thread throughout the session is the disruption of barrier integrity—whether in the airway epithelium or the blood-brain barrier—leading to heightened susceptibility to immune cell infiltration and sustained inflammatory damage. These effects are compounded by sex differences and neurohormonal regulation, with emerging data pointing to receptor-mediated crosstalk between stress and sex hormone pathways as modulators of pollutant response. Collectively, these talks emphasize the importance of context—metabolic, hormonal, and nutritional—in shaping individual vulnerability to air pollution. They also offer promising avenues for intervention, including dietary strategies (e.g., omega-3 fatty acids, vitamin D), pharmacological modulation of signaling pathways (e.g., MAPK, Rho-kinase), and hormone receptor targeting. This session underscores a growing recognition that personalized, systems-level approaches are essential for protecting vulnerable populations and mitigating the long-term health consequences of air pollution. Collectively, these presentations showcase the multifaceted nature of inhalation research and potential interventions to optimize health outcome, stories all shared by early career scientists. This session aims to foster discussions, specifically among trainees, encouraging collaboration and further exploration into the complex world of inhalation toxicology and therapeutic interventions during a concluding Q&A panel.

W 1256 Beyond Smoke and Mirrors: Introducing Inhalation Toxicology Therapeutics

S. Phatak. University of New Mexico, Albuquerque, NM.

The World Bank estimates that health damages from air pollution cost the global economy approximately \$6 trillion annually, equivalent to about 5% of global GDP. Air pollution is a persistent and evolving global health concern, with growing evidence linking environmental exposures to a wide array of adverse outcomes across organ systems. This session explores the mechanistic underpinnings and modifiers of health effects induced by various inhaled pollutants—ranging from nano-sized particles and woodsmoke to ozone—focusing on pulmonary and neurological outcomes, systemic inflammation, and susceptibility factors. A critical component in understanding pollutant toxicity lies in the physicochemical characterization of inhaled nanoparticles, including parameters such as size, surface charge, solubility,

and chemical composition, which influence their biological interactions and health effects. To contextualize the material that follows, it is essential to understand that inhaled pollutants interact with biological systems not merely through local airway effects, but also by influencing lipid mediators, immune signaling, and neurohormonal pathways. These interactions can vary based on underlying conditions such as metabolic syndrome, diet, sex, and genetic background. Lipid mediators—such as prostaglandins, resolvins, and protectins—play key roles in inflammation initiation and resolution, and disruption of these pathways can tip the balance toward chronic inflammation. Equally important are the structural and immunological functions of airway epithelial cells, which act as the first line of defense but can be compromised following pollutant exposure, leading to heightened immune cell infiltration and impaired tissue recovery. The structure of the session will be described, including the sequence of research presentations and the format of the Q&A discussion, where trainees are particularly encouraged to engage.

W 1257 Inhalation of Nanomaterials Disrupts Inflammatory Lipid Mediators in a Sex- and Disease-Dependent Manner

A. Pitchai. Purdue University, West Lafayette, IN.

Nanosized particles pose health risks following inhalation exposure. Most evaluations of nanoparticle safety have focused on healthy models. However, epidemiology studies have demonstrated individuals with metabolic disease are more vulnerable to particulate air pollution. Our research has determined a metabolic syndrome (MetS) male mouse model exhibits specific alterations in lipid mediators involved in inflammatory regulation and increased lung inflammation after exposure to silver nanoparticles (AgNPs), compared to a healthy male mouse model. Sex differences exist in lipid regulation between males and females, which may influence susceptibility to nanoparticle inhalation exposures. Further, as with males the prevalence of MetS in females has risen drastically and may influence exposure-induced susceptibility. Our study hypothesized sex-dependent inflammatory processes would be modulated due to MetS following AgNP exposure via lipid dysregulation. C57BL/6J male and female mice were fed either a healthy diet or a high-fat Western diet for 14 weeks. Subsets of mice were exposed to 50 μ l of water (control) or 50 μ l of 20 nm AgNPs at 1 mg/ml via oropharyngeal aspiration. Endpoints of lung and systemic injury, inflammation, and lipid dysregulations were evaluated 24 hours post-exposure. Analysis of bronchoalveolar lavage fluid revealed an exacerbation of AgNP-induced neutrophilic influx due to MetS in both sexes compared to healthy, while female MetS mice demonstrated elevated neutrophilia compared to male MetS mice. The exacerbation of neutrophils in female MetS was related to AgNP modulation of gene expression of pro-inflammatory mediators IL-6, CCL-2, and CXCL-2 as well as lipid metabolizing enzymes such as COX-2 and ALOX-15. Assessment of lung lipid alterations demonstrated exposure to AgNP induces inflammatory responses through prostaglandin E2 (PGE2) pathways and disrupts the protectin D1 (PD1) resolution pathway in female MetS mice. Overall, notable sex differences were identified, particularly in the presence of MetS, indicating a sex-specific vulnerability linked to the underlying disease. This vulnerability may be influenced by sex-specific dysregulation of lipid signaling following inhaled particle exposures.

W 1258 Woodsmoke-Induced Airway Injury Is Preventable with MEK Inhibition

C. Cherry. University of California Los Angeles, Los Angeles, CA.

From the warmth of woodburning stoves or campfires to the devastation of wildfires, woodsmoke (WFS) permeates both our ambient and household environment, but the health risks from these exposures are not known. Upper airway samples from patients exposed to the Los Angeles wildfires demonstrate epithelial tissue damage, including loss of the airway epithelial barrier and thickened basement membrane. Consequently, transmission electron microscopy demonstrates intracellular localization of metals and ultrafine particulates, including within surface airway epithelial cells and tight junctions. To further understand this phenotype, we developed an environmental exposure system to directly expose primary human airway cultures to woodfire smoke (WFS) that closely replicates the chemical and particulate composition of WFS from ambient biomass combustion. Exposure of the human airway cultures to WFS shows transcriptional downregulation of cytoskeletal and microtubule binding genes. While minimal changes occur in protein abundance, phosphoproteomic analysis reveals dephosphorylation of cilia-related, tight junction, and cytoskeletal proteins that contribute to impaired ciliary function. Ultimately, these changes lead to loss of epithelial barrier integrity, as well as ciliary paralysis, which only partially recovers over time. Furthermore, we demonstrate that inhibition of the MAPK pathway during or after WFS-induced epithelial injury preserves tight junction integrity together with ciliary motility, allowing for maintenance of the epithelial barrier. Overall, this work offers mechanistic insights into WFS-induced airway injury observed both *in vitro* and *in vivo* and highlights a promising therapeutic strategy for mitigating this injury. These findings underscore the potential of this therapeutic approach to protect populations at high risk of wildfire smoke exposure, including communities in fire-prone regions, firefighters, individuals with occupational exposures, and military personnel exposed to burn pits, offering a strategy to mitigate airway injury and improve respiratory health in these vulnerable groups.

K. Schichlein. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Ozone is a common respiratory irritant formed through photochemical reactions of nitrogen oxides (NOx) and volatile organic compounds (VOCs). Exposure is linked to increased risks of cardiopulmonary and neurological diseases, cancer, and mortality. In the respiratory tract, chronic ozone exposure can contribute to lung disease pathogenesis—including COPD and asthma—especially in adolescents, through mechanisms such as airway inflammation, hyperreactivity, reduced pulmonary function, increased infection susceptibility, and exacerbation of pre-existing conditions. Susceptibility to ozone's effects varies due to genetics, age, sex, comorbidities, and dietary factors. Our lab recently conducted an exploratory study examining how acute ozone exposure alters cholesterol biosynthesis derivatives in the lung and systemically. We found significant changes in cholesterol precursors and derivatives in plasma and sputum of asthmatic and non-asthmatic subjects. Notably, in non-asthmatics, the primary circulating form of vitamin D, 25-hydroxyvitamin D, positively correlated with lung function and sputum uteroglobin and negatively with sputum neutrophils, total cell count, and multiple cytokines—suggesting a protective role against ozone-induced inflammation and functional decline. Given these findings, we hypothesized that vitamin D supplementation could offer protection from ozone exposure. Although oral vitamin D has been proposed as a treatment for lung diseases such as COPD, asthma, influenza, and COVID-19, results have been mixed despite clear associations between vitamin D status and disease outcomes. We proposed that inhaled vitamin D may offer a more effective delivery route to protect the lungs from ozone damage. In this study, we expanded on prior findings by (a) examining vitamin D's effects on ozone-induced inflammation in airway epithelial cells, (b) evaluating the protective potential of nebulized apical vitamin D administration, and (c) investigating the cellular mechanisms underlying vitamin D's protective effects

W 1260 **Targeting Wildfire Smoke-Induced Neuroinflammation: Mechanisms of Immune Cell Infiltration and Emerging Interventions**

B. Baird. University of New Mexico, Albuquerque, NM.

Over the past four decades, wildfires in the U.S. have intensified, largely due to climate change. The resulting smoke poses serious health risks, including cardiovascular, respiratory, and neurological effects. A key neurological consequence is neuroinflammation, which may lead to both acute and long-term outcomes. This study investigates the immune timeline of woodsmoke-induced neuroinflammation and explores dietary and therapeutic interventions, including lipid mediators and Rho-Kinase inhibitors. Young female C57BL/6 mice were exposed to either filtered air or woodsmoke (500 µg/m³ particulate matter) for 4 hours/day on alternate days over 14 days. Exposure was generated using a smoldering temperature, creating a distinct particulate matter profile with unique physiochemical properties compared to complete combustion. Brains were examined at 1, 14, and 28 days post-exposure using high-dimensional flow cytometry to assess markers of peripheral immune infiltration (CD3, CD4, CD8, LFA-1), resident immune cells (CD11b, ACSA-2), and inflammation-related proteins. Two high-fat diets—a coconut oil diet and a Western diet—worsened immune cell infiltration and delayed resolution of inflammation. Additionally, the Rho-Kinase inhibitor fasudil was tested for its ability to stabilize the blood-brain barrier and reduce immune cell influx. The Omega-3 fatty acid Resolvin D1 (RVD1) was administered to assess its anti-inflammatory vascular effects. Results showed a diet- and time-dependent increase in CD4 T cells (CD3+, RORγ+, FOXP3-, CD44+) that may promote inflammation resolution. Immune markers such as LFA-1, ICAM, and VCAM peaked one day after the final exposure, indicating a sustained inflammatory response. Both high-fat diets prolonged this response beyond 28 days. Fasudil significantly reduced immune cell entry into the brain, suggesting that blood-brain barrier compromise contributes to neuroinflammation. RVD1 effectively countered the pro-inflammatory effects of the Western diet and accelerated recovery, shortening the inflammation timeline by two weeks. Overall, this study highlights the role of peripheral immune cells in CNS inflammation following woodsmoke exposure and demonstrates the potential of dietary and pharmacological interventions to mitigate these effects.

W 1261 **Air Pollution Derived Fe-Oxide Inhalation Produces Persistent Sex-Specific Behavioral and Morphological Deficits in Mice**

J. George. University of Rochester Medical Center, Rochester, NY.

New abstract to replace the EPA speaker's abstract (new abstract needed to remove the EPA references):

Iron-overload, a hallmark and potential contributor to neurodegeneration, comprises a large portion of ultrafine particulate (UFP) matter of air pollution, with especially high concentrations in US subway systems. Previous research demonstrated that

Fe-oxide nanoparticles can translocate along cranial nerves into the brain, form deposits within the brain, and associate with degenerating myelin. We hypothesize that the essential role Fe plays in myelination and the direct physical damage caused by Fe-oxide nanoparticle transport along axons can contribute to the sex-specific white matter dysregulation observed in neurodegeneration. To assess the impact of Fe-oxide nanoparticle inhalation and age-related increases in brain Fe content on white matter, two cohorts of 10-week-old C57BL/6 mice were randomly exposed to HEPA-filtered air or 1.5 ng/L iron-oxide UFPs for two hours daily for 20 days. An acute cohort was either acutely sacrificed followed by MRH or subjected to a behavioral battery. The other cohort aged undisturbed in their home cage until MRH, and a broad behavioral battery were performed at 12 and reassessed at 18 months. Micro-dissected corpus callosum from 18-month-old animals were sent for electron microscopy imaging. Acutely, Fe-exposure produced sex-specific diffusivity differences in olfactory bulb, with Fe-exposed females exhibiting increases in diffusion indices and males decreases. At 12 months, significant increases, not decreases, in fractional anisotropy in both sexes were observed in caudal regions along the olfactory circuit. In Novel Object Recognition, Fe-exposed female mice had significantly lower recognition indices acutely and at 12 months indicating a persistent, female-specific memory deficit. No locomotor or motor changes were observed in either sex at 12 months of age, however, at 18 months, Fe-exposed male mice exhibited significant hypoactivity on a locomotor assay and significantly more footslips on a 2.5cm and 1.25cm balance beam on days 2 and 3, representing an emergent male-specific motor deficit after early adulthood Fe-oxide exposure. Ultrastructural 18-month corpus callosum myelin analyses demonstrated Fe-induced female-specific decreases in g-ratio and increases in axon, fiber, and myelin area indicating thicker myelin sheaths. However, Fe-exposed female mice were also found to have significantly more split myelin sheaths indicating significant myelin dysregulation in Fe-exposed females. Contrastingly, Fe exposure significantly increased total fiber and myelinated areas in males without concomitant decreases to g-ratio or increases in axonal area. Similar to Fe-exposure in females, Fe-exposed males also had significantly more split myelin area. However, when considering geometry of the axons, significant sex-specific changes to circularity index were observed with Fe exposure reducing circularity index in females but increasing the index in males. This change in axonal geometry could potentially underlie sex differences in diffusivity. Early adulthood Fe-oxide nanoparticle inhalation produces sex-specific behavioral and morphological differences that persist and even, emerge, with age. The observed behavioral differences indicate that Fe-exposures produces sex-specific behavioral alterations with females exhibiting persistent short-term memory deficits and males exhibiting emergent motor deficits at 18 months. Fe-exposure produced acute sex-specific differences in white matter in the olfactory bulb and these diffusivity differences moved caudally with age. At the ultrastructural level, Fe-exposure produced sex-specific changes in g-ratio and axonal geometry which could potentially underlie diffusion differences. These data suggest that Fe-oxide inhalation can cause sex-specific white matter dysregulation with concomitant behavioral deficits.

IS 1262 **Advancing Risk Communication: Strengthening Collaborations Between Toxicologists and Exposure Scientists in the Face of a Changing Regulatory Landscape**

N. Erraguntla. American Chemistry Council, Washington, DC.

Clear and strategic risk communication among all stakeholders—including regulatory agencies at the state, federal, and international levels; industry; the scientific community; and the public—is essential to informed and effective decision-making. It enables all stakeholders to contribute as knowledgeable and trusted partners in conveying scientific evidence, operational practices, and exposure mitigation strategies. This collaborative communication fosters transparency; strengthens stakeholder trust; and supports the development of science-based, practical policies that protect public health and the environment. The 2016 amendments to the Toxic Substances Control Act (TSCA) ushered in a new era of comprehensive risk evaluation for high-priority existing chemicals and offered the opportunity to identify risk communication best practices among diverse stakeholders. The TSCA process provides an example of a complex regulatory process spanning chemical prioritization, risk evaluation, and risk management rulemaking. This process has created multiple layers of stakeholder engagement and information exchange. Key insights have emerged on how to successfully navigate and enhance these communication pathways to improve program outcomes. This session will examine effective risk communication strategies specific to the fields of exposure assessment, epidemiology, toxicology, and risk assessment. Regulatory experience has revealed common challenges and highlighted best practices for information clarity and stakeholder alignment. Refined methods for peer engagement—developed by the US EPA and stakeholders alike—are increasingly tailored to the goals of each communication effort. Research on selecting and optimizing these methods will be discussed. A critical lesson learned is the importance of a well-defined assessment purpose, clearly articulated through robust problem formulation. Case studies will illustrate how improved information flow supports US EPA analyses, particularly through comprehensive use-mapping that represents the full value chain. Product stewardship toxicologists are instrumental in providing context and clarity. Occupational toxicologists play an important role in contextualizing health risk values and fostering effective communication with workers and their representatives. Further, opportunities continue to emerge to more fully utilize exposure data to communicate risk characterization findings to communities adjacent to industrial facilities. As risk determinations give rise to

risk management rules, toxicologists serve a vital role in interpreting and conveying their implications to diverse audiences, including regulatory bodies, communities, and workers. Emerging technologies may further revolutionize how data and knowledge are shared in regulatory contexts. Toxicologists must develop proficiency in these evolving tools to remain effective communicators in the next generation of regulatory science. This session will highlight practical examples and innovative approaches to risk communication that are not only relevant to TSCA but also universally applicable across other regulatory frameworks in the toxicology field.

PL 2000 Multi-Task Neural-ODE Modeling of Nanoparticle Biodistribution in Tumor-Bearing Mice for Toxicological Risk Assessment

Z. Zhang, and Z. Lin. University of Florida, Gainesville, FL.

Background and Purpose: Understanding the biodistribution of nanoparticles in tumors and major organs is essential for advancing nanomedicine design, optimizing therapeutic efficacy, and minimizing off-target toxicity. Traditional pharmacokinetic (PK) models, while mechanistically interpretable, often struggle to generalize across heterogeneous nanoparticle formulations and tumor models. Conversely, purely data-driven machine learning methods can capture complex relationships but lack the temporal continuity and biological realism required for concentration-time prediction. Neural ordinary differential equations (Neural-ODEs) provide a promising framework by embedding differential equation solvers within neural networks, enabling flexible modeling of dynamic PK processes. We developed a multi-task Neural-ODE to predict nanoparticle biodistribution in tumors and six major organs of tumor-bearing mice, enabling zero-shot prediction for unseen formulations and providing a data-driven yet biologically grounded tool for nanomedicine development. **Methods:** This study compiled biodistribution data of nanoparticles from the Nano-Tumor Database reported by Chen et al. (2023, ACS Nano), which integrates 534 tumor datasets (2345 data points) and 1972 datasets (8461 data points) for five major organs (liver, spleen, lung, heart, and kidney). Categorical variables such as particle type and tumor model were represented through learned embeddings, while numeric features were log-scaled and standardized, with binary flags added for imputed values. A static context vector was formed by concatenating all embeddings and scaled features and was used to condition the Neural-ODE at three levels: the initial latent state after bolus dosing, the latent dynamics through feature-wise modulation, and the tissue-specific decoders. A multi-task learning framework was implemented by sharing one NODE backbone across all tissues, with organ-specific heads producing concentration-time profiles. Model training minimized mean squared error on log-transformed concentrations, with uncertainty-based loss weighting applied to balance tissue-specific prediction tasks. Feature screening was conducted within cross-validation using a consensus approach that combined LASSO regression, random forest permutation importance, and mutual information, retaining features consistently ranked among the most predictive. Data were split at the nanoparticle formulation level (80% training/validation set and 20% independent test set) to prevent information leakage across studies and to ensure generalization to unseen designs. Model evaluation was performed using a held-out test set, with performance assessed by coefficient of determination (R^2), root mean squared error (RMSE), and mean absolute error (MAE) on log-transformed concentrations. **Results:** The multi-task Neural-ODE model successfully captured the temporal dynamics of nanoparticle biodistribution across tumors and major organs. Cross-validation results demonstrated consistent performance across tissues, with mean R^2 values exceeding 0.70 for tumor and liver, and 0.60-0.68 for kidney, spleen, lung, and heart. The model effectively generalized to unseen nanoparticle formulations in the test set, achieving overall $R^2 = 0.65$, with root mean squared error (RMSE) $<0.25 \log(\%ID/g)$. Feature selection identified hydrodynamic size, zeta potential, targeting strategy, tumor size, and body weight as the most predictive covariates influencing biodistribution patterns. **Conclusions:** The development of a multi-task Neural-ODE framework that integrates nanoparticle physicochemical, tumor, and animal covariates has demonstrated strong potential for accurately predicting biodistribution time-courses across tumors and major organs in mice. Importantly, this framework provides a biologically grounded yet flexible approach for capturing both the therapeutic targeting of tumors and unintended accumulation in off-target organs, which are crucial for nanoparticle safety evaluation. This modeling strategy provides a powerful data-driven tool to support nanotoxicology assessment by predicting tissue-specific exposure patterns underlying efficacy-toxicity trade-offs. Future work may extend this approach to repeated dosing, species extrapolation, and mechanistic priors, advancing risk assessment and safer nanomaterial design.

PL 2001 RADisH: ROBOKOP Assisted Discovery of *in silico* Hypotheticals, A case study of mechanisms linking nuclear receptors to liver disease

N. Tucker¹, M. DeLuca¹, J. Beasley¹, J. Wellnitz¹, K. Fecho², K. Carter³, C. Bizon³, and A. Tropsha¹. ¹University of North Carolina at Chapel Hill, Chapel Hill, NC; ²Copperline Professional Solutions, Chapel Hill, NC; and ³RENCI, Chapel Hill, NC.

Background and Purpose: Adverse Outcome Pathways (AOPs) describe the cascade of biological events leading to toxic outcomes. An AOP is typically built through manual efforts of subject matter experts identifying empirical molecular or biolog-

ical evidence for each node in the chain beginning with Molecular Initiating Events (MIEs) and intermediary Key Events (KEs) that culminate in an Adverse Outcome (AO). Recent developments in biomedical information retrieval led to the emergence of biomedical Knowledge Graphs (KG), which integrate multiple elementary semantic triples, i.e., special 'subject-predicate-object' relationships between entities (such as 'chemical X causes hepatotoxicity') described in biomedical literature or databases. One KG, ROBOKOP (Reasoning Over Biomedical Objects linked in Knowledge Outcome Pathways), is a biomedical publicly available graph integrating 50+ databases to include over 9M nodes and 140M edges. ROBOKOP is a tool developed and maintained as a collaboration of the UNC's Molecular Modeling Laboratory and UNC's Renaissance Computing Institute (RENCI). **Methods:** ROBOKOP Assisted Discovery of *in silico* Hypotheses (RADisH) is a methodology for automated discovery of AOPs based on graph mining algorithms. We first evaluated the KG's ability to reconstruct known biological event networks, referencing Adverse Outcome Pathways (AOPs), by querying the KG against a reference list of well-supported AOPs and determining the portion successfully reproduced (recall). The recall metric, or the number of events from the reference that are identified by the KG divided by the total events identified, demonstrates the capacity of the KG to capture known biological mechanisms and validity of the tool to potentially propose hypothetical components. To test this hypothesis we consider the use case of nuclear receptor activation initiating events in the development of fatty liver disease by referencing the events described by the thirteen expert-defined AOPs in the AOPwiki.org. Queries to the graph are structured as (nuclear receptor → fatty liver disease) and the resulting list of genes is evaluated against the events described across all AOPs. **Results:** Of the approximately 50 unique events described across the thirteen AOPs in AOPwiki, KG queries considering just one nuclear receptor, AhR, resulted in 34 genes of which 26 were partial (i.e., LDLR is in the wiki but the result returned from ROBOKOP is LDLR variant LDLRAP2) or complete matches to AOP events implying a recall of ~70%. The remaining 8 genes not matched to existing AOP events, including SUMO2 and SOD2, were evaluated for plausibility within the context of fatty liver disease and investigated for potential applicability as hypothetical mechanistic event candidates. A comprehensive query considering all MIEs described in AOPwiki entries identifies nearly 160 genes, or some four times the number of explicitly identified genes or gene-products within AOPwiki entries for fatty liver disease. **Conclusions:** The use of novel hypothetical mechanisms identified through ROBOKOP mining can support future development of quantitative models predicting chemical toxicity. Furthermore, these hypothetical mechanistic events can be tested empirically by biomedical researchers using *in vitro* and *in vivo* tools to evaluate potential causality of the novel KEs and broaden the scope of biomedical knowledge. RADisH presents a methodology which may further enhance present applications of the AOPwiki database, and may contribute to the development of wholly computationally predicted AOPs (cpAOPs) by going beyond simple elaboration on events as identified in this work to instead suggest new chains of events in the AOP style.

PL 2002 From black boxes to chemical interpretability: explainable deep learning for mutagenicity prediction

D. Khasanova^{1,2}, C. H. Schwab¹, O. Sacher¹, T. Magdziarz¹, C. Barber³, and I. Tetko². ¹MN-AM, Molecular Networks GmbH, Nuremberg, Germany; ²Helmholtz Munich, Institute of Structural Biology, Neuherberg, Germany; and ³Lhasa Limited, Leeds, United Kingdom.

Background and Purpose: Deep learning models have become powerful tools for predicting chemical toxicity but often act as "black boxes", limiting trust among experimental scientists. Explainable artificial intelligence (XAI) addresses this by generating feature maps that highlight atoms or molecular scaffolds influencing toxicity predictions. Such interpretability helps users understand model behavior and refine models accordingly. However, the reliability of current XAI methods remains uncertain, as studies have reported inconsistencies across methods and with established chemical knowledge. Here, five widely used XAI techniques are benchmarked for their ability to identify molecular scaffolds and explain mutagenicity predictions. The structural motifs highlighted by these methods are compared with known toxicophores to assess interpretive value and limitations. Based on these insights, the model was refined by incorporating molecular descriptors: global physicochemical (e.g., HOMO-LUMO gap, logP), local electronic (Fukui indices), and geometrical (molecular shape) to improve predictive performance and clarify toxicological reasoning. **Methods:** Molecular structures were represented using SMILES strings. An encoder-decoder model was trained on ChEMBL to convert non-canonical to canonical SMILES. The pretrained encoder, with frozen weights, was then used to extract embeddings for scaffold or property prediction. These embeddings served as input to a Text-CNN trained on the Ames dataset (~7,000 molecules). The CNN used multiple parallel convolutional layers, followed by fully connected layers for multi-label (scaffold) or binary (toxicity) classification. Five explainability methods were evaluated: Integrated Gradients (IG), SHAP GradientExplainer, DeepLIFT, Occlusion, and Grad-CAM, representing gradient-based, backpropagation-based, and perturbation-based techniques. For properties requiring geometry optimization, molecules were protonated to their dominant forms at physiological pH (7.4) and converted into 3D structures using RDKit and custom scripts. Conformer ensembles were generated with CREST and further optimized via semiempirical and DFT calculations using ORCA. The resulting molecular descriptors were merged with CNN embeddings for the final prediction. **Results:** The model achieved a micro-averaged ROC-AUC of 1.0 for scaffold prediction, showing perfect discrimination, and 0.85

for Ames mutagenicity. Both models showed the same general tendency: attribution patterns from IG, DeepLIFT and SHAP were highly consistent, while Occlusion showed slightly larger deviations and Grad-CAM produced broader, more diffuse maps. Mean cosine distances between attribution vectors quantified method similarity, where lower values indicate better agreement. For Ames, mean cosine distances were $\sim 1.0 \times 10^{-4}$ (SHAP-IG), 7.0×10^{-4} (IG-DeepLIFT), 1.7×10^{-2} (Occlusion), and 1.8×10^{-1} (Grad-CAM). All methods correctly highlighted known toxicophores. Compared with toxicophore-based screening, the model reduced false positives by $\sim 51.3\%$, while false negatives remained nearly unchanged. After adding molecular descriptors, the Ames ROC-AUC increased to 0.88, and additional structural features, such as conjugated systems, were emphasized by XAI attributions. **Conclusions:** Explainable deep learning can achieve high predictive accuracy for chemical toxicity while preserving interpretability. Benchmarking multiple XAI methods showed that gradient- and backpropagation-based approaches yield consistent, chemically meaningful attributions aligned with known toxicophores. Integrating molecular descriptors with neural embeddings further improves both performance and interpretability, supporting more transparent identification of structural drivers of mutagenicity.

PL 2003 Leveraging Automated Data Mining and Machine Learning to Rank and Predict PFAS Toxicity

T. Yang, and P. Gao. Harvard University, Boston, MA.

Background and Purpose: PFAS are a large class of persistent chemicals. More than 1,400 have been identified in over 200 uses across 64 categories. Composed of carbon chains densely bonded with fluorine, these molecules possess exceptionally strong C-F bonds, which confer outstanding repellency to water and grease as well as remarkable resistance to environmental degradation. Although thousands of PFAS are widely used in commercial products, only a small fraction have been systematically studied for their toxic effects. Notably, two individual compounds, PFOA and PFOS, alone account for 21% and 39% of the entire dataset, respectively. While legacy PFAS such as PFOA and PFOS have been extensively studied, the overwhelming majority of PFAS remain largely untested, creating substantial data gaps that hinder comprehensive ecological risk assessments and effective regulatory decision-making. Despite recent advances, existing models remain constrained by **underutilization of qualitative non-animal-derived data, and reliance on relatively simple computational approaches** that fail to fully capture species-specific variability. Significant challenges remain in effectively addressing the PFAS toxicity data gap. **Methods:** we designed a framework that begins with systematic searches of databases such as PubMed, Web of Science, and EPA ECOTOX to identify relevant PFAS toxicity papers. We automatically retrieved publications from PubMed using Python scripts—via the official API, with a crawler based on requests and BeautifulSoup as a fallback. A multi-modal LLM (with the ChatGPT API) will then be applied to parse full texts and extract both quantitative endpoints and comparative ranking statements. A representative subset of the extracted data will be manually reviewed to verify the accuracy and validity of the ranking labels. Quantitative endpoints will be standardized into consistent units and harmonized across studies, while narrative comparative statements will be translated into relative ranking matrices. Uncertainty of the narrative comparison will be assigned based on a matrix of how comparable they are in literature. We then apply a pair-wise Learning to Rank framework to train machine learning models (e.g., Random Forest, XGBoost, LightGBM). **Results:** we demonstrated an automated Python extraction, pulling toxicity information from the PFAS-TOX database. To demonstrate applicability, we performed simple feature extraction and trained standard machine learning models (GAM, random forest, XGBoost) on a small PFAS-specific dataset. In parallel, we trained a Bayesian Matrix Factorization model on a larger dataset (PFAS-specific + ADORE) without feature extraction, considering only chemical-species comparison relationships. We compared the models on the same test dataset, models trained on the small dataset with limited feature extraction outperformed the larger dataset model despite having fewer samples. Moreover, Figure highlights carbon chain length as a key predictor of PFAS toxicity. Furthermore, we trained four machine learning models—random forest, SVM, MLP, and Naïve Bayes—within the pairwise learning-to-rank framework to demonstrate its feasibility. Figure shows the NDCG@5 comparison, with random forest achieving the best performance at 0.897. **Conclusions:** This approach directly advances the 3Rs by replacing animal testing with computational methods, potentially eliminating 10,000+ animal tests annually while providing regulators with urgently needed risk prioritization tools within weeks rather than years.

PL 2004 Deciphering exposure-driven biology through integrative multi-omics using tidyexposomics

J. Laird^{1,2}, T. Hartung^{1,2,3}, F. Sillé^{1,2}, and A. Maertens^{1,2}. ¹Johns Hopkins University, Baltimore, MD; ²Center for Alternatives to Animal Testing (CAAT), Baltimore, MD; and ³CAAT-Europe, Konstanz, Germany.

Background and Purpose: Human exposome research tackles the daunting task of integrating heterogeneous exposure, molecular and phenotypic data in order to understand exposure-response relationships. However, current analytical frameworks are fragmented, difficult to reproduce and lack standardization tools. To address these gaps, we developed tidyexposomics, an open-source R package that

provides a modular and reproducible framework for exposure assessment, multi-omics integration and downstream interpretation. **Methods:** The current implementation of tidyexposomics contains several modules. Data pre-processing functions allow for ontology-term assignment for interoperability of findings, missingness, imputation and data transformation assessment, sample clustering, and dimensionality reduction analysis. Exposome scoring enables exposure summarization to characterize the impact of multiple exposures. Association analysis can be performed between exposure, phenotype, and omics data. Network analysis modules can prioritize exposures with differential effects on omics features. Functional enrichment of exposure-responsive omics features supports biological interpretation. Several pivot functions enable the user to access data in a way to support custom analysis. Finally, pipeline tracking and result export features streamline transparent reporting. **Results:** We applied tidyexposomics to analyze exposomics and multi-omics data from children with and without asthma from a lower socioeconomic background from the ISGlobal Exposome Data Challenge 2021. Ontology categorization organized exposure variables into general groups (e.g. aerosols, polyatomic entities, and transition metals). Particulate matter and perfluorohexane sulfonic acid (PFHxS) exposure were correlated with the most principal components. Multi-omics integration identified several latent factors that jointly explained variation in asthma status. Omics features with high loadings on these factors were associated with exposures. Although no individual exposures were significantly associated with asthma status, the omics features linked to both asthma and exposure variation were enriched for biologically meaningful pathways. Gene expression features were associated with terms related to vesicle dynamics, while methylation features were associated with kinase activity and developmental processes. **Conclusions:** tidyexposomics provides a comprehensive and reproducible computational framework for exposome-omics research in toxicology. Overall, tidyexposomics enables toxicologists to systematically understand the potential molecular mechanisms of exposure effects and accelerates the translation of exposomics into actionable insights for human health.

PL 2005 Cross-Species Translatability Illuminated by Over 7,000 Marketed and Investigational Drugs: Modality and Species-Stratified Concordance Mapping Between Preclinical and Clinical Phenotypes

X. Liu, and F. Fan. J&J, San Diego, CA.

Background and Purpose: Translating preclinical safety findings into actionable insights for human risk assessment remains a central challenge in drug development. Despite advances in data curation, previous studies have faced limitations such as biased drug selection, insufficient stratification by species and drug modality, inadequate exposure control, inconsistent analytical approaches, and restricted data access. In this context, the purpose of this work is to systematically evaluate the relationship between preclinical toxicity phenotypes and clinical safety outcomes, offering a more robust and transparent foundation for translational safety assessment. **Methods:** Animal and human safety endpoints were harmonized via MedDRA mapping by integrating PharmaPendium with OFF-X platform, enabling standardized, cross-species analyses across five major preclinical species (mouse, rat, rabbit, dog, monkey) and humans. Our analytic strategy prioritizes likelihood ratios to minimize prevalence bias and systematically extends beyond identical-term mapping by including semantically and mechanistically related, non-identical adverse event pairs. Analyses were further broken down by species, drug type, and adjusted for drug exposure. We also linked safety findings to drug targets and biological pathways to understand the underlying mechanisms. Finally, all results were made accessible through a user-friendly web app and an AI-powered multi-agent system, enabling scientists to explore and use the data for decision-making. **Results:** Our concordance analysis produced a wealth of insights into how animal toxicity findings relate to human safety outcomes, covering more than 3,000 distinct toxicity phenotypes. Moving beyond strict identical-term mapping, the inclusion of semantically similar and mechanistically related adverse event pairs uncovers a broader spectrum of cross-species associations to clinical outcomes. Stratified analyses by species, drug modality, and exposure control enable better defined searches and more informative answers, which are much needed for human translation. Integrating both target and off-target annotation further enriches mechanistic interpretation, revealing biological pathways and potential safety targets for subsequent validation. To ensure that these advances translate into day-to-day impact, we developed the web app and the multi-agent AI system (ToxAgents), which transform concordance analytics into actionable decision support. The app provides an interactive interface for exploring concordance results, and the ToxAgents layers on structured, role-aligned reasoning for translational safety. The investigative scientist agent interrogates the concordance data, together with the safety-ome of safety-critical targets, to assemble mechanistic rationales and prioritize candidates for further evaluation. In parallel, the regulatory-affairs agent interprets outputs in the context of ICH safety guidelines and organized recommendations for study design. Together, the agents synthesize search results to support human risk assessment, species selection, mechanistic follow-up, and preparation for regulatory interactions. This architecture facilitates broad, standardized access to concordance analytics, promoting wider adoption across scientific and pharmaceutical communities. **Conclusions:** Altogether, this work offers a comprehensive and mechanistically informed concordance framework that directly addresses challenges in preclinical-to-clinical translation. By integrating statistical, pharmacological, and regulatory knowledge and making these insights

accessible through interactive tools, the study provides a transparent foundation for more informed safety assessment, mechanistic exploration, and early development decision-making.

PL 2006 Unique Nonclinical Safety Profile of PF-06835919, A Ketohehexokinase Inhibitor, Highlights A Species-Dependent Mechanism

J. Zhou¹, C. Houle¹, F. Geoly¹, S. Campion¹, and J. C. Cook^{1,2}. ¹Drug Safety R&D, Pfizer Research and Development, Groton, CT; and ²Retired, East Lyme, CT.

Background and Purpose: PF-06835919, a first-in-class ketohehexokinase (KHK) inhibitor, was developed for the treatment of non-alcoholic fatty liver disease (NAFLD). To support its clinical development, nonclinical safety studies were conducted according to regulatory guidelines. In rats, repeat-dose administration of PF-06835919 for up to 6 months produced various findings resembling those produced by peroxisome proliferator-activated receptor (PPAR) activation. Mechanistic studies were therefore conducted to understand the relationship between these findings and PPAR as well as their human relevance. **Methods:** Repeat-dose toxicity studies were conducted in Wistar Han rats (up to 6 months) and beagle dogs (up to 9 months). Investigative studies were conducted *in vitro* or in rats. **Results:** Based on exposures at no-observed-adverse-effect levels (NOAELs), rat was the more sensitive species, and clinical doses were limited to the rat NOAEL (30 mg/kg/day) exposure. Consistent with hepatic microsomal enzyme induction, hepatocyte hypertrophy and higher liver weight were observed in rat toxicity studies, together with secondary hypertrophy/hyperplasia of thyroid follicular cells and vacuolation of cells in the pars distalis of the pituitary gland. The severity/incidence of these findings increased with longer study duration, with preneoplastic eosinophilic foci of cellular alteration in the liver and follicular cell adenoma and diffuse follicular cell hyperplasia/hypertrophy in thyroid observed at higher doses in the 6-month toxicity study. Other findings in the 6-month rat study included increased heart weight, decreased lipid in the mesenteric white fat and increased brown fat (renal hilus) accompanied by changes in cholesterol and triglycerides, increased incidence of decreased/absent corpora lutea in the ovary, and degeneration of seminiferous tubules in the testis. Transmission electron microscopy (TEM) revealed increased endoplasmic reticulum as well as a non-uniform, variable, mild to marked increase in the size and number of peroxisomes in hepatocytes. In 2-, 6-, 16-, and 39-week toxicity studies in dogs, none of these findings, except for lower cholesterol and higher heart weight, were present. In rat liver tissues after 2 weeks of administration of PF-06835919, gene expression levels of CYP 2B1/2B2, 3A1/3A5, 3A2/3A4, UGT 1A1, and UGT 2B1 were significantly upregulated at high doses. In cells expressing a luciferase reporter gene functionally linked to a rat or human PPAR-responsive promoter, PF-06835919 showed no effects on PPAR α or β/δ activities and only weak activity on PPAR γ at 30 μ M, a concentration significantly higher than that required for inhibiting KHK activity or the predicted exposure at the highest planned clinical dose. **Conclusions:** PF-06835919 is not a direct PPAR agonist and does not pose risks in humans via PPAR activation at clinical planned doses. The liver findings and associated thyroid and pituitary gland changes were primarily mediated by test article-related enzyme induction. Induction of UDP-glucuronyl transferases correlated with enhanced thyroid hormone elimination. Hypothyroidism, secondary to the liver enzyme induction, likely caused the increased incidence of decreased/absent corpora lutea. The heart weight increase was an adaptive change to the hemodynamic effects of the test article (heart rate and blood pressure increase). Lipid changes were likely a pharmacological effect of KHK inhibition. Peroxisomes might be upregulated physiologically as an adaptive change associated with metabolic alterations related to the pharmacology of PF-06835919.

PL 2007 The application of New Approach Methods in drug discovery: Three case studies of fit-for purpose model development to improve human risk translation

A. Sedgwick, B. Cai, T. Wyseure, and W. Hu. Vividion Therapeutics, San Diego, CA.

Background and Purpose: New approach methodologies (NAMs) have rapidly evolved in recent years. These include *in vitro* systems and assays that provide much needed tools for modern toxicology in drug discovery and development, from mechanistic understanding of specific toxicities to cross-species translation and risk assessment. Implementing NAMs not only reduces animal use but also provides data-driven understanding and prediction of risks in humans at an early stage to help decision making. Here, we present three case studies in which *in vitro* assays were employed for early human risk prediction and assessment. In these studies we sought to understand the human translation of 1) unusual upper GI hyperplasia observed in rodents only following repeat-dose studies, 2) potential for reduced skin toxicity by selectively targeting a mutant form of target protein, 3) local muscle tolerability of different excipients for subcutaneous injection. **Methods:** In case study #1, an air-liquid interface model of primary cells was developed to compare the responses of mouse, rat, dog, and human esophageal epithelial cells to a panel of proprietary compounds being developed for an immunology indication. The cells were grown in Transwell culture and differentiated over the course of 8 days, followed by 7 days of treatment, and then assessed by transcriptomic anal-

ysis and histology. In case study #2, the MatTek EpiDermFT model, starting from an immature and partially differentiated stage, was treated for 10 days with tool molecules alpelisib (PI3K α inhibitor), capivasertib, or MK-2206 (pan-AKT inhibitors), or the AKT1-E17K mutant selective compound VVD-009, and toxicity was assessed by histology. In case study #3, L6 rat skeletal muscle myotubes and human primary skeletal muscle myotubes were differentiated in culture over 72 hours prior to treatment with increasing concentrations of the excipients sulfolbutylether-beta-cyclodextrin (SBE- β -CD) or hydroxypropyl-beta-cyclodextrin (HP- β -CD), and assessed by live cell imaging and ATP measurement of cell viability after 24 hours of treatment. **Results:** Case study #1: Only mouse and rat *in vitro* cultures exhibited a hyperproliferative phenotype as evidenced by increased cell layer thickness and irregularity in response to compound treatment whereas dog cultures did not. This is consistent with the *in vivo* phenotypes observed in the respective 2-4 week tox studies. Rodent cultures also showed increased expression of proliferative markers, indicating that this finding could be due to increased sensitivity to inhibition of this pathway in rodents. Human cultures, similar to that of dogs, did not display a proliferative response. Case study #2: Whereas alpelisib, capivasertib, and MK-2206 all caused a notable thinning of the epidermis and loss of skin barrier integrity, recapitulating their clinical skin toxicity, the AKT-E17K mutant selective inhibitor VVD-009 did not, at doses exceeding the predicted clinical exposures. Case study #3: Whereas a concentration-dependent increase in rat and human myotube death was observed for both SBE- β -CD and HP- β -CD at higher concentrations, SBE- β -CD demonstrated less toxicity at clinically-relevant concentrations. This data is consistent with exploratory studies in rats where SBE- β -CD showed superior local muscle tolerability as compared to HP- β -CD. Based on this data, SBE- β -CD was selected as the excipient for future studies and clinical formulation development for a better injection site safety profile. **Conclusions:** The qualification of NAMs for fit-for purpose use is an ongoing process across the pharmaceutical industry, with needs in many different facets of preclinical de-risking. These studies presented here demonstrate the utility of *in vitro* models for better understanding the clinical translation and potential mechanisms of non-clinical safety findings in animals, or for use where standard animal models have poorly predicted clinical toxicity.

PL 2008 Safety Evaluation of Supraphysiological Tradipitant Dosing under Differential Liver Metabolism

J. L. Carlin¹, S. Smieszek¹, G. Birznieski¹, C. Polymeropoulos¹, M. H. Polymeropoulos¹, J. Hickman², R. Brighton², M. J. Rupar², and C. Long². ¹Vanda Pharmaceuticals, Washington, DC; and ²Hesperos, Orlando, FL.

Background and Purpose: This project aimed to evaluate the safety of Neurokinin-1 receptor antagonist tradipitant in Hesperos, Inc's 4-organ system which is a multi-organ, microphysiological system composed of liver (primary biopsy), cardiac (iPSC-derived), kidney (primary biopsy) and neuronal (iPSC-derived) "organ" modules. **Methods:** Tradipitant (3 μ M, 30 μ M, and 100 μ M) was evaluated over a 14-day period of chronic dosing for toxicity, functional organ testing and biomarker assays in Hesperos, Inc's 4-organ system and compared to vehicle control and positive controls. Each concentration was tested in duplicate per experiment and across an n=4 biological replicates and stratified by low metabolizing liver, medium metabolizing liver, and high metabolizing liver cells. Systems were dosed daily and tested for functional activity at pre-dose, 1-day, 4-day, 7-day, 10-day, and 14-day post initial dose. At each timepoint functional recordings were taken as well as morphology monitoring by phase contrast imaging. For cardiac cells, beat frequency, force, conduction velocity, field potential duration (QT surrogate), and Troponin I were measured and terfenadine, doxorubicin were used as positive controls. For liver cells, a viability assay, toxicity imaging and albumin production were measured and losartan, chlorpromazine were used as positive controls. For kidney cells, kidney injury molecule 1 (KIM-1) release was measured and amphotericin B, gentamicin were used as positive controls. For cortical neurons, spontaneous firing rates were measured and kainic acid, nimodipine were used as positive controls. Medium from systems was also collected and the quantities of tradipitant and metabolites were measured. **Results:** Liver constructs showed the capability to metabolize tradipitant into its respective metabolites (M2, M3, and M4). Tradipitant 100 μ M dose showed potential hepatotoxicity as determined by viability assays and vacuole formation. However, moderate and low metabolizing liver constructs cytotoxicity was not observed at this dose. The moderate liver construct yielded significantly higher levels of albumin when compared to the low metabolizing liver and vehicle control conditions with 3 μ M tradipitant. When dosed with 100 μ M of tradipitant, the moderate liver construct yielded significantly lower levels of albumin when compared to the high metabolizing liver. Chronic exposure of tradipitant had a miniscule effect on cardiac force across all liver constructs and all dose administrations when compared to the vehicle control. However, significant variations between liver constructs were much more apparent. Across all doses, the high metabolizing liver construct showed significant increases in KIM-1 levels throughout the course of compound administration when compared to the vehicle control. The moderate liver construct showed significant increases in KIM-1 levels in only the 30 and 100 μ M doses. The low liver construct only showed significant increases in KIM-1 for the 30 μ M dose. Significant effects on cortical neuron firing rate were only observed in the high metabolic liver systems receiving a 30 μ M dose. Significantly higher levels were observed on day 1 post-dose, however this stabilized and returned to baseline over the course of the study. **Conclusions:** Chronic exposure of tradipitant in Hesperos, Inc's 4-organ system yielded only minor adverse effects in all organ constructs in which it was tested when

compared to the vehicle and positive control. When comparing the safety of the compound across systems containing either high, moderate, or low metabolic activity, significant effects could be observed. This suggests that liver function should be taken into consideration as it may influence physiological outcomes. Importantly, this system was able to demonstrate traditipant had minimal toxicity in the tested organs and is suitable for acute and chronic dosing given the absence of compensatory mechanisms observed.

PL 2009 Development of *in vivo* and *in vitro* Models for De-risking Adrenal Insufficiency

L. Liu, M. Pepper, D. Thudium, E. Besteman, M. Mulholland, C. Grace, T. Johnson, R. J. Gonzalez, and K. Pearson. Merck, West Point, PA.

Background and Purpose: Adrenal glands are common toxicological targets within the endocrine system, and adrenocortical hypertrophy is a relatively common observation, often identified in nonclinical species during drug development studies. In the absence of other indications of a stress response, an *in vivo* ACTH challenge study can be used to demonstrate drug-induced adrenal insufficiency. ACTH challenge studies in rats are typically conducted in male animals to avoid complexities introduced by the estrus cycle of females; however, a female model may be desired in some circumstances. Therefore, we attempted to establish and ACTH challenge model that could be used in both male and female rats. To complement the *in vivo* approach, we also evaluated two *in vitro* adrenocortical models for their potential as screening or mechanistic tools. Merck A is a small molecule drug candidate that caused adrenocortical hypertrophy in rats and monkeys in 1-month tox studies and in a 7-day dose-limiting toxicity study in female rats. The hypertrophy was determined to be an off-target effect. Although there were no degenerative changes and the adrenal findings were not considered adverse, the risk assessment asserted these changes were clinically translatable and likely to require nonclinical and clinical monitoring. The purpose of this research is to develop *in vivo* and *in vitro* models to characterize this toxicity and build our internal capability for de-risking adrenal deficiency. **Methods:** To examine the mechanism of adrenal hypertrophy and inform back-up derisking for Merck A, investigations were planned 1) to confirm/refute hypothesis that the adrenal changes were due to adrenal insufficiency; 2) to assess utility of commercially available adrenal cortical cultures for mechanistic investigation. We optimized dose, time and sampling conditions for the ACTH challenge model in both male and female rats. Adrenal insufficiency was demonstrated for four known steroidogenic inhibitors by measuring plasma corticosterone levels 15 minutes after ACTH or saline injection. Additionally, we developed human HAC15 cells and mouse Y1 adrenal cell culture models to detect perturbations in steroid biosynthesis. We monitored cell viability and distinct steroidogenic intermediates across multi-enzyme pathways for mode of disruption. **Results:** Merck A was evaluated in ACTH challenge model in female rats as previous studies have shown that female rats had higher drug exposure than male rats. A single dose of Merck A inhibited ACTH-stimulated corticosterone release, confirming the working hypothesis of adrenal insufficiency. *In vitro* tests with multiple steroidogenic inhibitors in HAC15 and Y1 cells demonstrated disruption in steroid production, and the responses corresponded with the mechanisms of enzyme inhibition. **Conclusions:** Taken together, we have established the conditions and utility of an *in vivo* ACTH challenge study in male and female Wistar-Han rats. Application of the model confirmed the working hypothesis of adrenal insufficiency for Merck A. In addition, we have developed resource-sparing human and mouse cells models to rapidly detect adrenocortical dysfunction. Further qualification of the *in vitro* platforms presents an opportunity to develop screening approaches and enhance our understanding of structural features associated with adrenal cortical hypertrophy risks.

PL 2010 Size-Dependent Pharmacokinetics of Oral Microplastics: Development of a Physiologically-Based Model with Local Gastrointestinal Binding

H. Nandula, W. Chou, and A. Canchola. University of California-Riverside, Riverside, CA.

Background and Purpose: Microplastic contamination in food and water poses emerging health concerns, yet a quantitative understanding of their absorption, distribution, and elimination kinetics remains limited. Existing physiologically-based pharmacokinetic (PBPK) models show poor predictive performance for gastrointestinal retention kinetics, with substantial discrepancies between model predictions and experimental measurements. We aimed to develop an improved PBPK model that accurately predicts size-dependent microplastic biodistribution following oral exposure and identifies the mechanistic basis for kinetic differences across particle sizes. **Methods:** We restructured a published PBPK model by incorporating a novel local gastrointestinal tissue binding compartment (AGI_{local}) to capture retention kinetics not explained by systemic absorption. The model was implemented in Julia and validated against experimental biodistribution data for polystyrene particles of four sizes (20nm, 220nm, 1000nm, 6000nm) at multiple timepoints (6h, 12h, 24h, 48h) following 0.1mg oral administration in mice. Parameter estimation was performed using Bayesian inference (NUTS sampler, 500 iterations) and optimization-based methods with weighted likelihood functions (10× GI lumen, 5× GI tissue,

1× systemic compartments). We systematically evaluated parameter requirements across particle sizes and assessed whether constant or time-varying elimination kinetics better describe multi-timepoint data. **Results:** The restructured model with local GI binding dramatically improved predictions across all particle sizes tested. For 20nm particles, prediction error decreased from 91% (original model) to 0.3% (restructured model) for GI lumen retention at 6 hours, with similar improvements for other compartments and sizes. Systematic parameter estimation revealed size-dependent model complexity requirements: smaller particles (20nm) were adequately described by 3 parameters, while larger particles required expanded parameter sets (4-5 parameters for 220nm and 1000nm), including size-specific kidney permeability and tissue binding terms. Kidney clearance rates varied 4-fold across particle sizes (0.079 to 0.020 h⁻¹), demonstrating size-selective renal handling. Critically, parameters optimized using single-timepoint data (6h) failed to predict later timepoints for all particle sizes, with prediction errors escalating from >1% at 6h to >100% at 12h and >900% at 48h. This systematic failure across all particle sizes indicates that time-varying elimination kinetics, rather than constant parameters, are necessary to capture gastrointestinal transit dynamics. Preliminary results suggest fecal elimination rates accelerate over time as particles transit from the stomach to colon, consistent with regional differences in GI motility. **Conclusions:** The integration of local GI binding kinetics into the PBPK models successfully captured experimental microplastic retention patterns that existing models could not predict. The findings have direct implications for human risk assessment, as they allow more accurate estimation of internal exposure and tissue burdens from ingested microplastics. By linking external intake (e.g., diet, water) to predicted tissue concentration, the model supports quantitative risk characterization and margin-of-exposure analysis. The approach also highlights the importance of size-dependent kinetic parameters, since nano- and micro-scale particles differ in retention time and elimination pathways that potentially lead to a higher risk for sensitive populations (e.g., infants and pregnant women). Continued refinement of this model, through empirical fitting of time-varying parameters and validation across particle sizes, is required to enhance the reliability for use in regulatory evaluation and reduce uncertainty in risk assessment.

PL 2011 Microplastics in Human Tissues: Examining Plastic Particulate Accumulative Patterns Across Decades (1980s vs 2020s)

R. R. Gullapalli, R. Kumar, A. Chinala, D. F. Gallego, E. E. Hayek, M. J. Campen, and M. A. Garcia. University of New Mexico, Albuquerque, NM.

Background and Purpose: Metabolic (Dysfunction) Associated Steatotic Liver Disease (MASLD) is an emerging liver disease of global concern. Chronic liver disease (CLD; including MASLD) rates are highest in the southwestern United States, including in the state of New Mexico (NM). NM has the highest rate of CLD in the US (36.4/100,000 in 2022), mainly among Hispanic and Native American populations for unknown reasons. We currently have a limited understanding of the role of environmental pollutants in MASLD etiopathogenesis. In particular, plastic pollution is an emerging concern which may underpin hepatic pathophysiology. We hypothesize environmental plastic pollutants can accelerate hepatic metabolic dysfunction in conjunction with established innate risk factors like type II diabetes and obesity. We currently have a limited understanding of NMP routes of bioaccumulation, cellular dysfunction and long-term effects on human health. **Methods:** In the current project, we evaluated NMP presence in decedent human liver tissues for the first time. A total of 32 human liver samples (M=19; F=13) from the years 2016-2024 were obtained from the NM Office of Medical Investigator (OMI) and analyzed for NMP accumulative patterns. Human liver tissues were tested for 12 common environmental plastics (PE, PVC, N66, PET, SBR, PC, PP, PS, ABS, PMMA, PU and N6) using pyrolysis-gas chromatography mass spectrometry (py-GCMS) testing. Additionally, novel imaging techniques (polarization wave microscopy) and fluorescence imaging are used to characterize polymer refractile elements in the hepatic tissues. We also obtained seven archived samples from 1981 for histopathological review and PWM imaging. **Results:** The total measured plastic quantity ranged from 0 µg/gm up to a maximum of 945.5 µg/gm in hepatic tissue, averaging 295.3 µg/gm across 32 liver samples. Next, a detailed histopathological analysis was performed delineating the NMP cellular distribution patterns within the hepatic tissue architecture. We implemented a novel optical imaging technique, polarization wave microscopy (PWM), to identify and measure polarization characteristics of putative, refractile NMP bodies in liver samples for the first time. Additional orthogonal multi-spectral fluorescence and transmission electron microscopy (TEM) imaging approaches confirm the refractile bodies identified using PWM imaging. All human liver samples except one (n=31) showed putative NMPs in the hepatic tissues. Preferential accumulation of NMPs in steatotic hepatic cells is a finding of major concern due to the rapidly increasing incidence of MASLD globally. Also, the hepatic tissues were assessed for key immunological biomarkers of interest - CD68 (Kupfer cells), CD56 (NK cells) and CD3 (Pan T-lymphocyte marker). Using digital pathology-based techniques for quantification, we identified elevated CD68+ macrophages in an NMP burden dependent manner. However, no differences were seen in the CD3 and CD56 immune burdens. Lastly, the seven archived histopathological tissues from 1981 reviewed using H and E and PWM microscopy did not show any refractile NMPs similar to the cases from 2016-2024. This is a novel finding we have observed for the first time reinforcing our main hypothesis of increasing plastic burdens in the past 1-2 decades among humans. **Conclusions:** These findings underscore the urgent need to study biological effects of NMP pollution in human liver tissues. Animal models are needed to understand

the role of chronic NMP pollution as a driver of MASLD pathophysiology and its potential role as an emerging environmental risk factor responsible for chronic liver (and metabolic) dysfunction increasingly observed among humans.

PL 2012 Advancing the method for isolating and quantifying MNPs in human cerebrospinal fluid for Brain Waste Clearance Studies

S. Patil¹, R. Herrera¹, M. Park¹, J. Kingston¹, M. Garcia¹, M. MazlouiBakhshayesh¹, R. Lui¹, T. Howard¹, J. Gross¹, J. Gonzalez-Estrella², S. Noor¹, K. Bhaskar¹, B. Shuttleworth¹, C. Cole¹, M. Campen¹, A. Carlson¹, and E. El Hayek¹. ¹University of New Mexico, Albuquerque, NM; and ²Oklahoma State University, Stillwater, OK.

Background and Purpose: Micro- and nano-plastics (MNPs) have been detected in human faeces, urine, blood, and various organs, raising concerns about human exposure and potential health implications. However, isolating and quantifying MNPs from complex biological matrices remains a major analytical challenge. Our team has made significant development by developing a novel approach to isolate and quantify MNPs from human tissues using advanced spectroscopic and microscopic techniques. The findings show significant MNPs accumulation in the human brain compared to the liver and kidney, raising concerns about brain waste management and potential toxic effects on the central nervous system (CNS) function. **Methods:** Here, we assess the quantity and physicochemical properties of MNPs in human cerebrospinal fluid (CSF) using pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS). The initial quantitative measurement was conducted on CSF samples (n=14) collected from a brain injury cohort. **Results:** Polymer concentrations ranging between 13.3 and 82.8 µg/ml were detected, with a mean of 22 µg/ml for the summed polymer concentrations. **Conclusions:** To validate our experimental approach, artificial cerebrospinal fluid (aCSF) spiked with known polymer standards will be analyzed to assess matrix interference removal and recovery efficiency. This will help us advance the methodological precision to facilitate the implementation of accurate correlation studies with brain waste clearance and CNS pathologies.

PL 2013 Detection of Microplastics and Other Contaminants in Banked Human Breast Milk Using FTIR

M. Bourgeois, S. Purohit, and R. Harbison. University of South Florida, Tampa, FL.

Background and Purpose: Concerns about the proliferation of plastic products has resulted in a significant body of research. Studies show microplastics (MP), commonly defined as plastic particles and fibers <5 mm, are widely distributed in environmental media, common foods and beverages, wildlife and humans. Once ingested, MP may move easily between compartments. They have been detected in most human organ systems, sputum, semen, blood, and placenta. This study used FTIR to analyze donated human breast milk samples for microplastics and other contaminants. **Methods:** Thirty breast milk samples were analyzed using Fourier Transform Infrared Spectroscopy on a Cary 630 (Agilent San Diego). Spectra were generated and contaminants identified using Open Analysis' Open Specy 1.0 software. Although breast milk is a complex body fluid, purification was not performed. Purification might so the matrix could be preserved. Digestion of organic matter has been shown to damage polymers. Microplastics were found in 46.7% (14 of 30) samples. The most common MPs detected were polypropylene (PP), (polyethylene (PE), and polyvinyl chloride (PVC). Other contaminants found include sodium chloride, weddellite, mab-chminaca, methyl cellulose, pargasite, and pollen. **Results:** Microplastics were found in 14 of 30 samples of breast milk. Sodium Chloride was found in 22 of 30 breast milk samples. The remaining compounds identified occurred far less frequently (weddellite - 4 specimens, mab-chminaca - 1 specimen, methyl cellulose - 3 specimens, pargasite - 2 specimens, and pollen - 1 specimen). **Conclusions:** Microplastics were identified in 14 of 30 samples of donated human breast milk. Donor identities are blinded so demographic data was unavailable. Lacking data such as the total number of pregnancies, duration of pumping session, elapsed time since the most recent birth, maternal age, diet, and occupation prevents more in-depth conclusions. Sodium chloride was found in most samples (22 of 30). Traces of minerals, fibers, pollen, and a synthetic cannabinoid were also detected. Further study should be conducted to elucidate sources of contaminants and their potential to adversely affect nursing infants.

PL 2014 Beyond the Brain: Perfluorooctanoic acid exposure disrupts serotonin signaling in the pancreas and causes gestational diabetes in mice

K. L. Bergman¹, M. Jerred¹, M. O'Connell¹, C. Mesaros², and M. Susiarjo¹. ¹University of Rochester, Rochester, NY; and ²University of Pennsylvania, Philadelphia, PA.

Background and Purpose: Gestational diabetes mellitus (GDM) is a form of diabetes that manifests during pregnancy and is characterized by hyperglycemia and glucose intolerance due to pregnancy-driven insulin resistance and inadequate pancreatic beta cell adaptation. GDM has a worldwide prevalence of 1.1-31.5% and is influenced by race, ethnicity, age, body composition, and screening and diagnostic criteria. The

rate of GDM in the US has increased by 30% from 2016 to 2020 and is expected to continue to increase in subsequent years. Women with GDM have an increased risk for pregnancy complications and adverse health conditions following pregnancy, while their fetuses face risks such as premature birth and future type 2 diabetes. Published studies have demonstrated that pancreatic beta cell proliferation is critical for maintaining healthy maternal glucose levels during pregnancy. One mechanism regulating beta cell proliferation is serotonin-dependent activation of the G1 cyclins for the cell cycle by binding of serotonin to the HTR2B receptor. This mechanism is driven by pregnancy-induced activation of the tryptophan hydroxylase 1 gene (*Tph1*) and local islet serotonin production. Previous work from our lab and others has shown that nutritional, genetic, and pharmacologic disruption of serotonin-mediated pancreatic beta cell proliferation causes GDM in a C57BL6/J mouse model. In this study, we sought to determine whether environmental contaminants can also disrupt the serotonin-dependent beta cell proliferation and cause GDM in mice. We chose to study perfluorooctanoic acid (PFOA), a ubiquitous and persistent environmental contaminant, as it is measurable in pregnant women and has been associated with increased risk for GDM in some epidemiologic studies. Preliminary studies from our lab show that gestational exposure to an environmentally relevant dose of PFOA induces glucose intolerance and insulin resistance in pregnant C57BL6/J mice and is accompanied by lower islet serotonin levels and beta cell proliferation rates. This is the first study to identify a potential mechanism by which PFOA induces GDM. Future studies aim to explore how genetic variants may alter serotonin-driven beta cell proliferation and influence susceptibility to GDM. **Methods:** We exposed C57BL6/J female mice to a control or PFOA (8 µg PFOA/kg body weight/day) diet for two weeks prior to mating and throughout gestation (gestational day (GD) 12.5 or 16.5). To assess the metabolic phenotype of these mice, mice underwent glucose tolerance testing (GTT) and insulin tolerance testing (ITT). Another subset of these mice was used for histological analyses, utilizing immunohistochemistry (IHC) staining to measure for islet serotonin abundance, beta cell proliferation, and islet morphology. To validate that the mechanism is dependent on serotonin-dependent activation of the serotonin receptor 2b (HTR2B) signaling, we treated mice with a HTR2B agonist from GD9.5-12.5 or 15.5, the critical window by which *Htr2b* mRNA expression and beta cell proliferation peaks, and assessed beta cell proliferation rates and glucose tolerance, at GD12.5 and 16.5, respectively. **Results:** Gestational PFOA exposure leads to glucose intolerance and insulin resistance in gestational day (GD) 16.5 pregnant mice, but not in non-pregnant or GD12.5 mice, suggesting that this is a pregnancy-specific phenotype that manifests in late gestation. Furthermore, PFOA exposure significantly lowers islet serotonin abundance and beta cell proliferation in GD 12.5 pregnant mice, without significantly altering islet morphology. Treatment with the serotonin receptor 2b (HTR2B) agonist improves beta cell proliferation in GD12.5 PFOA-exposed mice. Ongoing studies seek to assess whether HTR2B agonist treatment improves glucose tolerance in GD16.5 PFOA-exposed mice. **Conclusions:** These results suggest that disrupted serotonin-driven beta cell proliferation is a mechanism causally linked to GDM development in a C57BL6/J mouse model. This is the first study to reveal a potential mechanism by which PFOA induces GDM. Understanding the underlying mechanism can reveal areas for clinical intervention to prevent and treat GDM, improving the health of pregnant women and their offspring.

PL 2015 Fetal rat testis toxicity of a nine-phthalate mixture

J. Helmbreck, Z. Zhao, J. Scott, M. Woodcock, C. Su, S. J. Hall, K. Pennell, A. Badea, and D. J. Spade. Brown University, Providence, RI.

Background and Purpose: Phthalic acid esters (phthalates) are male reproductive toxicants that disrupt fetal testis development, resulting in well-characterized effects in rats, including reduced testicular testosterone production, enlarged seminiferous cords, germ cell clusters, and multinucleated germ cells (MNGs). There is evidence that the human fetal testis is less sensitive to phthalate-induced testosterone reduction than the rat fetal testis, but that induction of MNGs by phthalates is not dependent on testosterone production. We previously showed that the ED₅₀ for dipentyl phthalate-induced MNGs was lower than the ED₅₀ for reduction of testosterone in late gestation, which indicates that fetal testicular germ cells are sensitive to non-androgen-dependent toxic effects of phthalates. Here, we hypothesized that a mixture of nine phthalates would produce a dose-dependent, dose-additive increase in the density of MNGs in the rat, at a lower dose than the dose required to reduce testosterone. **Methods:** We generated a mixture of nine phthalates with well-characterized anti-androgenic effects in fetal rats: benzyl butyl phthalate, di-n-butyl phthalate (DBP), dicyclohexyl phthalate, di-(2-ethylhexyl) phthalate, diheptyl phthalate, dihexyl phthalate, diisobutyl phthalate, diisooheptyl phthalate, and dipentyl phthalate, which each compound being 0.5-log below its ED₅₀ for testosterone reduction in the highest dose group, and covering a 2-log dose range. Timed pregnant dams were treated with the mixture or corn oil vehicle by daily oral gavage from gestational day (GD) 17-21. On GD 21, MNGs were counted in H&E-stained sections, phthalate metabolites were measured in dam serum by GC-MS, and testosterone production was measured by LC-QTOF-MS in media from an ex vivo assay. **Results:** Eight phthalate metabolites showed a log-linear increase in dam serum across the dose range, and additional metabolites were identified in non-targeted analysis. The mixture produced a dose-dependent increase in MNGs with an ED₅₀ of 23.64 mg/kg/d DPeP equivalent (95% CI = 17.63, 23.91); and a dose-dependent decrease in testosterone production with an ED₅₀ of 40.55 (12.47, 147.2) mg/kg/d DPeP equivalent. **Conclusions:** We conclude that phthalates cause germ cell toxicity in a dose-dependent, dose-additive manner, and that this effect is at least as sensitive as reduction of testosterone production.

PL 2016 DDT's Lasting Legacy: Endocrine Activity and Developmental Toxicity of DDT+ and the Emerging Co-Contaminant Tris(4-chlorophenyl)methanol (TCPMOH)

A. J. Torres-Berrios¹, S. Khanum², J. Domaol², K. Polemi¹, R. Felton³, C. Tubbs³, N. Dodder², E. Hoh², and K. E. Sant¹. ¹Michigan State University, East Lansing, MI; ²San Diego State University, San Diego, CA; and ³San Diego Zoo Wildlife Alliance, San Diego, CA.

Background and Purpose: The legacy pesticide dichlorodiphenyltrichloroethane (DDT) is an endocrine disrupting compound associated with reproductive and developmental defects across species. Our collaborators have found >50 DDT-related metabolites and manufacturing byproducts (DDT+) in wildlife near dumping sites, many of which have limited or no toxicity data available. Tris (4-chlorophenyl) methane (TCPM) and tris (4-chlorophenyl) methanol (TCPMOH), also known as TCPMs, are of unknown sources but believed to be DDT byproducts of because of their co-occurrence in the environment and structural similarities to DDT. Here, we investigate the acute and developmental toxicity of the understudied and newly characterized DDT+ with the legacy DDT. We hypothesized that TCPMs would retain similar bioactivity mechanisms to DDT. **Methods:** *IN VITRO STUDIES.* Endocrine disruption was determined by *in vitro* California condor estrogen (ER) activation measured by a luciferase reporter assay. With the Presto Blue assay, we evaluated the cytotoxicity of TCPMs and 12 select DDT+ in HEPG2 cells. LD₅₀ values were calculated by nonlinear regression, and BMD, BMDL, and BMDU were determined using the Hill model at 0.5 BMRF. *IN VIVO STUDIES.* Developmental effects were assessed in zebrafish embryos exposed to DDT+ and TCPMs from 24-120 hpf. Mortality, hatching rate, and morphological deformities were monitored. At 120 hpf, behavioral assays were conducted to monitor larvae movement in response to light and tap stimuli using the Noldus DanioVision Observation Chamber. Total RNA was isolated at 120 hpf, and a clustered heat map was created to compare gene expression changes between DDT+ and TCPM upon exposure. KEGG pathway analysis was conducted to compare responses to acute (96-120hpf) and developmental TCPM and TCPMOH exposure. **STATISTICS.** Cytotoxicity was analyzed by one-way ANOVA and behavioral assays by two-way ANOVA followed by Tukey's multiple comparison test. Developmental outcomes and differences in group frequencies were compared by Fisher's exact test ($\alpha = 0.05$). **Results:** DDT+ activated condor and human ERs, with condor ERs showing greater sensitivity. TCPMOH was most cytotoxic of all tested DDT+, significantly reducing cell viability from 12.5 μ M ($p < 0.05$) and yielding an LD₅₀ of 32.52 μ M. Benchmark dose modeling produced a BMD of 33.959 μ M, with confidence limits ranging from 31.685 μ M (BMDL) to 36.401 μ M (BMDU). Developmental exposures to TCPMOH in zebrafish embryos increased mortality, impaired growth, and induced teratogenic defects: pericardial edema, swim bladder deflation and craniofacial deformities were most pronounced at 1 μ M at 5 dpf. Behavioral assays showed TCPMOH exposure during zebrafish development altered locomotor activity, causing hyperactivity manifested as increased total distance traveled, mean velocity, and time in movement in the Light/Dark assay. Heatmap analysis shows the para-substituted compounds *p,p'*-DDD, *p,p'*-DDT and *p,p'*-DDE cluster closely together, whereas TCPM and TCPMOH form a separate branch. KEGG pathway analysis revealed developmental transcriptomic responses to TCPM and TCPMOH were correlated ($R^2 = 0.8$), with downregulated steroid hormone biosynthesis, circadian rhythm, and retinol metabolism. **Conclusions:** DDT+ presented endocrine disrupting potential through ER receptor activation. Among the tested compounds, TCPMOH showed the greatest acute toxicity and induced significant developmental effects, including morphological abnormalities and altered behavioral patterns. *P,p'* isoforms seem to act through similar modes of action, as they showed comparable estrogenic activity, cytotoxicity, and transcriptomic patterns. Ongoing analyses with additional DDT+ are being conducted to further characterize and compare their induced developmental outcomes. Overall, this study characterizes the developmental toxicity of the emerging DDT+ and highlights the need to further investigate their ecological and health impacts, especially TCPMs which may be particularly toxic but understudied.

PL 2017 Co-Exposure to Mono(2-ethylhexyl) Phthalate and High Temperature Inhibits Mouse Antral Follicle Growth and Estradiol Synthesis *In Vitro*

S. Ghunaim, G. Ruschman, C. Harper, M. Wilson, and P. Hannon. University of Kentucky, Lexington, KY.

Background and Purpose: Di(2-ethylhexyl) phthalate (DEHP) is a plasticizer found in common consumer goods, such as food and beverage packaging, floor and ceiling tiles, automobile and furniture upholstery, and medical devices. DEHP is rapidly metabolized upon ingestion to mono(2-ethylhexyl) phthalate (MEHP), which is bioactive and known to exert endocrine-disrupting toxicities. Due to the extensive use of DEHP in consumer goods, humans are ubiquitously exposed and therefore vulnerable to endocrine and reproductive dysfunction by MEHP. Studies have shown that MEHP exposure disrupts the essential ovarian processes of antral follicle growth and steroidogenesis, both critical for ovarian function and female fertility. Simultaneously, humans are ubiquitously exposed to non-chemical stressors like rising global temperatures, and studies have shown that exposure to elevated temperatures can also impair female reproductive health. Given the unavoidable exposure to both increasing heat and DEHP, this study used an *in vitro* follicle culture system to test the hypothesis that exposure to high temperature will exacerbate

the negative effects of MEHP exposure on antral follicle function. **Methods:** Antral follicles were isolated from 4-5-week-old CD-1 mice and cultured for 24-96hr in media containing follicle-stimulating hormone (FSH) at a control temperature (CT; 37°C) or high temperature (HT; 42°C). Follicles were treated with vehicle control (dimethyl sulfoxide; DMSO) or MEHP (0.2-20 μ g/ml) in both temperature groups. Separate incubators were used for the CT and HT treatment groups, in which all HT treatments occurred for 8hr per 24hr period to model daytime, occupational exposure to high temperatures. Follicular growth was measured every 24hr. Follicles and media were collected at 24, 48, 72, and 96hr for gene expression analyses and sex steroid hormone measurements, respectively ($n = 3-7$ with 5-10 follicles/group/replicate; $p < 0.05$). **Results:** At 24hr, mRNA levels of *Ccnd2*, *Hsd17b1*, and *Cyp19a1* were decreased by HT+MEHP while mRNA levels of *Cdkn1a* were increased by HT+MEHP compared to CT+DMSO. Additionally, mRNA levels of *Fshr* at 24hr were increased by HT+DMSO and HT+MEHP compared to CT+DMSO. At 72hr, follicle growth, mRNA levels of *Ccnb1* and *Cyp11a1*, and estradiol levels were decreased by HT+MEHP compared to CT+DMSO. Additionally, mRNA levels of *Cyp19a1* and estrone levels at 72hr were decreased by HT+DMSO and HT+MEHP compared to CT+DMSO. At 96hr, follicle growth was decreased by HT+MEHP and both estrone and estradiol levels were decreased by CT+MEHP, HT+DMSO, and HT+MEHP compared to CT+DMSO. **Conclusions:** These results suggest that HT+MEHP co-exposure dysregulates cell cycle gene expression and decreases steroidogenic gene expression at earlier time-points leading to inhibited antral follicle growth and estradiol synthesis over time. The early increase in *Fshr* gene expression by HT+MEHP co-exposure may indicate a compensatory mechanism as a result of the impaired cell cycle progression and steroidogenesis. Further, several of the defects in cell cycle regulation, follicle growth, and steroidogenesis occur by HT+MEHP co-exposure but not by individual exposures to HT or MEHP alone. These findings demonstrate that HT and MEHP co-exposure may exert additive/synergistic effects. Thus, exposure to ubiquitous chemical and non-chemical stressors like MEHP and HT disrupt critical ovarian processes and may potentiate ovarian dysfunction when combined. Supported by R01ES033767, UL1TR001998, and P30ES026529.

PL 2018 Acute Exposure of Imidacloprid Affects Uterine Homeostasis in Mice

S. E. Caron, L. Williams, R. Shukla, J. Oladosu, A. Kannan, J. A. Flaws, and I. C. Bagchi. University of Illinois Urbana-Champaign, University of Illinois Urbana-Champaign, IL.

Background and Purpose: Imidacloprid (IMI) is the most widely used neonicotinoid insecticide, leading to ubiquitous environmental and human exposure. IMI exerts its insecticidal action by binding to and activating nicotinic acetylcholine receptors (nAChRs). Although mammalian nAChRs exhibit lower binding affinity, IMI exposure has been associated with neurological, immune, metabolic, and reproductive dysfunction. However, the potential uterine effects of IMI remain largely unexplored. This study aimed to determine whether low-dose, subacute IMI exposure disrupts uterine homeostasis and early pregnancy-related remodeling. **Methods:** Adult non-pregnant CD1 female mice ($n = 15$ /group) were exposed to IMI via drinking water for 30 days at 0 (vehicle), 0.2, 2, 20, 200, or 2000 μ g/L, representing environmentally relevant to high-end exposure levels. Uterine tissues were collected and processed for histological and molecular analyses. Hematoxylin and eosin (H&E), KI67, F4/80, and Picrosirius Red staining were used to assess cellular proliferation, macrophage infiltration, and collagen deposition, respectively. qPCR quantified expression of genes related to oxidative stress, inflammation, and fibrosis. To further understand the impact of IMI on pregnancy-related processes, we examined the differentiation of uterine stromal cells into decidual cells—a step critical for the establishment of pregnancy. Mouse endometrial stromal cells (MESC) were isolated from day-4 pregnant mice, cultured, and treated with IMI. *Igfbp4* protein expression was evaluated by immunocytochemistry as a marker of stromal differentiation during decidualization. **Results:** Low-dose IMI exposure (0.2 μ g/L) appears to increase luminal epithelial proliferation and myometrial thickness based on H&E staining, with KI67 analysis underway to verify proliferative activity. Enhanced macrophage recruitment was observed through F4/80 immunoreactivity. Picrosirius Red staining showed early collagen deposition within the stroma, suggesting activation of fibrotic remodeling. qPCR analysis showed upregulation of inflammatory and oxidative stress-related transcripts, while *Igfbp4* expression was possibly reduced *in vitro*, indicating potential impairment of stromal cell differentiation processes. **Conclusions:** These findings demonstrate that environmentally relevant IMI exposures may alter uterine remodeling pathways, promoting glandular hyperplasia, inflammation, and early fibrotic activity. This work identifies previously uncharacterized effects of low-dose neonicotinoid exposure on uterine remodeling and early pregnancy-related changes, underscoring IMI as a potential reproductive toxicant of concern. Supported by NIH R21 ES036520, NIH R25 ES025059

R. Marathe, S. Jovanovic, N. Pascual, Z. Vahora, B. Lawate, L. Villareal, R. Rayala, H. Chen, S. Khetani, and A. Veiga-Lopez. University of Illinois Chicago, Chicago, IL.

Background and Purpose: Neonicotinoids are among the most widely used insecticides globally. Epidemiological studies have associated gestational exposures to neonicotinoids with fetal growth restriction and developmental abnormalities. Although designed to target insect nicotinic acetylcholine receptors (nAChRs), several neonicotinoid metabolites have greater binding affinity to mammalian nAChR subunits. nAChRs are also present in the human placenta, raising concern for pregnancy-specific toxicity. This study investigated the placental transfer and functional impact of neonicotinoid parent compounds and their metabolites. **Methods:** To evaluate pregnancy kinetics of neonicotinoids, pregnant C57BL/6J mice received a single oral dose of a neonicotinoid mixture (10 mg/kg-bw; acetamiprid (ACE), imidacloprid (IMI), clothianidin (CLO), and dinotefuran (DINO)). Plasma, maternal liver and brain, placenta, and fetal liver and brain ($n = 3/\text{timepoint}$) were harvested at 0, 3, 6, 12, 24, 48, and 72 h after exposure for mass spectrometry detection. Concentrations of parent compounds and their biotransformation products (desmethyl-N-acetamiprid (D-ACE), desmethyl-clothianidin (D-CLO), dinotefuran-urea (DU), 5-hydroxy-imidacloprid (5-OH-IMI)) were quantified and toxicokinetic parameters ($t_{\max}$, $C_{\max}$, CL_{plasma}) were assessed. To examine the functional impact of neonicotinoids, human placental extravillous trophoblasts (EVTs; HTR8/SVneo cell line) were exposed to ACE, IMI, CLO, DINO, D-ACE, D-CLO, DU, imidacloprid-olefin (IMI-O), desnitro-imidacloprid (DNI), and 3-hydroxy-imidacloprid (3-OH-IMI) individually or in mixtures (4-parent or 4-metabolite mixtures) across environmentally relevant concentrations (0.002, 0.02, 0.2, or 2 μM). Proliferation (5 d) and migration (24 h) were assessed using live-cell imaging and scratch wound assays, respectively. In addition, EVT invasion was assessed over 96 h after 2 μM exposures to neonicotinoid parent and metabolite compounds using a novel 3-D microphysiological platform, where collagen bead microtissues coated with GFP-tagged EVTs are embedded in a collagen-Matrigel mixture. **Results:** All parent neonicotinoids and their metabolites were detected in plasma and maternal, placental, and fetal tissues within 3 h post-exposure with peak concentrations ($t_{\max}$) observed at 3 h. Notably, concentrations of D-ACE and 5-OH-IMI were higher in fetal vs. maternal liver at most timepoints. Plasma clearance (CL_{plasma}) occurred between 12-24 h for most compounds. Maximum concentration ($C_{\max}$) for all compounds ranged between 0.16 and 508.93 ng/mL, with D-ACE reaching the highest concentration. CLO exhibited the highest placental-to-plasma ratio of ~ 0.144 . *In vitro*, EVT proliferation was significantly reduced after 5-day exposures to IMI-O (0.002 μM) and 3-OH-IMI (0.2 and 2 μM). Migration measured at 18 h decreased with D-ACE (0.002 and 0.02 μM), DNI (0.02 μM), 3-OH-IMI (0.002 and 0.2 μM), and DU (2 μM). Parent compounds did not alter proliferation or migration at any concentration individually or in a mixture. In the 3-D placental microtissue model, exposure to 3-OH-IMI for 96 h increased EVT invasion at all doses tested. **Conclusions:** This study provides the first integrated evidence that neonicotinoid metabolites pass through placenta and rapidly reach fetal tissues, including the brain, within hours of maternal exposure. Moreover, they selectively impair key placental functions in a compound-specific manner. Our findings highlight the need to consider metabolite-specific toxicity and placental-fetal transfer in environmental risk assessments.

PL 2020 **Advancing Dermal Toxicity Assessment for Botanicals: *in silico* approaches**

A. Islas-Robles¹, C. Mitchell², V. Lough¹, I. Lee³, C. Bascoul⁴, P. Wages⁵, and W. Cheng⁵. ¹Institute for In Vitro Sciences, Gaithersburg, MD; ²Health and Environmental Sciences Institute, Washington, DC; ³Research Institute for Fragrance Materials, Mahwah, NJ; ⁴dōTERRA, Pleasant Grove, UT; and ⁵The Estée Lauder Companies, Melville, NY.

Background and Purpose: Botanicals, including derivatives from plants, fungi, and algae, have long been used in cosmetics and personal care products, with growing consumer demand for natural ingredients. However, their complex and variable chemical compositions pose challenges for traditional toxicology testing. Because skin contact is a primary route of exposure, assessing dermal toxicity is essential to identify potential risks including skin irritation, sensitization, or phototoxicity. In this study, we focused on endpoints such as sensitization and evaluated whether *in silico* tools could predict this endpoint for botanical constituents and determine if these predictions fall within their applicability domain. **Methods:** We selected 86 chemical constituents from 10 botanicals based on their potential to induce dermal toxicity, including skin irritation, sensitization, and phototoxicity. The set of botanical materials included poison ivy ethanol extract, which is positive for sensitization; bergamot essential oil, positive for phototoxicity; and cypress spurge ethanol extract, positive for irritation, as well as botanical extracts not expected to cause adverse effects. Two predictive platforms were used: the OECD (Q)SAR Toolbox, which groups chemicals and fills data gaps using read-across and structure-activity relationships, and Derek Nexus which predicts sensitization, irritation, and phototoxicity by applying structural alerts from historical *in vivo* data, fragment-based rules for negative outcomes, and k-Nearest Neighbors modeling for potency estimation. Each constituent was assessed for domain applicability and predicted outcome for the dermal endpoints. A negative prediction outside the applicability domain was considered inconclusive.

Results: Among the 86 botanical constituents analyzed for skin sensitization, 83.7% were predicted as sensitizers by Derek Nexus and 70.9% by the OECD Toolbox, while 5.8% and 17.4% of the respective predictions were inconclusive. The two models showed a 66% concordance rate. Strong concordance was observed for constituents derived from hops, thyme, and cypress spurge, whereas notable divergence was found among models for poison ivy constituents. Sensitizing compounds were identified in all the botanicals analyzed. **Conclusions:** *In silico* tools can support dermal safety assessment of botanicals on a constituent-by-constituent basis, provided chemical characterization is available. For the sensitization endpoint, although both models are included as Defined Approaches in OECD Guideline 497, their predictions were not as concordant as expected, suggesting that *in silico* sensitization tools may not yield consistent outcomes for some natural complex substances components. While their predictive power is constrained by the complexity and variability of botanical compositions, the results can complement other non-animal methods and contribute to hazard identification and weight-of-evidence approaches for regulatory safety evaluations. Integrating computational approaches into dermal safety assessment frameworks will accelerate evaluations and establish additional scientifically robust foundations for botanical toxicity screening. These findings highlight both the utility and the current limitations of applying *in silico* methods to complex botanical mixtures.

PL 2021 **Understanding the Toxicity of Plant-Derived Prenylated Phenolics using QSAR Modelling and Molecular Dynamics Simulations**

J. H. Ritsema^{1,2}, X. Zhang², A. Bombelli¹, C. Araya-Cloutier¹, J. Vincken¹, and N. I. Kramer². ¹Laboratory of Food Chemistry, Wageningen University and Research, Wageningen, Netherlands; and ²Toxicology Chair Group, Wageningen University and Research, Wageningen, Netherlands.

Background and Purpose: Prenylated phenolics are plant-derived compounds with promising antimicrobial activity. Although *in vitro* cytotoxicity has been widely reported, structure-activity relationships (SARs) remain poorly understood because of variability in experimental conditions. This study aimed to establish a consistent cytotoxicity dataset suitable for quantitative structure-activity relationship (QSAR) modelling and to identify molecular features influencing cytotoxicity in prenylated phenolics. **Methods:** A structurally diverse set of 41 prenylated phenolics was evaluated for cytotoxicity in human osteosarcoma (U2OS) cells using the resazurin (Alamar Blue) and CFDA-AM viability assays after 48 hours of exposure. The octanol-water partition coefficient ($\log K_{ow}$) was estimated using EpiWeb (v4.1) to predict general cytotoxicity as described by Kramer et al. (Toxicology *in Vitro*, 2009, 23, 1372-1379). Molecular structures were energy-minimized, and descriptors were calculated *in-silico* using Molecular Operating Environment (MOE v.2024.06). The dataset was divided into a training and test subsets. QSAR models were generated using genetic algorithm-multiple linear regression (GA-MLR), and model performance was assessed based on fitting performance and external predictivity. For candidate compounds, steered molecular dynamics (MD) simulations were performed to investigate phospholipid membrane interactions and assess insertion behavior, providing mechanistic context for the observed cytotoxicity. **Results:** Cytotoxicity of prenylated phenolics, as measured by the resazurin assay, ranged from $IC_{50} = 3.0 \mu\text{M}$ (Kurarione) to $IC_{50} = 74.1 \mu\text{M}$ (α -Isowighteone). A weak but statistically significant correlation was observed between measured and predicted IC_{50} values (Pearson's $r = 0.345$, $p = 0.027$), indicating limited predictive power of the general cytotoxicity model. These findings emphasize the need for more robust, compound class-specific QSAR approaches for prenylated phenolics. Development of such models is ongoing and will be reported at the conference. Preliminary data analysis showed a significant positive correlation (Pearson's $r = 0.50$, $p < 0.05$) between cytotoxicity (pIC_{50} , resazurin assay) and the fractional negative surface area (FCASA-), as well as a weak positive trend (Pearson's $r = 0.26$, $p < 0.10$) with hydrophobicity ($\log P(o/w)$). MD simulations showed more favorable and deeper membrane insertion for prenylated phenolics with increased hydrophobicity. **Conclusions:** This study established a robust cytotoxicity dataset for a structurally diverse set of prenylated phenolics. The limited predictive accuracy of general cytotoxicity QSAR models underscores the need for class-specific modelling approaches. Preliminary insights indicate that both increased fractional negative surface areas and hydrophobicity contribute to toxicity. Ongoing work focusses on developing class-specific QSAR models to support the rational design of prenylated phenolics with optimized antimicrobial efficacy and reduced mammalian toxicity.

PL 2022 **Integration of computational models to predict botanical phytochemical constituent clearance routes by the Extended Clearance Classification System (ECCS)**

Y. Liu¹, M. Lawless², A. Roe³, and S. Ferguson⁴. ¹Food and Drug Administration, Laurel, MD; ²Simulations Plus, Inc, Durham, NC; ³The Procter & Gamble Co., Cincinnati, OH; and ⁴National Institute of Environmental Health Sciences, Durham, NC.

Background and Purpose: The Extended Clearance Classification System (ECCS) is a framework that predicts a chemical's predominant rate-determining clearance route: metabolism, hepatic uptake, or renal clearance. The ECCS prediction is based

upon molecular weight, ionization state, and membrane permeability, which could be predicted by quantitative structure-activity relationship (QSAR) models. The ECCS also indicates potential chemical interactions via drug-metabolizing enzymes and transporters. This study used the ECCS to evaluate phytochemical constituents and predicted drug-metabolizing enzyme and transporter pathways to understand botanical clearance in humans. **Methods:** First, 82 phytochemical constituents were classified into six ECCS classes based on QSAR-predicted properties. Next, constituents in classes 1A and 2 were further explored as potential substrates for 18 drug-metabolizing enzymes followed by predictions for hepatic clearance, while constituents in classes 3 and 4 leveraged predictions for glomerular filtration and renal transporters. Finally, potential interactions between phytochemical constituents and drugs were discussed. **Results:** Results showed that more than half of the phytochemical constituents were in ECCS class 2, whose Phase I metabolism were predicted to be predominantly mediated by CYP3A4, CYP2D6, and CYP1A2. Additionally, over 20% of the phytochemical constituents fell into ECCS class 4, which were predicted to be predominantly cleared in unchanged forms by glomerular filtration and active renal secretion by OAT1/3 or OCT2. Classes 1A and 2 compounds exhibit high interaction potential via CYPs, while classes 3 and 4 compounds have relatively low potential for renal uptake transporter mediated interactions. **Conclusions:** This study represents a data-driven framework for exploring and contextualizing botanical constituent information to inform safety evaluations. Additionally, it introduces the term “botanickinetics” as a more generalizable term for the ADME kinetics of complex botanical exposures.

PL 2023 Roots to Neurons: Evaluating Developmental Neurotoxicity (DNT) Potential of Botanicals Using an *In Vitro* Testing Battery

Z. Henry, J. Hsieh, C. McPherson, S. Marvel, L. Hall, J. Stanko, and C. Rider. Division of Translational Toxicology, NIEHS, Research Triangle Park, NC.

Background and Purpose: The usage of botanicals is widespread and growing in the United States. Most botanicals have not been evaluated for developmental neurotoxic (DNT) potential, and some have been shown to adversely affect the central nervous system, raising concern and calling for evaluation. International efforts have proposed new approach methodologies (NAMs) for DNT testing resulting in the DNT *In Vitro* battery (DNT IVB) which consists of multiple assays designed to detect changes in key neurodevelopmental processes (KNDPs) of proliferation, apoptosis, cell migration, neuronal differentiation, neurite outgrowth, neuronal maturation and synaptogenesis, oligodendrocyte differentiation, and network formation using human and rat (primary cortical) cells. The objective of this project was to screen botanicals in the DNT IVB and evaluate the resulting data using Pareto frontier analysis of potency, selectivity, and activity confidence to comparatively assess potential DNT hazard. **Methods:** Eight botanicals selected based on signals of neurotoxicity in the literature (Aconite, Bupleurum, Cassava, Guarana, Kratom, Oleander, Wormwood, and Yohimbe) were assessed for DNT potential using a DNT Battery comprised of 2D and 3D *in vitro* assays to assess the impact on neurodevelopmental processes and a zebrafish assay to measure neurobehavior. Multiple samples for each botanical, except for Oleander and Cassava, were evaluated in the battery, which varied by preparation (i.e., powders vs extracts) and plant parts (i.e., leaf vs whole plant). **Results:** Oleander exhibited the greatest potential for DNT effects compared to the other botanicals as it displayed the highest selectivity and potency in multiple DNT assays. Fu Zi (Zhi), a popular Chinese herbal medicine and a processed root of Aconite, was the only botanical sample that showed no activity in any of the assays, suggesting the least potential for DNT effects. Our findings also show that potency and activity of the botanicals can differ not only by ingredient but also by preparation of the same ingredient and by lot number (e.g., Kratom samples differed across preparations and lot numbers). Wormwood samples were the most similar in terms of potency and activity. Additional observations include differences between test systems and test methods that resulted in diverse outcomes from assays for the same neurodevelopmental process (e.g., migration). For example, out of the 3 DNT assays that measure neural cell migration, ‘Guarana Extract’ was active only in the NPC2b assay that uses neurons and was inactive in the NPC2a assay that uses radial glial cells and the NPC2c assay that uses oligodendrocytes. Out of the 22 tested botanical-derived samples, only five were active in the zebrafish neurobehavioral assay, suggesting limited toxic potential of these botanicals on neurobehavior. **Conclusions:** In summary, exposure to botanical extracts affects neurodevelopmental activity, although consistent results across samples of the same ingredient were not observed. These inconsistencies are likely due to the variations in botanical processing and preparation which affects their chemical composition and potency. The diverse activity phenotypes of botanicals and botanical-derived compounds further highlight the complexity of hazard characterization, including DNT evaluation.

PL 2024 Emerging Mycotoxins and Fungal Contaminants in Seized Cannabis in Arizona and California, 2023-2024

P. Romero¹, T. Porter², J. Brunkhorst³, B. Andersano¹, C. Chen⁴, H. Centner², K. Lee², E. Driebe², J. Caporaso², B. Katchmann⁴, M. Rahnama⁵, K. Gwinn⁶, D. Engelthaler⁷, and M. Leung¹. ¹Arizona State University, Glendale, AZ; ²Translation Genomics Research Institute, Flagstaff, AZ; ³Trilogy Analytical Laboratory, Washington, MO; ⁴PathogenDx, Inc., Tucson, AZ; ⁵Tennessee Tech University, Cookeville, TN; ⁶Department of Entomology and Plant Pathology, University of Tennessee, Knoxville, TN; and ⁷Arizona Health Observatory, Arizona State University, Phoenix, AZ.

Background and Purpose: The contamination level of cannabis in the illicit market - including unlicensed production (i.e., black market cannabis) within a legalized state and products that failed compliance testing in the gray market - is largely unknown. **Methods:** The Maricopa County Sheriff's Office and the U.S. Postal Inspection Service collected 118 illicit cannabis flower samples between 2023 and 2024. Previous analysis identified 7 *Aspergillus* and *Fusarium* mycotoxins and metabolites (Stephens et al., 2023, Environmental Health Perspectives 133). In this follow-up study, we evaluated 8 additional emerging mycotoxins in a subset of samples using liquid chromatography-mass spectrometry. Twenty-three samples' fungal communities were sequenced through three separate targeted amplicon sequencing assays using NovaSeq1k p1 600 cycle kit run with 250bp forward and reverse reads. A primer set amplifying the transcription elongation factor 1α (EF1α), Internal Transcribed Spacer-1 (ITS-1), and ITS-2, before sequencing, was performed to speciate *Aspergillus* and *Fusarium* spp. **Results:** Three out of the eight tested emerging mycotoxins - alternariol, enniatin A, and beauvericin - were detected in 11 samples. Using targeted amplicon sequencing of the EF1α gene, we identified *F. cateniforme*, *F. languescens*, *F. cuspidatum*, *F. clavus*, *F. annulatum*, and unknown *Fusarium* species complexes. In further analysis, using the ITS-1 and ITS-2 sequencing data, more species of *Aspergillus* and *Fusarium* were identified. Six *Fusarium* species, including *F. chlamydosporum*, *F. oxysporum*, *F. proliferatum*, *F. solani*, *F. trinctum*, and *F. venenatum*, detected by ITS-1 and/or ITS-2 all came from separate species complexes. All but one *Fusarium* species identified (*F. solani*) are known producers of mycotoxins. The *Aspergillus* species detected in samples came from three general subgenera: *Circumdati*, *Aspergillus*, and *Nidulantes*. The six identified *Aspergillus* species are *A. flavus*, *A. insuetus*, *A. ochraceus*, *A. piperis*, *A. ruber*, *A. sclerotiorum*, and *A. versicolor*. Three of the six species of *Aspergillus* detected have not been recognized as producers of mycotoxins (*A. insuetus*, *A. piperis* and *A. ruber*). *A. versicolor* has been reported to produce sterigmatocystin, and was identified in two out of three sterigmatocystin-positive samples by both ITS-1 and ITS-2. There were eight sterigmatocystin negative samples that contained *A. versicolor*, as well. Overall, species of *Aspergillus* and *Fusarium* were identified in both samples that were mycotoxin positive and negative. **Conclusions:** Emerging mycotoxins and toxicogenic *Fusarium* and *Aspergillus* spp. pose a health risk to cannabis consumers. Seized illegal cannabis products contain *Fusarium* and *Aspergillus* spp. in both samples that were mycotoxin positive and negative; suggesting the possibility of production of mycotoxins in samples.

PL 2025 Case studies: Assuring consumer safety of botanical extracts, as cosmetic ingredients, through conscious safety design, new approach methodologies, and next-generation risk assessment (NGRA)

S. Kim¹, and I. Garcia². ¹Ashland Inc, Lincoln, CA; and ²Ashland Specialties France, Sophia Antipolis, France.

Background and Purpose: Due to increased consumer demand for naturally sourced cosmetic ingredients and bans on animal testing, new non-animal safety assessment methods have become essential. This research presents the integration of New Approach Methodologies (NAMs) and Conscious Safety Design (CSD) concept in assessing consumer safety of botanical extracts to be used as cosmetic ingredients. **Methods:** CSD is a holistic approach that integrates safety considerations into the early design process of botanical extract preparations. This approach emphasizes the importance of early collaboration among toxicologists, analytical chemists, applied research scientists, engineers, and quality/regulatory staff among others to create safer botanical extracts that are not only functional for their intended biological activities but also safe for all end-users when formulated into cosmetic products. The four elements of CSD and NAM/NGRA are: (1) extraction: water, solvent, supercritical fluid, or electrokinetic (source identification, biological activities, effective concentration, substances of toxicological concern), (2) NAM and toxicology gap analysis: phytochemical/compositional analysis, literature review, use history, *in silico*, in chemico and *in vitro* assays, read-across, (3) next-generation risk assessment (NGRA) and validation: in-use simulated exposure assessment, qualitative and quantitative risk assessment, panel testing (effectiveness & safety), and (4) postmarketing surveillance. **Results:** Our case studies demonstrate the effectiveness of CSD and NAM/NGRA approaches in assuring the consumer safety of botanical extracts being used as cosmetic ingredients. The emphasis was given on in-depth review in historic botanical use, characterizing product categories and exposure, conducting *in vitro* irritation, sensitization, phototoxicity, mutagenicity tests, and confirming compatibility through human volunteer human patch tests on over 3,000 volunteers.

across 20 ingredients and more. **Conclusions:** CSD and NAM/NGRA approaches are effective animal alternative methods in assuring the consumer safety of botanical extracts being used as cosmetic ingredients.

PL 2026 Profiling Human Hepatic Biotransformation Enzyme Gene Expression According to PFAS Exposure

K. Otersen¹, J. Agudelo Areiza², K. Kosicka-Noworzyn³, L. Aleksunes¹, A. Slitt², and L. Brunetti¹. ¹Rutgers, The State University of New Jersey, Piscataway, NJ; ²University of Rhode Island, Kingston, RI; and ³Poznań University of Medical Sciences, Poznań, Poland.

Background and Purpose: Exposure to per- and polyfluoroalkyl substances (PFAS) has been associated with adverse health outcomes, including cardiometabolic disease, decreased immune function, and malignancy. The widespread exposure of humans to PFAS along with the high utilization of pharmaceuticals to treat these associated diseases raises concern about potential pharmacokinetic and pharmacodynamic interactions. PFAS and pharmaceuticals share disposition pathways including binding to serum albumin, cell membrane transport in key tissues via drug transporters, enterohepatic recirculation, along with renal reabsorption and excretion. As PFAS bioaccumulate in livers and kidneys, they activate transcription factors and nuclear receptors that regulate the expression of drug metabolizing enzymes. Therefore, the purpose of this study was to evaluate associations between PFAS concentration in banked human liver specimens and expression of mRNAs encoding drug-metabolizing enzymes. **Methods:** Human liver biospecimens were obtained from 34 cadaver donors through the National Disease Research Interchange. 54 PFAS were measured in the liver biospecimens using targeted liquid chromatography high-resolution mass spectrometry (LC-HRMS). Individual PFAS that were detected in more than 60% of the samples were included in the subsequent statistical analysis. For each PFAS, samples were ranked by concentration and divided into tertiles for comparison of mRNA expression levels. SYBR Green-based RT qPCR was conducted using 96-well plates formatted for the Human Drug Metabolizing Enzyme RT2 Profiler PCR Array System to measure relative mRNA abundance of 150 phase-I and -II biotransformation enzymes and 5 housekeeping genes. Target gene expression was normalized to housekeeping genes, and fold changes were calculated as $2^{-(\Delta\Delta Ct)}$. All data were analyzed using descriptive statistics. Differences in gene expression changes according to PFAS concentration were assessed using Welch's T-test. **Results:** PFAS were detected in all 34 individuals, with 17 compounds, including linear and branched isomers, found in ≥ 3 livers and 6 detected in 60% of specimens. The six most frequently detected PFAS were perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), perfluoroundecanoic acid (PFUDA), linear-perfluorohexanesulfonic acid (L-PFHxS), linear-PFOS (L-PFOS), and branched PFOS (Br-PFOS). The gene expression of phase I metabolizing enzymes: Alcohol dehydrogenase (ADH) 1A, 1B, 1C, 4 and 6; Cytochrome P450 (CYP) 1A2, 2E1, 3A4, 3A43 and 7A1; and Flavin-containing Monooxygenase 3 were elevated at high PFOA, PFNA, L-PFHxS, PFUDA, L-PFOS and Br-PFOS concentrations. Similarly, phase II enzymes: Epoxide Hydrolase 1, Glycine-N-Acyltransferase, Glutathione S-transferase alpha 1, Sulfotransferase (SULT) 1A1, 1A2, 1E1, UDP-glucuronosyltransferase (UGT) 1A9, UGT2B4, 2B7, 2B10, 2B17, 2B28, and Thiosulfate Sulfurtransferase were enriched compared to samples in the lowest 33rd percentile. The phase I enzyme CYP21A2 and phase II enzyme Indolethylamine N-methyltransferase were lower at high PFAS concentrations. **Conclusions:** This study revealed novel associations between hepatic PFAS levels and altered expression of genes encoding Phase-I and -II biotransformation enzymes, suggesting potential effects of the ADME of pharmaceuticals and endogenous compounds. Supported by T32ES007148 and P30ES005022.

PL 2027 Per- and Polyfluoroalkyl Substances (PFAS) Antagonize Retinoic Acid Receptor (RAR) and Retinoid X Receptor (RXR) Activity

M. Hvizdak, and J. N. Lampe. University of Colorado Anschutz Medical Campus, Aurora, CO.

Background and Purpose: Defects of the head and face account for approximately one-third of all congenital abnormalities worldwide and are a significant threat to neonatal and infant mortality. Prenatal exposure to per- and polyfluoroalkyl substances (PFAS) is associated with significant birth defects in humans and laboratory animals, including craniofacial abnormalities impacting eye and philtrum development. In chordates, craniofacial development is highly dependent on retinoic acid homeostasis and signaling, which regulates the expression of over 500 target genes through agonism of the nuclear retinoic acid receptor (RAR; $\alpha/\beta/\gamma$) and retinoid X receptor (RXR; $\alpha/\beta/\gamma$). Activation of the RAR/RXR heterodimer is driven by RAR agonism, with binding to RXR yielding synergistic effects on transcription. Throughout pregnancy, systemic concentrations of the predominant RAR agonist, all-trans-retinoic acid (atRA) are tightly maintained at approximately 5 nM. This homeostasis is achieved through an autoregulatory feedback loop in which excess atRA drives the transcription of genes encoding members of the cytochrome P450 (CYP) 26 and 3A families, which actively metabolize retinoic acid. PFAS share many structural similarities with atRA, affording them an increased capacity for ligand recognition in other biological pathways mediated by retinoid gradients. We have previously demonstrated the ability for PFAS to inhibit the homeostatic oxidative activities of CYP26A1 and

fetal/neonatal CYP3A7. Additionally, we found that perfluorodecanoic acid (PFDA) significantly downregulates transcription of retinoid target genes in female primary human hepatocytes. We therefore hypothesize that PFAS antagonize RAR and RXR activity, thereby contributing to the craniofacial defects associated with prenatal exposure. **Methods:** Twelve PFAS (FBSA, PFBS, PFPeA, GenX, FHxSA, PFHxS, 4:2 FTS, PFOA, PFOS, PFNA, PFDA, and PFUnDA) were tested at 10 and 100 μ M for their capacity to antagonize RAR $\alpha/\beta/\gamma$ and RXR $\alpha/\beta/\gamma$ activity based on their widespread use and/or presence in fetal or maternal tissues. Screenings were conducted using the INDIGO Biosciences cell-based luciferase reporter assay for each isoform (State College, PA). Briefly, incubations were performed in the presence of atRA or 9-cis-RA agonist at the EC₅₀₋₈₀ for each respective receptor. Reference compounds (RAR α , BMS 195614; RAR β/γ , CD 2665; and RXR $\alpha/\beta/\gamma$, UVI 3003) were included as positive controls for antagonism. Following a 22-24 h incubation period (37°C, 5% CO₂), media was removed, and luciferase detection reagent was added. After 5 min, luminescence was quantified with a microplate reader (TECAN; Männedorf, Switzerland) at 500 mSec per well. The log₂(FoldChanges) of each treatment were quantified against the vehicle control, and statistical significance was calculated using a two-way ANOVA with Dunnett's post hoc test for multiple comparisons. Experiments were performed in triplicate. **Results:** Our results indicate that FBSA, PFBS, PFPeA, GenX, FHxSA, 4:2 FTS, PFNA, PFDA, and PFUnDA significantly antagonized RAR and RXR activity ($p_{adj} < 0.05$). An inverted U-shaped relationship was observed between carbon chain length and receptor activity, in which the shorter ($\leq C6$) and longer PFAS ($\geq C9$) were more potent antagonists compared to mid-length PFAS (e.g., PFOA and PFOS (C8)). The 11-carbon PFUnDA demonstrated the highest potency for receptor antagonism across all six isoforms. PFUnDA (100 μ M) significantly antagonized RAR activity with log₂(FCs) of -4.62 (α), -1.35 (β), and -4.52 (γ) ($p_{adj} < 0.001$). PFUnDA (100 μ M) also inhibited RXR activity with log₂(FCs) of -0.52 (α), -1.39 (β), and -2.31 (γ) ($p_{adj} < 0.05$). In addition to PFUnDA, FHxSA and PFDA both significantly antagonized all six RAR and RXR isoforms ($p_{adj} < 0.01$). **Conclusions:** Nine of the twelve PFAS tested (FBSA, PFBS, PFPeA, GenX, FHxSA, 4:2 FTS, PFNA, PFDA, and PFUnDA) significantly antagonized retinoid receptor activity *in vitro*. Interference with retinoid signaling during human development leads to severe congenital defects and malformations of the head and face. Biomarkers of PFAS teratogenicity largely overlap with those implicated in altered retinoid signaling during development. We therefore offer our findings as further mechanistic evidence for PFAS teratogenicity through altered retinoid signaling via RAR and RXR antagonism.

PL 2028 Identification of PFAS-binding proteins by a toxicoproteomic tool

M. Bondesson¹, S. Somalraju², and S. C. Janga². ¹University of Illinois, Springfield, IL; and ²Indiana University, Indianapolis, IN.

Background and Purpose: Although transcriptomic and proteomic approaches are informative in toxicological research, they often fail to pinpoint the precise molecular targets of chemicals. To address this gap, we developed a proteome-wide binding assay and a computational pipeline to identify proteins binding to per- and polyfluoroalkyl substances (PFAS). **Methods:** Perfluorooctanoic acid (PFOA) and perfluorononanoic acid (PFNA) were covalently attached to carboxyl-functionalized ferrite-glycidyl methacrylate (FG) beads using click chemistry. The PFAS-conjugated beads were incubated with whole-cell extracts derived from mouse P19 teratoma cells and Hepa1c1c7 liver cells. After several washing steps, bound proteins were first visualized by gel electrophoresis and silver staining, and subsequently identified by liquid chromatography-mass spectrometry (LC-MS). Differential Enrichment analysis of Proteomics data (DEP) software was used to identify differentially bound proteins to PFAS-conjugated beads compared to control beads and to predict molecular pathways affected by PFAS exposure. **Results:** PFOA-conjugated beads differentially captured 474 proteins from P19 cell extracts and 378 proteins from Hepa1c1c7 cell extracts compared with control beads. PFNA-conjugated beads bound 470 proteins in P19 cells and 448 proteins in Hepa1c1c7 cells. Most bound proteins overlapped between the two cell types (306 for PFOA and 344 for PFNA) indicating that PFAS targets were not restricted to specific cell types. Functional enrichment analysis suggested that the bound proteins participate in fundamental cellular processes, including DNA, RNA, protein, and macromolecule metabolism; RNA processing; and the organization of chromosomes, organelles, and protein complexes. Proteins involved in xenobiotic responses and cellular stress were also detected. **Conclusions:** Toxicoproteomic tools enable rapid and systematic identification of chemical targets and offer a more direct route to identifying molecular initiating events. In our assays, each PFAS captured hundreds of proteins with substantial overlap between the two cell extracts, indicating that PFAS interact with large protein complexes critical for essential cellular functions.

PL 2029 Individual chemical concentration-responses predict neurobehavioral effects of a human-relevant PFAS mixture in larval zebrafish

R. Owen¹, J. Raab¹, S. Gutsfeld¹, D. Herzke², L. Haug², O. Myhre², and T. Tal¹.
¹Helmholtz Centre for Environmental Research, Leipzig, Germany; and ²Norwegian Institute of Public Health, Oslo, Norway.

Background and Purpose: Humans are ubiquitously and simultaneously exposed to per- and polyfluoroalkyl substances (PFAS), a class of widespread environmental contaminants comprised of >14,000 unique structures. Some PFAS transfer through the placenta and bioaccumulate in the brain, indicating the need to investigate the potential of these compounds to cause developmental neurotoxicity (DNT). Epidemiological studies report conflicting findings on the link between early life PFAS exposure and DNT in humans, which may be attributed to the limited focus on co-occurring chemical mixtures. Here, we aimed to assess exposure of six prominent PFAS detected in the blood of Scandinavian populations and their mixture to elucidate effects on neurodevelopment in an early life-stage zebrafish behavior assay. Furthermore, we applied mixture modeling approaches to examine whether mixture effects were predictable from individual chemical concentration-response profiles, revealing a novel application of behavior-based New Approach Methods (NAMs) in chemical mixture risk assessment. **Methods:** Zebrafish were developmentally exposed to single PFAS (perfluorooctanesulfonic acid (PFOS), perfluorohexanesulfonic acid (PFHxS), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), or perfluoroundecanoic acid (PFUnDA)), a mixture in ratios found in the blood at 10-100x the blood level, or the solvent control from 1-5 days post fertilization (dpf). At 5 dpf, larvae were subjected to the Visual and Acoustic Motor Response (VAMR) NAM. To derive concentration-response curves, motor activity was modeled using Generalized Additive Mixed Effects Models for visual motor response data and Linear Mixed Effects Models for startle response data. Frechet distances were calculated between chemical concentrations and control modeled responses. The winning model was selected out of 10 curve-fitting models by the tcpl2 v3.0 pipeline. To predict mixture effects on different endpoints, Concentration Addition (CA) and Independent Action (IA) models were computed and predictions were compared to observed mixture responses. **Results:** Larvae exposed to PFOS, PFUnDA, PFOA, PFNA, or 10-100x the human blood level mixture displayed heightened startle in response to high intensity acoustic stimuli. Exposure to PFOS, PFHxS, PFUnDA, or the mixture at 56-100x the human blood level caused dark-phase hyperactivity. Best fit concentration-response curves for single compounds active in the acoustic startle and dark phase endpoints demonstrated concentration-dependent relationships in the same direction as the observed mixture effect, thereby allowing their inclusion for mixture toxicity predictions. CA and IA predicted mixture curves for these endpoints revealed similar fits with the observed mixture curves, indicating model predictions could accurately capture experimental mixture effects. AC50 values derived from CA and IA mixture predictions were within $\pm 0.8 \mu\text{M}$ of the observed mixture AC50 values, suggesting active compounds within an endpoint obey rules of additivity and single component response curves can be used to predict mixture effects. **Conclusions:** This work demonstrates the applicability of additive mixture predictions for rapid, behavior-based assessment of co-occurring chemical mixtures. By examining a PFAS mixture comprised of compounds found in human blood at a fixed ratio, we extend the implementation of zebrafish embryo NAMs for DNT testing to a real-life exposure scenario. Analytical chemistry is ongoing to link behavioral effects to zebrafish tissue doses, ultimately allowing for extrapolation to human blood concentrations.

PL 2030 PFAS compounds potentiate DNA damage in HEK293T cells and zebrafish embryos at parts per billion exposure levels and below.

S. M. Matthews, B. J. Hinchcliff, C. R. Propper, and M. Salanga. Northern Arizona University, Flagstaff, AZ.

Background and Purpose: Per- or Polyfluoroalkyl substances (PFAS) are persistent environmental contaminants, some of which have been shown to cause injury and disease, such as immune deficiencies, cancer, and metabolic disease in humans. For this study, we selected three PFAS compounds with differing carbon chain lengths: perfluorooctanoic acid (PFOA, 8C), perfluoropentanoic acid (PFPeA, 5C), and perfluorobutane sulfonic acid (PFBS, 4C), to determine if chain length corresponds with genotoxicity *in vitro* and *in vivo*. **Methods:** To determine genotoxicity, we separately tested each chemical against vehicle control at dose levels ranging from 0.02 to 20 parts per billion in HEK293T cells for 24 hours and in zebrafish embryos from 4 hours post-fertilization to five days using single-cell electrophoresis (i.e., comet). Each compound was tested at least twice under neutral and alkaline electrophoresis conditions using HEK293T cells and zebrafish embryos. The webtool, CometScorer 2.0, was used to compute Olive Tail Moments (OTM) that describe the length, width, and brightness of comet features, with higher OTMs indicating increased damage. **Results:** Our data show increased genotoxicity, *in vitro* and *in vivo*, for all chemicals tested and under alkaline or neutral electrophoresis conditions. The lowest observable effect levels were 0.02 and 0.2 ppb, depending on the exposure paradigm and host system. **Conclusions:** Our results indicated that the PFAS compounds tested induce DNA damage at environmentally relevant levels. OTMs between neutral and alkaline comet conditions were different in effect amplitude, with alkaline comet showing higher OTMs. We interpret these data as the PFAS potentiating

DNA damage that is realized in alkaline comet but not neutral comet conditions. Furthermore, DNA damage in zebrafish showed similar relationships to the *in vitro* model, supporting our hypothesis that PFAS potentiate DNA damage independent of the host cell. Finally, we are seeing effects at parts per trillion (ppt) concentrations. The EPA has set the maximum contamination level for PFOA at 4 ppt; based on our data, we conclude that the EPA MCL is appropriately low.

PL 2031 PFAS Exposure Attenuates Tryptophan Metabolism through the Kynurenine Pathway in the Human Placenta

N. Prout, S. P. Murphy, M. Susiarjo, and T. G. O'Connor. University of Rochester, Rochester, NY.

Background and Purpose: The placenta is an essential organ that forms the interface between the maternal and fetal bloodstreams. The placenta performs numerous functions essential for successful pregnancy, including transfer of nutrients, removal of waste, and protection from infections and maternal-immune mediated rejection. Impaired placental function is associated with pregnancy complications that adversely impact maternal and fetal health and survival. A key pathway in the placenta is tryptophan (TRP) catabolism through the Kynurenine Pathway (KP) which is active from mid to late gestation in human pregnancy. Indoleamine dioxygenase (IDO1) is the rate limiting enzyme that initiates TRP catabolism in the KP. Studies in pregnant mice revealed that the KP is essential for promoting a tolerogenic maternal-fetal environment that allows the survival of the semi-allogenic fetus. Deficiency in this pathway, when the ratio of available TRP is high relative to KYN levels, is associated with growth restriction, preeclampsia, and miscarriage in human pregnancy. Published studies using animal models show that placental TRP catabolism is vulnerable to environmental toxicant exposures, but to the best of our knowledge, no study has been performed in humans. Per or Polyfluoroalkyl Substances (PFAS) are widespread toxicants that are extremely stable in the environment and have been detected in human pregnancies in maternal blood and placenta samples. Previous murine studies have found that PFOA exposure alters several amino acid metabolic pathways, including TRP metabolism in the brain and liver. Additionally, PFAS exposure is associated with liver inflammation and reduced Tryptophan 2,3-dioxygenase (TDO), the enzyme responsible for TRP metabolism in the liver in humans. The current project investigates TRP catabolism in the human placenta. **Methods:** The cohort in this investigation is part of an ongoing, prospective longitudinal study Understanding Pregnancy Signals and Infant Development (UPSIDE) that has prospectively followed a diverse sample of dyads from the first trimester of pregnancy into childhood. During trimester 2, pregnant women consented to a blood draw, from which serum was separated for PFAS assessment (n=286). PFAS analytes were measured in serum samples using LC/MS analysis by the Wadsworth Human Health Exposure Analysis Resource (HHEAR) laboratory. Placental samples were also collected at the time of birth, aliquoted into 50ml tubes, and stored at -80C. Metabolomics assessments for amino acids were completed on a subset of placental samples (n=40) using LC/MS analysis by the University of Pennsylvania's Metabolomics Core Facility. This study focused on TRP, Kynurenine (KYN) and the KP metabolites Kynurenic Acid (KA) and 3-Hydroxy-Kynurenine (3-HK). Samples were shipped to University of Pennsylvania's Metabolomics Core for LC/MS analysis. Prior to analysis, PFAS values below LOD were imputed with the LOD/sqrt2, a common statistical method for linear regression analyses. Analytic methods planned for this investigation include Pearson's Correlations, linear models, and Bayesian Kernel Regression Model (BKRM). **Results:** Serum samples from all 40 women had detectable levels of PFOS, PFOA, PFNA, PFHxS, and PFDA levels. There were slightly lower rates of detection for PFPEA (75%) and PFUNDA (65%). Preliminary analysis of linear models suggests that levels of PFPEA (est= -0.59, se= 0.34, p= 0.09) and PFUNDA (est= -2.9, se= 1.3, p= 0.03) have an inverse relationship with TRP levels in the placenta. PFPEA levels have a positive relationship with KYN (est= 1.3, se= 0.37, p= 0.001) and with the KYN/TRP ratio (est= 0.34, se= 0.12, p= 0.007). **Conclusions:** These preliminary results suggest that PFAS analytes, especially PFPEA, are associated with indicators of increased KP activity. This is a unique and significant finding considering no other studies have investigated the influence of PFAS on placental KP activity. Analyses are ongoing and will include additional statistical models and assessments of IDO protein levels in the human placenta, a key mediator of KP activity.

PL 2032 Extracting Medical Devices: A Solution for Multilaminates, Soft Polymers, Superabsorbers and Various Adhesives

L. Williams, and B. Rollins. Convatec, Lexington, MA.

Background and Purpose: The diversity of materials used in producing medical devices often results in difficulties when testing for biocompatibility. Soft polymers, hydrogels, various adhesives, multilaminate structures and superabsorbent materials typically degrade or become otherwise compromised when performing traditional extractions as per ISO 10993, resulting in non-compliant extracts which are both physically unsuitable for biocompatibility testing and not clinically representative of the patient chemical exposure profile. The quantity of available material is overestimated, and this impacts the accuracy and appropriateness of the Toxicological Risk Assessment. Furthermore, further modification (i.e.: filtration) is often required before the extract can be used within biocompatibility test systems,

an approach which is currently not accepted by certain regulators (e.g.: the FDA). **Methods:** Extraction of wound dressings was performed in compliance with the requirements of ISO 10993-12 using two different extraction vessels: traditional (polybag) and novel (fixture). Following visual observation, the chemical profiles of extracts generated in both vessels were compared using gravimetric analysis (NVR), GCMS, QTOF-LCMS, ICP-MS and GPC. To verify the analytical evaluation, a few devices were confirmed through traditional *in vivo* systemic toxicity endpoint testing (acute and repeated dose) to verify any incompatibility with the use of the fixture; with the *in vivo* work, the pH and osmolality of the fixture extracts were also measured. **Results:** Generating extracts from wound dressing medical devices was feasible using the novel fixture extraction method. Comparing fixture extraction to extraction using a traditional (polybag) extraction vessel, device degradation was significantly minimized and the physical destruction of test articles was eliminated. NVR highlighted a significant reduction in the quantities of degradation particulates, and analytical chemistry (GCMS and LCMS) indicated no unaccountable difference in the chemistries present within the extracts generated using both the traditional and novel extraction method. Furthermore, GPC demonstrated a small reduction in the average molecular weight of extracted polymers, and it was demonstrated that the pH and osmolality of fixture extracts was not significantly changed from that of the extraction solvent. ICP-MS was determined to be incompatible with fixture extraction. Finally, systemically injecting the polybag extract resulted in equivocal results and failing to meet the test criteria in the acute and repeated dose systemic toxicity studies, respectively, whereas exposure to the fixture extracts following the same dosing protocols showed no evidence of systemic toxicity. **Conclusions:** Using a commercially available and standardized fixture for extracting medical devices (i.e.: wound dressings) composed of materials such as soft polymers, hydrogels and adhesives, multilaminates, and superabsorbers allows for the generation of extracts in compliance with ISO 10993 which are both (i) representative of an exaggerated patient chemical exposure profile and (ii) suitable for using in biocompatibility testing.

PL 2033 Approaches for the Biocompatibility and Toxicological Assessment of Absorbable-Degradable Medical Devices with Extraction Vehicle Solvent Incompatibility

C. Parker, and S. Campbell. Nelson Labs, Salt Lake City, UT.

Background and Purpose: Medical devices which have absorbable/degradable properties or are incompatible with test systems (biological and analytical), pose unique challenges for assessing their safety per the traditional ISO 10993 testing paradigm. Adaptations to these methods are required, in particular test article/dose preparation and how chemical characterization and the associated toxicological risk assessment can be performed. Non-solid materials, and those intended to change form during clinical use, such as hydrogels, collagens, wound rinse solutions, bone putties and degradable polymer sutures and implants. Certain materials can be incompatible with various extraction parameters within ISO 10993-12 leading to adaptations in approach. For many medical devices, a traditional approach to determining extractables includes an exhaustive extraction, and when a device is intended to change its physical and chemical properties during clinical use (eg, bioabsorbable/degradable devices), determining exhaustivity due to these intended properties may not be feasible. These challenging material types require a customized approach to best determine their complete safety profiles and efforts are underway by ISO TC 194 and ISO TC 150 working groups to create guidance on considerations and a potentially predictive pathway. These considerations are presented from a historical evaluation of bioabsorbable/degradable devices with the purpose of providing solutions, but also solicit feedback from industry for a collective approach. **Methods:** A historical review of ISO 10993 testing approaches resulting in a successful evaluation of safety for absorbable/degradable devices was performed and determined: 1) common challenges for sample preparation for absorbable/degradable material types, 2) sample preparation adjustments were necessary, 3) the particular biological and analytical chemistry methods they are incompatible with, 4) solutions for ensuring applicable biological endpoint(s) could be addressed, and 5) potential drawbacks to approaches used. **Results:** While the majority of material types and individual methods had solutions to any incompatibilities which were found to be suitable, it was determined that a robust pre-emptive mitigation plan was missing from a robust biological evaluation plan in some instances. When biological testing was performed via an extraction, sample preparation was found to require the greatest level of adaptation due to the variety to dose methods required across the applicable ISO 10993 series. Direct testing methods were best optimized for cytotoxicity, irritation, hemocompatibility and systemic toxicity while the rabbit material mediated pyrogen test was one of the most challenging. The strategic use of comparative controls allowed for a real-world clinical impact assessment of results which may have otherwise shown a "positive" result. For extractables chemical characterization testing and particular genotoxicity vehicles, the greater challenge of material compatibility with extraction solvent compared to most biological extractions vehicles lead to an expansion of incompatible materials including soft plastics. An Analytical Evaluation Threshold (AET) could not be met for certain cases and utilizing biological testing was required to support required endpoints (systemic toxicity and genotoxicity) which may have otherwise been addressed by chemical characterization. The findings, in particular for ISO 10993-12, have led to a proposal for an ISO Technical Specification document which uses known data to predict the results of extraction based on material type. **Conclusions:** The challenge with any approach that may

operate tangentially to a standard or guidance, is simultaneously ensuring both testing feasibility and regulatory acceptance. This historical review presents options and pathways which have been shown to generate optimal data using risk-based and historical perspective for modifications of ISO 10993 methodology, while promoting and helping predict the success of future medical devices with intended physical and chemical property changes during clinical use. Medical device manufacturers and the lab community can coordinate efforts to create a least burdensome (time, cost, and effort) pathway for the evaluation of absorbable/biodegradable materials and those with extraction vehicle incompatibility for testing.

PL 2034 Target Selection for Leachables Testing Using Historical Data of Pharmaceutical Container Closure Systems

Y. Yu-Rice, J. Liu, D. G. Dolan, A. Gallegos, S. B. Bandara, and Y. Nashed-Samuel. Amgen Inc, Thousand Oaks, CA.

Background and Purpose: Extractables and leachables (E&L) testing is widely used to identify and quantify impurities originated from the polymeric materials used in pharmaceutical manufacturing, packaging, and medical devices. Leachables testing provides a direct measurement of chemical migration under actual or accelerated conditions and serves as an important step in the overall E&L assessment process verifying patient safety and affording opportunities for risk mitigation. While regulatory guidelines such as draft ICH Q3E, USP <1664>, and ISO 10993-18 provide direction on when and how to conduct leachable testing, these guidelines do not explicitly define the scientific rationale or criteria for selecting leachable targets. **Methods:** Leachable target selection is guided by the extractables profile of the test article and is based on four main considerations: 1) the known toxicity or safety threshold of the compound; 2) its prevalence in extraction studies of similar materials; 3) its representativeness of specific material classes with known leachables profiles; and 4) the physiochemical properties and potential leachability under relevant storage/contact conditions. Ideally, leachable targets should be both targetable and quantifiable using an established analytical assay. Following these criteria, 27 leachable targets were selected and monitored in annual stability samples from multiple drug substance and drug product containers. Additionally, non-targeted analysis (NTA) was also conducted to identify any unanticipated leachables. **Results:** The four selection factors ensure the leachable target is toxicologically relevant and representative of compounds with a high likelihood of migrating from container materials under real-world use conditions. Among the 27 targets under annual monitoring, 11 were detected in the leachables testing of 25 drug products and 10 drug substances over a 5-year period. Two compounds, caprolactam and polyethylene glycols (PEGs) (molecular weight between 400 to 600 dalton), were consistently detected above their analytical assay limits of quantification. Caprolactam was reported in the leachable samples from the drug substance bags (detection frequency: 75%; n=24) with a maximum patient exposure of up to 36.4 µg/dose. PEGs were reported in the leachable samples from the vial-stopper systems (100%; n=33) with a maximum patient exposure of up to 875.7 µg/dose. Notably, bisphenol A (BPA), a compound identified in the extraction study of polycarbonate carboys (n=7), was not detected in any drug substance samples analyzed. With a few exceptions, no new leachables were detected in any drug products or drug substances using NTA with highly sensitive analytical assays capable of detection at ppm-ppb levels. **Conclusions:** This study demonstrates a systematic approach to leachable target selection which integrates extractable data interpretation, compound safety assessment, and analytical feasibility. Historical leachable data from pharmaceutical container systems indicates that the proposed approach effectively identifies representative leachable compounds with minimal unexpected findings from NTA general screening. Moreover, all leachables were reported at levels well-below their respective permitted daily exposure (PDE) values at all time points, providing empirical evidence that the current quality management system is effectively ensuring patient safety with respect to potential leachables exposure.

PL 2035 A Novel Alternative to Headspace Sampling for the Detection of Volatile Organic Compounds Utilizing Passive Headspace Concentration

K. L. Pacholke¹, S. M. Street¹, M. Giffin², E. K. Long¹, and K. A. Chaffin¹. ¹Medtronic Inc., Minneapolis, MN; and ²Medtronic Inc., Ogden, UT.

Background and Purpose: The current method used for analysis of volatile organic compounds (VOCs) from medical devices per ISO 10993-18:2020 is static headspace sampling, where a medical device is extracted with a polar aqueous solvent in a clean vessel for a set duration of time at a specific temperature using continuous mechanical agitation. The resulting liquid extract is then analyzed via headspace gas chromatography-mass spectrometry (HS GC-MS) to identify and quantify the compounds present. This information is then used in a toxicological risk assessment (TRA) to evaluate potential patient safety risks arising from exposure to these compounds. Recent deficiency questions from the U.S. Food and Drug Administration (FDA) are challenging whether VOCs are substantially lost during transfer of the polar aliquot to a vessel. The proposed FDA approach to address these deficiencies is to perform headspace analysis on the entire device. However, most medical devices are not compatible with the headspace vial configuration used for HS GC-MS analysis, as the

maximum available volume is limited to 20 mL with an inner neck diameter of only 11 mm. To address the FDA's request, a new semi-quantitative method was developed for medical devices: Passive Headspace Concentration for Medical Devices (PHC-MD). This approach was based on ASTM E1419-19 and ASTM E1618-19, standards originally created for fire debris analysis. It uses passive headspace concentration (PHC) to extract VOCs from an entire medical device without the need for a polar solvent. PHC has historically been used as a qualitative method for the identification of ignitable liquid residues in fire debris. In this study, we adapted, developed, and validated a PHC method for VOCs in medical devices that can provide quantitative amounts of VOCs which can then be evaluated in a TRA to understand the exposure risk to a patient. **Methods:** Residual Solvents Class 1 mix and Class 2 Mix A at various concentrations were spiked into gas-tight glass vials. PHC extraction was performed by hanging a small piece of activated charcoal into the headspace of the vial. The vials were sealed and heated for 24 hours at 100°C to drive volatiles into the headspace of the container, allowing interaction with the activated charcoal, which acted as sink for volatile organic compounds. The activated charcoal was removed from the container upon cooling and desorbed using dichloromethane. Sample analysis was performed on an Agilent Technologies 8890 gas chromatograph equipped with an Agilent 5977B mass selective detector. The resulting data was compared to traditionally conducted HS GC-MS data then evaluated using ISO 10993-17:2023 toxicology methods. **Results:** Method accuracy, precision, specificity, limit of quantitation (LOQ), and linearity were established to understand the robustness of this method for use in medical devices. When the results from the PHC-MD method were compared to historical data from traditional HS GC-MS analysis, we found that the PHC-MD method identified more compounds. This shows that the new method is both more sensitive as it is able to detect lower levels of volatiles, and more conservative than the previous approach. Permitted daily exposure limits for several VOCs specified in USP <467> (Residual Solvents) were evaluated as a toxicologically relevant framework for determination of suitable reporting limits for VOCs to ensure that the results were meaningful for toxicological risk assessments. **Conclusions:** Establishing a passive headspace concentration method for the detection of volatiles from an entire final, finished medical device is critical to address repeated FDA deficiencies surrounding the analysis of VOCs. It is also important for the accurate toxicological risk assessment to ensure patient safety has been adequately evaluated. This new method can be used on the entire medical device without the use of a polar solvent, expanding its applicability to medical devices that are incompatible with standard HS-GC vial configurations.

PL 2036 CN Bio Microphysiological System Platform to Assess Mechanisms of Hepatotoxicity

A. Rizzolo¹, V. Bhaskaran¹, Y. Zhang¹, F. Landry¹, C. Garrison¹, A. Fossier², and R. N. Hardwick². ¹Bristol Myers Squibb, Lawrenceville, NJ; and ²Bristol Myers Squibb, San Diego, CA.

Background and Purpose: While advancements have been made in 2D hepatocyte culture, there have remained gaps in the ability to predict human drug-induced liver injury (DILI). Complex *in vitro* models, such as microphysiological systems (MPS), which integrate 3D architecture and media microfluidics have aimed at improving the ability to predict DILI. However, their widespread use in pharmaceutical research has remained limited. We optimized a human liver MPS with hepatocytes, Kupffer cells (KCs), liver sinusoidal endothelial cells (LSECs), and stellate cells (SCs) at physiologically relevant ratios. We then evaluated whether the liver MPS could reliably distinguish between cholestatic and mixed DILI mechanisms by assessing functional markers, bile acid secretion, and gene expression profiles following administration of known mixed and cholestatic DILI compounds and controls. **Methods:** To recapitulate native human liver composition and function, we optimized cellular input of hepatocytes, KCs, LSECs, and SCs at relative proportions representative of native human liver. Cells were seeded at a density of 600,000 total cells per well in Williams E media in the CN Bio PhysioMimix® platform. Media was exchanged every other day for 22 days. To determine whether the model could distinguish cholestatic DILI from mixed DILI, 10 positive and negative controls were evaluated, with compound administration initiated on Day 8 at 1x, 5x, 15x and 50x Cmax. Samples were collected at 24 hours, 1 week, and 2 weeks post-administration. Non-terminal readouts included albumin, LDH, and bile acids as markers of liver health and function. At Day 22, expression of 21 genes involved in bile acid transport, metabolism, and homeostasis was profiled. **Results:** Administration of mixed and cholestatic DILI compounds resulted in significant, dose- and time-dependent cell damage, as indicated by decreased albumin production and increased LDH at all time points. Mixed DILI compounds had a greater impact on albumin output and overall toxicity, particularly at higher concentrations (15x and 50x Cmax), while cholestatic DILI compounds caused more pronounced downregulation of genes involved in bile acid metabolism (CYP7A1, CYP8B1) and transport (NTCP, BSEP). Of the five bile acids (TCDCa, CA, TCA, GCA, GCDCA) profiled, significant reductions in GCA and GCDCA over two weeks were observed. **Conclusions:** Collectively, these findings demonstrate that mixed and cholestatic DILI compounds disrupt hepatobiliary homeostasis, impair liver cell viability, and alter key regulators of bile acid regulation. Successful integration of MPS into pharmaceutical research relies on careful characterization, definition of relevant context(s) of use (COU), and COU qualification. Current data demonstrate the feasibility of utilizing the liver MPS to assess mechanisms of hepatotoxicity, including cholestatic DILI, *in vitro*.

PL 2037 Role of Hepatocyte-Specific Egr1 in Liver Injury and Regeneration After Acetaminophen Overdose

D. Paine-Cabrera, D. Roberts, M. Kotulkar, K. Venneman, and U. Apte. University of Kansas Medical Center, Kansas City, KS.

Background and Purpose: Acetaminophen (APAP) overdose is the leading cause of acute liver failure (ALF) in Western countries. Current treatment options for APAP-induced ALF are limited, including N-acetylcysteine effective only when administered within the first 24 hours after overdose and liver transplantation, which presents significant challenges. Studies from our laboratory and others have shown that timely liver regeneration is critical for patient survival. However, the mechanisms of liver regeneration after APAP overdose and the transcriptional factors that drive the regenerative response are not entirely clear. Early Growth Response 1 (Egr1) is an early response transcription factor rapidly activated after liver injury. Previous studies have shown that Egr1 protects after APAP overdose at early time points during the injury phase, improving mitochondrial respiratory function and fatty acid β -oxidation activity. While Egr1 deficiency exacerbates liver injury, its role during regeneration remains unclear. Studies from our lab performed using the incremental dose model, which includes a moderate/regenerative dose and a severe/nonregenerative dose, showed a steady decline in Egr1 expression in both doses during the first 24 hours but a significant increase only in the moderate/regenerative dose at 48 hours, coinciding with hepatocyte proliferation. Based on these studies, we hypothesize that increased Egr1 during APAP-induced liver injury regulates liver regeneration.

Methods: Two-month-old male Egr1 floxed mice were injected with AAV8-TBG-iCre to generate hepatocyte-specific Egr1 knockout (hEgr1 KO) mice. Wild-type control mice were injected with AAV8-TBG-GFP. One week after AAV administration, mice were fasted overnight and then administered a 300 mg/kg overdose of APAP. Liver and blood samples were collected at multiple time points over 72 hours. **Results:** hEgr1 KO mice exhibit a significantly greater liver injury compared to controls at 6 and 24h after APAP administration, as determined by elevated ALT activity in serum and hepatic necrosis. CYP2E1 protein level shows no difference at baseline. The absence of Egr1 was associated with low GSH levels and high JNK and ERK phosphorylation. Importantly, despite significantly greater initial injury, hEgr1 KO mice showed recovery similar to that of controls. Both groups display similar levels of proliferation at 48h and 72h after APAP overdose, exhibiting no significant difference in Ki67-positive cells by IHC. hEgr1 KO mice show a reduction of Cyclin D1 protein at 24h compared to control, but no difference was observed at 48 and 72h after APAP treatment. This was accompanied by increased protein levels of CDK4 and phospho-Rb in hEgr1 KO mice. hEgr1 KO mice had increased AKT phosphorylation at 72h after APAP overdose. The expression of cytokines *Il6*, *Il1b*, and *Il10* is increased at 6 and 24h after APAP overdose in hEgr1 KO mice, associated with higher injury levels. *Ifng* shows no significant difference between the mouse groups. Key mediators of liver regeneration, *Tnfa* and *Tgfb1*, had increased expression in hEgr1 KO mice at 48h, but *Il6* mRNA levels were lower. Nuclear receptors, other liver regeneration mediators, *Ppara*, *Car*, and *Fxr* showed higher expression in control mice at 24h after APAP overdose than in hEgr1 KO mice, with *Ppara* alone showing high expression in control mice at 48h. **Conclusions:** Taken together, these data indicate that hepatocyte-specific Egr1 protects from initial liver injury after APAP overdose, but its loss during the regenerative phase does not affect liver regeneration. In fact, rapid recovery of hEgr1 KO mice despite significantly higher injury suggests that inhibition of Egr1 during the regenerative phase may improve liver regeneration by stimulating pro-regenerative cytokines (TNF α) and inhibiting anti-regenerative cytokines (IL-6). Supported by NIH R01DK98414

PL 2038 MRP4 Modulates Hepatic Response to Phenobarbital by Regulating Proliferative and Metabolic Pathways

A. P. Laddha, H. Wu, and J. E. Manautou. University of Connecticut, School of Pharmacy, Storrs, CT.

Background and Purpose: Membrane transporters are essential for hepatic homeostasis by mediating the movement of metabolites and xenobiotics. Among these, Multidrug Resistance Associated Protein 4 (Mrp4/ABCC4) plays a role in hepatic defense and adaptation to chemical stress. Our laboratory previously showed that hepatic Mrp4 expression increases after acetaminophen intoxication and colocalizes with zones of hepatocyte proliferation. Notably, Mrp4 deficiency did not reduce hepatocellular proliferation following partial hepatectomy (PH). Rather, knockout mice developed significant hepatic steatosis post-PH. To further delineate the role of Mrp4 in hepatocyte growth and metabolic remodeling, we used a phenobarbital-induced hepatomegaly model, a classical mitogenic stimulus that promotes hepatocellular proliferation and metabolic adaptation. **Methods:** Adult wild-type and Mrp4^{-/-} mice received daily intraperitoneal doses of phenobarbital (50 or 100 mg/kg) for 10 days. Liver-to-body weight ratios and serum ALT levels were measured to assess hepatic growth and injury. Histological evaluation was performed on formalin-fixed, paraffin-embedded liver sections using H&E staining to assess hepatocellular hypertrophy and mitotic figures. Hepatocyte proliferation was quantified by Ki67 immunohistochemistry. Hepatic triglyceride content was measured in frozen liver tissue using a colorimetric triglyceride assay following lipid extraction, and neutral lipid accumulation was visualized via Oil Red O staining. Gene and protein expression of markers involved in cellular proliferation, xenobiotic metabolism, and lipid regulation were quantified using qPCR and immunoblotting, respectively. **Results:** Mrp4^{-/-}

mice exhibited significantly higher liver-to-body weight ratios and elevated ALT levels compared to wild-type counterparts, indicating amplified hepatic enlargement and injury. Histology revealed hepatocellular hypertrophy with increased mitotic figures in phenobarbital-treated Mrp4^{-/-} livers. An increase in Ki67-positive hepatocytes was observed in Mrp4^{-/-} mice treated with 100 mg/kg phenobarbital, although this change was not statistically significant compared with wild-type mice treated with the same dose. Gene and protein analyses showed upregulation of proliferative markers (Pcna, Cdk1/2, Cyclin B1, c-Myc) and xenobiotic metabolism-related genes (Cyp3a11, Cyp2b10, Cyp2c29, Ugt1a1, Sult1a1, Nqo1, Ahr), with concurrent suppression of Cyp7a1, Cyp2e1, and Gstp1, consistent with selective reprogramming of hepatic detoxification pathways in phenobarbital-treated Mrp4^{-/-} animals. Mechanistically, increased phosphorylation of cAMP response element-binding protein (CREB) and decreased Salt-inducible kinase 2 (SIK2) levels indicate activation of CREB-mediated transcription. Lipid-regulatory genes (Lpl, Fabp4, Ppar α , Dgat1, Acot2) were elevated, whereas Fasn, Acc, and Ppara were downregulated, in line with early lipid accumulation confirmed by Oil Red O staining. Consistently, liver triglyceride levels were significantly higher in Mrp4^{-/-} mice compared to wild-type animals. **Conclusions:** Loss of Mrp4 markedly amplifies phenobarbital-induced hepatic proliferation and metabolic remodeling. This phenotype involves enhanced xenobiotic enzyme expression, activation of CREB signaling, and dysregulation of lipid metabolism, revealing a previously unrecognized role for Mrp4 in maintaining hepatic metabolic balance under mitogenic stress.

PL 2039 Silencing hepatic CAPN4 protects against diet-induced MASH in mice

L. Walker¹, J. Li¹, C. Vanderpuye¹, P. Muddasani¹, S. Chaudhary¹, S. Taborski¹, J. I. Beier¹, I. Sipula¹, M. J. Juczak¹, M. L. Merchant², and G. E. Arteel¹. ¹University of Pittsburgh, Pittsburgh, PA; and ²University of Louisville, Louisville, KY.

Background and Purpose: Metabolic dysfunction-associated steatohepatitis (MASH) is a severe liver disease characterized by hepatocellular inflammation and fibrosis that affects a significant portion of the population. Plasma proteomic profiling reveals a distinctive pattern of protein degradation in MASH compared to healthy liver, with computational analysis implicating elevated calpain-mediated proteolysis. Calpains (particularly Calpain 1/2 isoforms) are Ca²⁺-dependent proteases activated under cellular stress that regulate tissue remodeling and inflammation, yet their specific role in MASH pathogenesis remains poorly understood. This study investigated whether hepatic Calpain 1/2 activity is necessary for MASH development. **Methods:** C57BL/6J mice received rAAV8 vectors encoding shRNA targeting Capn4 or scrambled control sequences under hepatocyte-specific (albumin) promoter control. After 4 weeks of vector integration, mice were fed either a low-fat control diet (13% saturated fat) or a Western-style high-fat, high-fructose diet (42% saturated fat) for 12 weeks. Hepatic Capn4 expression was quantified by qPCR. Analysis included plasma biochemistry, histopathological assessment of liver injury and steatosis, and quantitative PCR analysis of inflammatory gene expression to determine the contribution of calpain activity to MASH pathogenesis. **Results:** rAAV8-mediated knockdown achieved robust suppression of hepatic Capn4 expression. As expected, Western diet induced obesity, insulin resistance, and severe SteatoHepatitis. Despite minimal systemic differences in obesity and adiposity metrics, Capn4 knockdown substantially attenuated liver injury and fibrosis as well as suppressed key inflammatory genes associated with MASH progression. **Conclusions:** This study reveals that Capn4-mediated hepatic calpain activity is a critical driver of MASH development, specifically affecting disease initiation rather than advanced fibrosis progression. Blocking hepatic calpain proteolysis disrupts early pathogenic mechanisms while having minimal impact on systemic metabolic parameters. These findings establish Capn4 targeting as a potential therapeutic strategy for early intervention in MASH and highlight the critical role of hepatic Calpain 1/2 in disease development.

PL 2040 The Impact of Cyp2e1 KO and Sex on Response to DDC Diet

K. M. Stayer¹, M. N. Thornton¹, K. R. Driggers¹, M. A. Engevik¹, K. E. Chetta¹, K. Nejak-Bowen², and J. H. Hartman¹. ¹Medical University of South Carolina, Charleston, SC; and ²University of Pittsburgh, Pittsburgh, PA.

Background and Purpose: Cytochrome P450 2E1 (CYP2E1) is a mammalian monooxygenase that is expressed at high levels in the liver. Within hepatocytes, CYP2E1 localizes to both the endoplasmic reticulum and the mitochondria. CYP2E1 metabolizes small hydrophobic compounds and often generates toxic metabolites. Although the enzyme is well studied for its role in xenobiotic toxicity such as metabolism of benzene or acetaminophen, its role in endogenous metabolism is less well understood. CYP2E1 is also highly conserved among mammals, and no clearly deleterious polymorphisms have been reported. Our previous work identified pathological changes in the bile duct region of CYP2E1 knockout (KO) mice, with more severe changes observed in females. To determine how this baseline biliary pathology affects liver function, we fed twelve-week-old mice a diet containing 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC), a toxic porphyrinogenic compound. DDC prevents incorporation of iron into protoporphyrin IX, leading to its accumulation in hepatocytes, the formation of bile duct plugs, and pathology similar to primary sclerosing cholangitis. We hypothesized that female KO mice would experience worse outcomes compared to KO males and female wild-type (WT) controls, as measured by fibrosis

and increases in serum ALP, ALT, AST, and GGT. **Methods:** Two cohorts of male and female CYP2E1 KO mice were placed on a diet containing 0.1 percent DDC for two weeks beginning at twelve weeks of age. Histology was assessed by hematoxylin and eosin staining and picrosirius red staining for fibrosis. For serum biochemistry, approximately 500 microliters of blood were collected from each animal, allowed to clot for thirty to sixty minutes, and centrifuged at 10000 times g at 4 degrees Celsius. One hundred microliters of serum were submitted to our Department of Laboratory Animal Resources for a comprehensive diagnostic chemistry panel, which included ALT, total bilirubin, albumin, ALP, amylase, BUN, calcium, phosphate, creatinine, glucose, sodium, potassium, total protein, and globulin. **Results:** All groups displayed significant (p<0.05) elevations in total bilirubin, ALP, amylase, BUN, calcium, phosphate, sodium, and potassium compared to normal ranges. All males on the DDC diet (12 of 12) showed elevated ALT regardless of genotype. In contrast, among females, four of six animals in both KO and WT groups did not show ALT elevation. Other serum measures remained within the normal range across groups. Histological analysis with hematoxylin and eosin and picrosirius red staining revealed characteristic onion ring fibrosis in portal tracts and the presence of bile duct plugs in all animals. Quantification of fibrosis severity and statistical comparison is ongoing. To further define the effects of DDC, ongoing work will assess total bile acids, proliferation markers, and levels of Sox9 and CK19. **Conclusions:** CYP2E1 knockout did not alter the overall pathology induced by the DDC diet, despite baseline biliary differences in KO animals. An unexpected observation was that female mice of both genotypes showed no ALT elevation, suggesting that their hepatocytes may be protected from DDC-induced injury. These findings underscore a sex specific response to DDC injury that warrants further investigation, particularly given the strong male predominance (2-3x higher in males) observed in human PSC.

PL 2041 Real-Time Hepatic Surveillance in Residents Following the East Palestine, OH Chemical Disaster

O. P. Okonkwo¹, A. Craig¹, A. M. Monroe¹, K. M. Stello¹, J. P. Fabisiak¹, C. A. Ng¹, O. Ghosh¹, F. R. Schumacher², M. Y. Lichtveld¹, and J. I. Beier¹. ¹University of Pittsburgh, Pittsburgh, PA; and ²Case Western Reserve University, Cleveland, OH.

Background and Purpose: The February 2023 train derailment in East Palestine, Ohio, released vinyl chloride and other hepatotoxic chemicals, creating urgent need for health surveillance. This study represents the first systematic liver function assessment in residents potentially exposed to these environmental toxicants, establishing critical baseline data for long-term health monitoring. **Methods:** Adults ≥ 18 years within 8 miles of the derailment site have been recruited since June 2024. Participants provided informed consent for blood sampling and complete questionnaires on demographics, alcohol consumption, medical history, and health status. Liver function was assessed via serum ALT and AST levels. FibroScan examinations were performed to evaluate liver stiffness and hepatic steatosis. Body mass index (BMI) was calculated from measured anthropometric data. **Results:** To date, 88 participants enrolled (mean age 65.4 $\pm$ 1.9 years, range 18-87; 67% female), representing robust community response. All participants self-identified as non-Hispanic White. Mean BMI was 29.2 $\pm$ 0.6 kg/m² (range 15.8-44.9) with 2.3% underweight, 21.6% normal weight, 30.7% overweight, and 45.5% obese. Alcohol consumption: 65.9% drank < 4 times weekly, 19.3% never drank, and 8% consumed alcohol ≥ 4 times weekly. Mean liver enzyme levels remained within normal ranges in 79 participants with available data: ALT 17.5 $\pm$ 0.8 U/L (range 6-48 U/L) and AST 20.8 $\pm$ 0.9 U/L (range 11-75 U/L). Using sex-specific thresholds, 29.6% of women had ALT ≥ 19 U/L and 9.3% had AST ≥ 25 U/L, while 12% of men had ALT ≥ 30 U/L and 12% had AST ≥ 30 U/L. Notably, a 53-year-old female participant living less than 0.25 miles from the derailment site (highest exposure proximity) presented with normal ALT (12 U/L) and AST (15 U/L), normal BMI (22.57 kg/m²), and no alcohol use, yet demonstrated elevated liver stiffness (10.8 kPa) on FibroScan suggesting F2-F3 fibrosis and moderate hepatic steatosis (280 dB/m). This case highlights the potential inadequacy of traditional liver enzymes in detecting early hepatotoxicity from environmental exposures. As recruitment remains active, these preliminary findings may evolve. **Conclusions:** This pioneering surveillance study reveals critical findings: despite potential vinyl chloride exposure, the majority demonstrate normal or near-normal liver enzyme levels using sex-specific thresholds, yet FibroScan analysis uncovered significant liver abnormalities in a participant with highest exposure proximity and normal enzymes, demonstrating that traditional biomarkers ALT and AST may not detect early hepatotoxicity. The case of F2-F3 fibrosis with moderate steatosis in a young, normal-weight, non-drinking individual living nearest the derailment site raises urgent concerns about subclinical liver damage that standard screening misses. Continued vigilance remains essential. Future analyses of the bio banked samples will include CK-18, which has demonstrated superior predictive value for vinyl chloride-related liver damage. These baseline data enable longitudinal tracking of hepatic health in this uniquely exposed population. This study represents a critical model for environmental health response with implications extending beyond East Palestine to communities worldwide facing similar toxicant exposure threats, emphasizing the necessity of advanced imaging techniques alongside traditional biomarkers for comprehensive liver health assessment.

M. R. Call¹, K. D. Hart¹, Y. Zahoor², R. Nault², T. Zacharewski², M. Goedkin³, and J. D. Clarke¹. ¹Washington State University- Spokane, Spokane, WA; ²Michigan State University, East Lansing, MI; and ³Rutgers University, New Brunswick, NJ.

Background and Purpose: Cyanobacterial blooms are increasing in frequency and magnitude due to rising water temperatures and nutrient enrichment. These blooms produce over 300 hepatotoxic microcystin (MC) congeners. Among these, microcystin-LR (MCLR) is one of the most hepatotoxic, common and studied. MCLR has been classified by the International Agency for Research on Cancer as a group 2B carcinogen. Recent preclinical evidence indicates MCLR can exacerbate the chronic liver disease, metabolic dysfunction-associated steatotic liver disease (MASLD), which has a global prevalence of approximately 25%. This study investigated the effects of MCLR on liver cell type populations in healthy mice and a MASLD model. **Methods:** C57BL/6J mice received either a control diet or a MASLD-inducing high fat/high cholesterol (HFHC) diet for 14 weeks, followed by an oral gavage with vehicle or 0.8 mg/kg MCLR every 24 h for 14 days, resulting in 4 treatment groups: control diet + vehicle (CV), control diet + MCLR (CM), HFHC diet + vehicle (HV), and HFHC diet + MCLR (HM). Animals were euthanized after final MCLR dose and liver samples were collected for histology and single nuclei RNA-sequencing (snRNA-seq) analysis. H&E staining was scored by a veterinary pathologist. snRNA-seq identified 10 distinct cell populations: hepatocytes, cholangiocytes, hepatic stellate cells (HSCs), liver sinusoidal endothelial cells (LSECs), macrophages, neutrophils, B cells, T cells, plasmacytoid dendritic cells (pDCs), and an undefined immune cells population. Gene expression counts were pseudobulked by cell type, dose, and diet for differential expression analysis. Marker genes identified hepatocytes as centrilobular, midzonal, or periportal. Zonation inference used trajectory analysis, with center of expression (CoE) calculated as the pseudospacial center-of-mass for gene expression along the portal-to-central axis. Gene set enrichment analysis (GSEA) applied the Kyoto encyclopedia of genes and genomes, Gene ontology, and Reactome libraries. CellChat was used to assess ligand-receptor signaling between cell types. **Results:** Hepatocyte and immune cell proportions were altered by MCLR and HFHC diet. Hepatocytes decreased from 70.0% in CV to 55.2%, 49.2%, and 26.9% in CM, HV, and HM groups, respectively. In contrast, immune cell proportions increased from 11.6% in CV to 26.3%, 30.0%, and 43.2% in CM, HV, and HM groups, respectively. The number of unique differentially expressed genes in hepatocytes was higher in CM compared to HM (3,693 vs. 2,393, respectively), whereas immune cells, such as macrophages, showed the opposite trend (740 vs. 1,247, respectively). The top 50 genes with the most variable CoE revealed MCLR and HFHC diet elicited a shift in zonation from centrilobular to periportal. Specifically, MCLR in both diets caused a substantial periportal shift, and the HFHC diet moved CoE closer to an intermediate phenotype between centrilobular and periportal. Approximately 680 pathways were enriched across all cell types in the different dose and diet groups based on GSEA. In hepatocytes, 79 pathways were enriched, including some associated with MASLD progression and carcinogenesis such as the negative regulation of gluconeogenesis, anti-apoptotic response (Birc5), and cell cycle check points (Bub1). CellChat revealed increased cell-to-cell communication in the HM compared to the CV group (1,213 connections to 374 connections, respectively). **Conclusions:** The greater effect of MCLR on immune cells, liver zonation, and intracellular communication in the context of the HFHC diet indicate increased immune response and loss of hepatocyte zonal structure may be cellular mechanisms that contribute to how MCLR exposure exacerbates MASLD. Overall, these data highlight important differences in liver cell type-specific responses to MCLR in healthy versus MASLD livers and suggest increased risk of MCLR hepatotoxicity in populations with pre-existing liver disease.

PS 3001 Sex-specific roles of LKB1 in acetaminophen hepatotoxicity in mice

D. Bhadra, and M. R. McGill. University of Arkansas for Medical Sciences, Little Rock, AR.

Background and Purpose: Acute liver failure (ALF) is a rare but devastating condition with high mortality. Liver transplantation, the only life-saving treatment for ALF, is limited by an enduring shortage of healthy donor livers. In addition, transplant recipients face numerous life-threatening risks such as graft rejection and infection. New treatments are clearly needed to improve transplant-free survival and reduce dependence on transplantation. Interestingly, our prior work revealed that LKB1 signaling is strongly activated in non-survivors compared to survivors in patients with APAP-induced ALF. Based on that, we hypothesized that LKB1 is detrimental during APAP hepatotoxicity and inhibiting LKB1 may be a novel therapeutic strategy. To test that hypothesis, we generated liver-specific LKB1 KO mice, overdosed them with APAP, and measured liver injury. **Methods:** LKB1 KO and control animals were generated by treating LKB1 floxed mice with adeno-associated viruses carrying plasmids encoding Cre recombinase or eGFP, respectively, under the hepatocyte-specific thyroglobulin promoter. After 2 weeks, male and female mice were treated with 300 mg/kg APAP or 500 mg/kg APAP, respectively. The higher dose in females is necessary to achieve the same extent of liver injury as the males because females are less susceptible to APAP toxicity. Liver and blood were then collected at 2, 6, and 24 h post-APAP. Liver injury was assessed at all time points by measuring serum alanine transferase (ALT). JNK activation was measured by immunoblotting for phosphorylated

JNK. Cyp2e1 levels were measured by both immunoblotting and Cyp2e1 activity. NAPQI formation and protein binding in the liver were assessed by measuring total glutathione and APAP-protein adducts. Oxidative stress in the liver was assessed by measuring oxidized glutathione. **Results:** Serum ALT was reduced in LKB1 KO mice compared to WT animals at 6 and 24 h post-APAP (6 h mean±SE: 1269±365 vs. 3693±747 U/L, p<0.05; 24 h mean±SE: 1614±747 vs. 8491±946 U/L, p<0.05). JNK activation was also reduced in the KO mice. Total glutathione was increased in male KO mice compared to male WT animals (mean±SE: 0.51±0.06 vs. 0.27±0.02 μmol/g, respectively, p<0.05), indicating inhibition of NAPQI formation in the males. Consistent with that, Cyp2e1 protein and activity were lower in the male KO mice, as well as APAP-protein adducts (mean±SE: 0.2606±0.07834 vs. 1.251±0.1159 nmol/g, p<0.05). However, there was no difference in total glutathione, Cyp2e1, or APAP-protein adducts between female KO and WT mice. Instead, oxidative stress was significantly reduced in the KO females (%GSSG mean±SE: 1.8±0.2 vs. 2.9±0.3, p<0.05), indicating an antioxidant effect. **Conclusions:** Consistent with our hypothesis, LKB1 KO protected against APAP-induced liver injury. However, the mechanisms of protection are sex-specific: Male mice have reduced Cyp2e1 expression, while female mice have less oxidative stress. Additional research is needed to determine how LKB1 regulates Cyp2e1 and reactive oxygen species in males and females, respectively. (Support: NIH R01 DK135752 (PI: McGill)).

PS 3002 Hepatic stellate cell-specific HuR deficiency protects female mice from CCl4-induced liver fibrosis development

Z. Xing¹, E. Jones², N. Eppler², and Y. Zhang². ¹Northwestern University, Evanston, IL; and ²University of Kansas Medical Center, Kansas City, KS.

Background and Purpose: Chronic liver injury drives hepatic stellate cell (HSC)-mediated fibrosis, ultimately progressing to liver cirrhosis, the leading cause of liver-related mortality. Thus, developing liver-targeted anti-fibrotic therapies is imperative. In cultured HSCs, the RNA-binding protein Human antigen R (HuR) exhibits pro-fibrotic activity; however, its role in liver-wide fibrogenesis remains incompletely defined. Furthermore, fibrosis mechanisms in females are underexplored. To address these gaps, we characterized CCl4-induced liver injury in female HSC-specific HuR deficient (HuRHSC-/-) mice. **Methods:** Female HuRHSC-/- mice and their wildtype (WT) counterparts were administered 0.5 μl/g CCl4 either as a single dose (acute injury) or biweekly for six-weeks (chronic injury); corn oil served as control. Livers and serum were collected 48-hours post treatment. **Results:** In oil injection controls, HuRHSC-/- livers showed a 1.5-fold decrease in HuR mRNA, while cytochrome P450 2e1 expression was similar between genotypes. Acute CCl4 exposure caused comparable serum ALT elevations and centrilobular necrosis in both groups. Contrastingly, pericentral F4/80+ macrophage accumulation and pro-inflammatory and pro-fibrotic gene induction occurred only in WT livers and were blunted in HuRHSC-/- livers. Following chronic treatment, WT livers exhibited extensive collagen deposition and macrophage infiltration, whereas these features were largely absent in HuRHSC-/- livers. Correspondingly, the induction of pro-fibrotic gene expression decreased in HuRHSC-/- livers. **Conclusions:** In summary, HSC-specific HuR deletion protects females from CCl4-induced inflammation, macrophage accumulation, and fibrosis without altering CCl4 metabolism. These findings identify HSC HuR as a key regulator linking hepatotoxic injury to macrophage recruitment and collagen deposition, highlighting HuR as a promising therapeutic target.

PS 3003 Combined Liver-Specific Deletion of RNA-Binding Proteins, ZFP36L1 and ZFP36L2, Promote Hepatocarcinogenesis

R. Kumar¹, J. Chen², S. Patil³, and Y. Saini¹. ¹North Carolina State University, Raleigh, NC; ²Louisiana State University, Baton Rouge, LA; and ³National Institute of Environmental Health Sciences, Durham, NC.

Background and Purpose: Environmental carcinogens often promote endogenous mutagenic processes in human liver cancer. While transcriptional regulation and mutational landscape have been studied in this process, the role of post-transcriptional gene regulation mediated by RNA-binding proteins (RBP) remains poorly understood. Our previous study showed that combined liver-specific deficiency of two RBPs, Zinc Finger Protein 36 Like 1 (ZFP36L1) and Zinc Finger Protein 36 Like 2 (ZFP36L2), results in spontaneous hepatic inflammation and activation of oncogenic pathways. Since inflammation drives liver cancer, we hypothesized that ZFP36L1 and ZFP36L2 regulate hepatocarcinogenesis. We tested this hypothesis using a diethylnitrosamine (DEN)-induced mouse model of hepatocarcinogenesis. **Methods:** Liver-specific ZFP36L1 and ZFP36L2 double knockout (L1/L2^{dKO}; AlbCre⁺/Zfp36l1^{fllox/fllox}/Zfp36l2^{fllox/fllox}) and flox-only control (L1/L2^{FLX}; AlbCre⁺/Zfp36l1^{fllox/fllox}/Zfp36l2^{fllox/fllox}) mice of both sexes were administered DEN (25mg/Kg BW) intraperitoneally at postnatal day 14 and euthanized at 24 h and 6 months post-injection to assess DEN-induced DNA damage and hepatocarcinogenesis, respectively. Additionally, we assessed the expression of these RBPs in hepatocellular carcinoma cohorts from the TCGA database. **Results:** The expression of yH2AX, a DNA damage marker, was comparable between groups at 24 h post-DEN administration, suggesting no difference in the initiation of DEN-induced carcinogenesis. Interestingly, a higher percentage of DEN-treated L1/L2^{dKO} mice (~85%) developed liver tumors compared with DEN-treated L1/L2^{FLX} mice (~16.6%) at 6 months post-exposure. L1/L2^{dKO} livers

exhibited a greater tumor burden and predominantly high-grade lesions characteristic of hepatocellular carcinoma (HCC), whereas L1/L2^{FLX} livers displayed only a few low-grade preneoplastic foci. Additionally, L1/L2^{dko} livers had higher immune cell infiltration and collagen deposition - two key drivers of HCC - compared to L1/L2^{FLX} livers. Furthermore, the expression of HCC-promoting target genes, including *Bcl2*, *Cybb*, *Fgf21*, *Igf1p1*, *Mmp13*, *Plau*, and *Zeb2*, was significantly upregulated in the livers of DEN-treated L1/L2^{dko} mice compared with those of DEN-treated L1/L2^{FLX} mice. Finally, ZFP36L1 and ZFP36L2 were significantly downregulated in the human liver cancer cohort (n=374) compared to controls (n=50) retrieved from the TCGA database. Overall, the combined liver-specific deletions of ZFP36L1 and ZFP36L2 promoted hepatocarcinogenesis by augmenting inflammation, fibrosis, and stabilizing HCC-associated target genes. **Conclusions:** Our findings uncover a novel tumor-suppressive role of ZFP36L1 and ZFP36L2 in liver cancer and provide a mechanistic association between post-transcriptional gene regulation and environmental carcinogenesis.

PS 3004 Enhancement of acetaminophen-induced hepatotoxicity in Spontaneously Diabetic Torii-Lepr^{fa} (SDT fatty) rats

K. Kondo, N. Yamada, Y. Suzuki, T. Takahashi, and T. Shoda. Toxicology Research Laboratories, Yokohama Research Center, Shionogi & Co., Ltd., Yokohama, Kanagawa, Japan. Sponsor: E. Spicer

Background and Purpose: Acetaminophen (APAP) is widely used as a relatively safe antipyretic and analgesic. However, when administered at high doses, it can cause liver injury due to the binding of a reactive metabolite, NAPQI, produced via cytochrome P450 metabolism, to proteins. In most cases, NAPQI is detoxified through conjugation with glutathione (GSH). However, when the amino acid supply is interrupted, even low doses of APAP can induce liver injury. In patients with type 2 diabetes, GSH levels are reported to be lower than in healthy individuals, suggesting a higher susceptibility to APAP-induced liver injury. However, the relationship between diabetes-induced enhancement of gluconeogenesis and GSH synthesis capacity remains unclear. Therefore, we investigated the impact of the diabetic condition on hepatic GSH synthesis capacity and APAP metabolism using Spontaneously Diabetic Torii-Lepr^{fa} (SDT fatty) rats, a spontaneous non-obese type 2 diabetes model, and sought to determine whether SDT fatty rats exhibit increased susceptibility to APAP-induced liver injury and to elucidate the underlying mechanisms. **Methods:** APAP was administered orally, once daily, to Sprague-Dawley (SD) and Spontaneously Diabetic Torii-Lepr^{fa} (SDT fatty) male rats (6 weeks of age, 6 or 7 animals per group) at the dose levels of 300 and 500 mg/kg for 42 days. The animals in the matched control groups (6 animals of both sexes) were administered only the vehicle (0.5% methylcellulose aqueous solution). Plasma hepatic-function parameters (aspartate aminotransferase (AST), alanine aminotransferase (ALT), glutamate dehydrogenase (GLDH)) were measured before the initiation of dosing, and on days 14, 28 and 42. At the end of the dosing period, hepatic glutathione (GSH) levels and hepatic mRNA expression of gluconeogenesis-related gene (*Pck1*, *Fbp1* and *G6pc*), drug metabolizing enzyme-related gene (*Ugt1a6*, *Cyp1a2* and *Cyp2e1*), drug metabolizing enzyme activity (CYP2E1) and GSH synthesis-related gene (*Gclc* and *Gclm*) were measured. **Results:** In SD rats, there were no changes in plasma AST, ALT, or GLDH activities at any dose level. In contrast, in SDT fatty rats, the activities increased during the latter half of the administration period at 500 mg/kg. In comparison between the matched control groups, the mRNA levels of *Cyp1a2* and *Cyp2e1* were higher in SDT fatty rats, whereas no strain differences were observed for *Ugt1a6*. Upon APAP administration, *Ugt1a6* mRNA levels significantly increased in both strains in a dose-dependent manner; however, the degree of increase was smaller in the SDT fatty rats compared to SD rats. There were no changes in hepatic CYP2E1 activity at any dose level in the SD rats, but in the SDT fatty rats, a significant decrease in activity was observed at 500 mg/kg compared to the control group. Hepatic GSH concentrations significantly increased in the SD rats at 300 and 500 mg/kg, whereas in the SDT fatty rats, hepatic GSH levels decreased at 500 mg/kg. Although mRNA levels of *Gclm* and *Gclc*, which encode subunits of γ-glutamylcysteine synthetase, the rate-limiting enzyme in GSH synthesis, did not change in response to APAP administration in either strain, comparison of control groups revealed that SDT fatty rats had lower mRNA levels of both genes compared to SD rats. **Conclusions:** SDT fatty rats were shown to have a higher susceptibility to APAP-induced liver injury compared to SD rats, through decreased glutathione conjugation capacity and reduced GSH synthesis by enhanced gluconeogenesis and lower gene expression levels of GSH-synthesizing enzymes.

PS 3005 Cholesterol mediated endotoxic liver injury is enhanced by sitagliptin in Sprague-Dawley rats.

T. Pala, G. Breaux Jr, R. Pathak, A. Kumar, and S. N Murthy. Southern University A & M, Baton Rouge, LA.

Background and Purpose: Animal products like dairy, poultry, and meat are rich in methionine (Met) and cholesterol (Cho) and therefore are consumed together. Homocysteine (formed from Met) and Cho are documented risk factors for liver and heart disease, to mention some. Emerging evidence suggests an association between high cholesterol and dysbiosis, leading to endotoxemia and liver damage, among others. In view of the known pleiotropic effects of sitagliptin (an anti-type

2 diabetic drug), studies were conducted to investigate its role in reducing endotoxemia. **Methods:** After taking an initial blood sample, adult male Sprague Dawley rats were divided into four groups. These were fed *ad libitum* a) control (Con) diet, b) enriched with 1.5% Methionine, c) 2.0% Cholesterol, and d) the combination (1.5% Methionine + 2.0% Cholesterol) for 35 days. From day 10, an aqueous suspension of sitagliptin (100mg/kg) was orally gavaged till the end of the experiment. On day 36, after overnight fasting, the rats were euthanized for collecting blood, liver, heart, and other tissues. Liver samples were analyzed for markers of endotoxemia by qPCR and substantiated by other methods. **Results:** Preliminary results suggest significant increases in the markers of endotoxemia (**Lipocalin-2 (LCN-2)**, **Cyclooxygenase-2 (COX-2)**, and **Hemoxygenase-1 (HMOX-1)**) in the liver samples of rats fed high-cholesterol diet. Such increases were not seen in the liver of high methionine-fed rats. In the combination diet, these parameters were significantly reduced and could be attributed to the presence of methionine. Sitagliptin, when tested, exacerbated endotoxemia markers in high cholesterol-fed rats instead of attenuating them. Interestingly, methionine was able to counter even the exacerbated responses due to sitagliptin in high cholesterol-fed rats. **Conclusions:** Hepatic endotoxemic markers were significantly increased in rats fed high-cholesterol diet, and these were exacerbated by sitagliptin. These results substantiate our previous findings of increases in hepatic inflammation, oxidative stress, and fibrotic responses (typical of Non-alcoholic steatohepatitis-NASH) in high cholesterol-fed rats which were further enhanced by sitagliptin (Pathak R et al. (2019, 2022), Kumar A et al. (2020), Palfrey et al. (2024)). Therefore, the present studies help in bridging the understanding of the association between hepatic endotoxemia, (which is increased due to high cholesterol) and sitagliptin-mediated enhancement of NASH responses. Additional studies will likely yield a better understanding about the role of sitagliptin in endotoxemia, especially during hypercholesterolemia.

PS 3006 Application of immunofluorescence for analysis of zone-selective hepatic steatosis driven by perfluorooctane sulfonate (PFOS) and 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)

J. A. Mickel, A. P. Gilbert, K. Yuan, S. Shrestha, Y. Zahoor, and R. Nault. Michigan State University, East Lansing, MI.

Background and Purpose: Liver toxicity by environmental contaminants often develops in a zone-selective manner, driven by physiological and functional gradients along the periportal to centrilobular axis. Perfluorooctane sulfonate (PFOS) and 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), two persistent environmental pollutants, are reported to elicit zone-selective lipid accumulation by H&E. Given the importance of cellular and spatial heterogeneity of the liver in response to chemicals and drugs, there is a need for definitive methods to characterize molecular changes associated with liver zonation. Our goal was to develop a multiplexed immunofluorescence-based method that anchors changes such as hepatic lipid accumulation and inflammation, to established markers of zonation. **Methods:** We developed a workflow based on the Iterative Bleaching Extends Multiplicity (IBEX) method to evaluate the zonation of hepatic features. The method was modified to enable the staining of neutral lipids using BODIPY, paired with zonation markers ASS1 (portal hepatocytes) and GLUL (central hepatocytes), as well as cell type markers GFAP (quiescent hepatic stellate cells), ADGRE1 (F4/80; Kupffer cells), and ACTA2 (αSMA; vascular smooth muscle cells and activated hepatic stellate cells). Using these markers, hepatic lobules were computationally inferred to establish a zonation map and subsequently used to quantitatively assess zonation of immunofluorescence signal. Livers from male C57BL/6J mice treated with PFOS (0.3 or 1 mg/kg/day in 0.5% Tween-20 drinking water for 84 days) or fed a Gubra Amylin NASH (GAN) diet for 12 weeks were used as models of centrilobular steatosis, while those treated with TCDD (3 μg/kg in sesame oil via oral gavage every 4 days for 84 days) represented a periportal steatosis. **Results:** BODIPY staining revealed dose-dependent lipid accumulation in the centrilobular regions of PFOS treated mice, beginning with small droplets at 0.3 mg/kg/day and progressing to large droplet accumulation at 1 mg/kg/day. In contrast, lipid accumulation in livers of TCDD treated mice was more skewed towards the midzonal and periportal region. After 12 weeks on a GAN diet, livers exhibited a more homogenous lipid accumulation with larger droplets localized near centrilobular vessels. Each of these models showed increased lipid accumulation compared to vehicle control where minimal or no lipid accumulation was observed. While no treatment related changes were seen for GFAP or ACTA2, each showed zone-selective distribution. ADGRE1 showed enrichment in the periportal region consistent with their role in responding to cues entering the liver via the portal vein. **Conclusions:** Through development of a multiplexed immunofluorescence imaging workflow, this study was able to more definitively characterize the zone-selective changes in livers of mice treated with the environmental contaminants PFOS and TCDD, or a steatogenic diet. Notably, incorporation of BODIPY staining revealed clear differences in lipid accumulation patterns between PFOS and TCDD reflecting two different mechanisms. Ultimately, this strategy represents a versatile framework for studying spatially resolved toxicological responses in the liver.

PS 3007 Potential mechanisms of hepatic Cyp2e1 over-expression in diet-induced obesity mouse model, associated with aggravated acetaminophen-induced liver injury

I. Park¹, S. Cho¹, N. Kim¹, E. Lee¹, H. Jo¹, E. Choi¹, Y. Jeon¹, J. Che², and J. Yun¹.

¹Laboratory of Veterinary Toxicology, College of Veterinary Medicine and Research Institute for Veterinary Science, Seoul National University, Seoul, Korea, Republic of; and ²Biomedical Center for Animal Resource Development, Seoul National University College of Medicine, Seoul, Korea, Republic of.

Background and Purpose: Obese individuals are known to have different drug metabolism profiles compared to lean populations due to altered hepatic CYP450s expression, which makes them prone to drug-induced liver injury (DILI). Among these enzymes, hepatic Cyp2e1 plays central role in metabolizing numerous drugs and has been reported to modify drug toxicokinetics particularly in obesity. Consequently, Cyp2e1 may contribute to higher risk of liver-related drug adverse effects in obese populations. However, the exact cause-and-effect relationship of obesity, Cyp2e1, and DILI is not fully understood. Moreover, the molecular mechanisms underlying Cyp2e1 alterations are poorly defined. Here in this study, we confirmed the elevation of Cyp2e1 in diet-induced obesity (DIO) mouse model and demonstrated its causal involvement in aggravated acetaminophen-induced liver injury (AILI) through a unique liver-biopsy-based approach, which enabled individual tracking of Cyp2e1's contribution to drug hepatotoxicity. In addition, we shed light on the potential mechanisms that may be responsible for Cyp2e1 elevation in obesity. **Methods:** Male C57BL/6J mice were fed either a high-fat diet (HFD) or a low-fat diet (Normal Diet, ND) for 24 weeks to establish DIO model and its lean control. Then, liver biopsy was performed to obtain liver samples prior to drug administration and Cyp2e1 expression level was analyzed. After a 3-week recovery period, acetaminophen (300 mg/kg, P.O.) was administered and blood, liver and fecal sample were collected. Hepatotoxicity was evaluated through serum chemistry, LC-MS/MS quantification, histopathology, RT-qPCR, and western blotting (WB). Furthermore, 16s rRNA sequencing, fecal metabolomics (LC-MS/MS), single-cell RNA sequencing (scRNA-seq), and *in vitro* fatty acid treatment using liver cells were performed to investigate the mechanisms of Cyp2e1 alteration. **Results:** After 24 weeks of HFD feeding, DIO mice showed significantly higher body weight and impaired glucose tolerance compared to their lean controls. Liver biopsy samples of DIO mice revealed marked elevation of Cyp2e1 expression. Animals selected to examine Cyp2e1 level by biopsy also exhibited marked increase in serum ALT and AST level as well. Following acetaminophen exposure, 3-cysteiny-acetaminophen (APAP-Cys), a serum biomarker reflecting N-acetyl-p-benzoquinone-imine (NAPQI) and liver protein adduct formation, also increased in DIO mice. Histopathological and molecular analysis further confirmed aggravated hepatic inflammation and oxidative stress. In addition, fecal metabolomics identified a few microbial-origin metabolites which may affect hepatic metabolizing enzyme expression level via the gut-liver axis. Cell culture and scRNA-seq results gave knowledge to possible gene networks that may regulate Cyp2e1 expression. **Conclusions:** Our findings indicate that DIO mice are more susceptible to AILI, which can be attributed to hepatic Cyp2e1 upregulation. Our study also shows the potential microbial and transcriptional mechanisms responsible for Cyp2e1 elevation in obesity. Our research emphasizes the need for further in-depth research on the mechanism behind the change of Cyp2e1 expression and expanding research interest to other drug-metabolizing enzymes as well in order to predict and prevent DILI in obese patients in the future.

PS 3008 18β-glycyrrhetic acid regulates cuproptosis by p65/STAT3-STEAP4 axis to ameliorate acetaminophen-induced liver injury

M. Lei^{1,2}, J. Chen^{1,2}, and L. Gong^{1,2}. ¹Center for Drug Safety Evaluation and Research, State Key Laboratory of Drug Research, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China; and ²Zhongshan Institute for Drug Discovery, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Zhongshan, China.

Background and Purpose: 18β-Glycyrrhetic acid (GA) is a main metabolic product of glycyrrhizin which is a type of triterpenoid compound found in the roots and stems of the traditional Chinese medicine licorice. Modern pharmacological researches have revealed the benefit of GA in alleviating acute liver injury (ALI), but the mechanism is still obscure. We first discovered that GA downregulated STEAP4 protein level which is a metal reductase that reduces Cu²⁺ to Cu⁺ to promote copper absorption and utilization in a model of alpha-naphthylisothiocyanate (ANIT)-induced cholestasis by mass spectrometry, implicating a potential role for GA in the regulation of copper homeostasis. As reported, there is a potential association between cuproptosis and acetaminophen-induced liver injury (AILI). However, the correlation between GA alleviation of AILI and cuproptosis has not been touched. **Methods:** The effect of GA on cuproptosis induced by Es-Cu in HepG2 cells was examined by CCK8 assay for cell viability. The AILI mouse model was constructed by an intraperitoneal injection (i.p.) of APAP (350 mg/kg) in C57BL/6 mice, and the alleviating effect of GA (20 and 50 mg/kg) on AILI was evaluated by serum biochemical analysis and H&E staining. The correlation between the treatment of AILI with GA and cuproptosis was investigated by copper measurement, RT-qPCR, western blotting, and siRNA transfection. **Results:** GA could inhibit Es-Cu-induced cuproptosis in a concentration-dependent manner *in vitro* assay. *In vivo*, 50 mg/kg of GA improved AILI, manifested as the lower ALT, AST, and GLDH, the decreased area of hepatic necrosis around the central

vein. GA regulated the expression of genes critical to copper homeostasis (STEAP4, SDHB, COX17, ATOX1, CCS) and mitochondrial TCA cycle (LIAS, FDX1, DLAT, SDHB), accompanied by lower concentration of copper ion in cells and liver tissue. GA could bind to p65 and STAT3 and reduce the ratio of p-STAT3/STAT3 and p-p65/p65 obviously. Knockdown of p65 or inhibition of STAT3 activity could block the relief of GA in STEAP4 mRNA and cuproptosis. **Conclusions:** GA regulates the phosphorylation levels of p65 and STAT3 to further affect the transcription of STEAP4 to inhibit cuproptosis, thereby ameliorating AILI.

PS 3009 Delta-8-tetrahydrocannabinol mitigates ConA-induced hepatotoxicity through epigenetic regulation of immune dynamics

H. Hamida, M. Palrasu, A. Marudamuthu, X. Yang, P. Nagarkatti, and M. Nagarkatti. University of South Carolina School of Medicine, Columbia, SC.

Background and Purpose: Concanavalin A (ConA) induces immune-mediated hepatotoxicity characterized by an imbalance between effector and regulatory immune responses. Epigenetic regulation via microRNAs (miRNAs) has emerged as a key determinant of immune signaling. Cannabinoids are increasingly recognized for their immunosuppressive and anti-inflammatory properties; however, the impact of delta-8-tetrahydrocannabinol (Δ⁸-THC), a minor cannabinoid with reduced psychoactivity compared to Δ⁹-THC, remains entirely unexplored in the context of immune-mediated hepatotoxicity. To address this gap, we investigated whether Δ⁸-THC protects against ConA-induced hepatotoxicity and delineated the underlying cellular and epigenetic mechanisms. **Methods:** miRNA sequencing and flow cytometric analysis were performed using hepatic immune cells from female C57BL/6 mice treated with ConA (12.5 mg/kg, i.v.) and Δ⁸-THC (20 mg/kg, i.p.). Differential miRNA expressions were analyzed using the edgeR, and miRNA targets were predicted using Ingenuity Pathway Analysis. Target gene expression was validated by qRT-PCR and Western blot, with functional assays using miRNA mimics/inhibitor transfection and CD4⁺ T-cell differentiation assays. **Results:** We found that Δ⁸-THC effectively ameliorated ConA-induced hepatotoxicity by restoring intrahepatic innate and adaptive immune homeostasis through the preservation of tolerogenic Kupffer cells (KCs) and the suppression of inflammatory monocytes, neutrophils, and natural killer cells (NKs). Moreover, Δ⁸-THC reversed the inflammatory lymphoid microenvironment in the liver caused by ConA by decreasing inflammatory CD4⁺ T cells and promoting the expansion of regulatory T cells. These effects were associated with the preservation of hepatoprotective miR-199a-3p and miR-100-5p expression in hepatic immune cells, which were markedly downregulated in ConA-treated mice. Ingenuity Pathway Analysis identified mTOR, a key immune regulator of T-cell differentiation, as a target of these miRNAs. Consistently, Δ⁸-THC treatment reduced hepatic mTOR expression *in vivo*. Functional assays using miRNA mimics and inhibitors confirmed direct regulation of mTOR by these miRNAs, whereby miR-199a-3p/miR-100-5p-mediated mTOR suppression promoted regulatory T cells differentiation and inhibited inflammatory Th1 and Th17 responses. **Conclusions:** Δ⁸-THC protects against immune-mediated hepatotoxicity by restoring hepatic immune balance through epigenetic regulation of microRNA-mTOR signaling and promoting tolerance by enhancing regulatory T-cell responses. By preserving anti-inflammatory miR-199a-3p and miR-100-5p and suppressing mTOR-driven inflammatory responses, Δ⁸-THC reduces hepatocellular injury and immune dysregulation, revealing a novel epigenetic mechanism and highlighting its potential as a therapeutic candidate for immune-related liver toxicity.

PS 3010 Sex-Dependent Hepatotoxicity of Trichloroethylene in Humanized PPARα Mice Fed a Western Diet

A. Ekuban¹, P. Ames¹, F. A. Ekuban¹, J. Luo¹, O. E. Bolatimi¹, Y. Hua¹, M. Iyer¹, C. Gorga¹, J. Hardesty¹, J. Schlezinger², B. Wahlang¹, M. Cave¹, and W. H. Watson¹. ¹University of Louisville, Louisville, KY; and ²Boston University, Boston, MA.

Background and Purpose: Consumption of a high fat western-style diet is a major risk factor for metabolic dysfunction-associated steatotic liver disease (MASLD). Environmental exposures to toxic chemicals may contribute to the progression of this disease. Trichloroethylene (TCE) is a commonly used industrial solvent and environmental contaminant that has been linked to metabolic dysfunction and hepatic steatosis. Metabolites of TCE activate the transcription factor PPARα, a major regulator of lipid metabolism in the liver. Both diet and sex have been identified as important modifying factors in MASLD development. Therefore, we sought to test the hypothesis that TCE exposure exacerbates western diet-induced metabolic dysfunction and liver injury in a sex-dependent manner using a humanized PPARα mouse model. **Methods:** Mice expressing human PPARα were used in this study because they are a better model for human responses to PPARα agonists. Male and female humanized PPARα C57BL/6J mice aged 9-12 weeks were placed on either a low-fat diet (LFD; 10% fat) or a western diet (WD; 42% fat) with concurrent exposure to 0.5 mg/mL of TCE or 1% ethoxylated castor oil (used to emulsify TCE) in drinking water for 12 weeks. Body weight and water consumption were measured each week. A glucose tolerance test was performed at week 10, and EchoMRI was performed at week 11. At week 12, blood and tissues were collected for measurement of plasma AST and ALT, tissue weights, and analysis of liver histopathology with H&E and Oil Red O. Statistical analyses were performed using two- and three-way ANOVA followed by Tukey's post hoc test, with significance set at p ≤ 0.05. **Results:** Male

mice on WD, independent of TCE exposure, exhibited increased body weight, fat mass, white adipose tissue, and liver weight compared to their female counterparts. Interestingly, the female mice on WD and TCE exposed exhibited a significant decrease in body weight, white adipose tissue and fat mass relative to WD-fed females. TCE exposure relative to body weight was greater in females than in males. Glucose tolerance was impaired in male mice on a WD diet, independent of TCE exposure, whereas their female counterparts maintained glucose tolerance. Plasma AST and ALT levels were elevated in WD-fed males, independent of TCE exposure, but remained unchanged in females. Histological analysis revealed enhanced steatosis in WD-fed males, regardless of TCE exposure, as confirmed by H&E and Oil Red O staining, compared with their female counterparts. **Conclusions:** This study revealed marked sexual dimorphism in diet- and TCE-induced hepatotoxicity in humanized PPAR α mice. Male mice were more susceptible to liver injury and toxicity, whereas female mice showed alterations in systemic fat deposition.

PS 3011 Inhibition of Apoptosis-Mediated Kidney Cell Death Improves Survival Following Acetaminophen Overdose

F. Ahamed, H. Jaeschke, and A. Ramachandran. University of Kansas Medical Center, Kansas City, KS.

Background and Purpose: Acetaminophen (APAP), commonly called Tylenol, is widely used to relieve pain and reduce fever. However, an APAP overdose can lead to acute liver failure (ALF) and acute kidney injury (AKI). The current standard treatment, N-acetyl-L-cysteine (NAC), only prevents liver injury and does not influence kidney damage. Although the liver is the primary target organ for APAP-induced injury, renal dysfunction occurs in over 50% of APAP-induced ALF patients and contributes significantly to mortality. Clinical data indicate that APAP-induced ALF is associated with more severe kidney injury than ALF of other etiologies, suggesting a direct nephrotoxic effect of APAP. Our recent observations revealed elevated plasma creatinine and renal failure in APAP overdose patients, predominantly in patients with severe liver injury. Though mechanisms of renal cell death are distinct from those in the liver (apoptosis in the kidney vs necrosis in the liver), it remains unclear whether concurrent kidney damage after an APAP overdose worsens liver injury and accelerates ALF progression. In this study, we investigated whether selectively inhibiting kidney cell death by blocking apoptosis with a caspase inhibitor could improve survival after a severe APAP overdose in the human-relevant mouse model. **Methods:** Male C57BL/6J mice were fasted overnight and given 600 mg/kg of APAP intraperitoneally (n=9), a dose sufficient to induce both liver and kidney injury. A subset (n=7) of mice received 3 mg/kg of Ac-DEVD-CHO, a caspase inhibitor, thirty minutes before APAP. Mice were euthanized 48 hours after APAP injection, and blood, liver, and kidney samples were collected for further analysis. **Results:** Mice treated with both APAP and the caspase inhibitor showed a significantly higher survival rate (71%) than those receiving APAP alone (22%). Plasma ALT levels were comparable in both groups, indicating similar degrees of liver injury. However, mice in the caspase-inhibitor group exhibited significantly lower blood urea nitrogen (BUN) and kidney injury molecule 1 (KIM-1) levels, suggesting preservation of kidney function and reduced kidney injury. Liver histology showed a significant decrease in areas of necrosis around central veins in the caspase-inhibitor group, suggesting enhanced liver regeneration at 48 hours post APAP-exposure. Consistent with this observation, liver proliferating cell nuclear antigen (PCNA) staining demonstrated significantly greater numbers of PCNA-positive hepatocytes in the perinecrotic regions of the caspase-inhibitor group, further confirming improved liver regeneration compared with APAP alone. **Conclusions:** Selective inhibition of apoptosis-mediated kidney cell death improves survival following APAP overdose by preserving renal function and promoting hepatic regeneration, even without directly reducing initial liver injury. These findings highlight the therapeutic potential of targeting kidney apoptosis to improve outcomes after APAP toxicity.

PS 3012 Rust Belt Toxicants Amplify Diet-Induced Hepatotoxicity in Mice

H. Arbore, H. Siddiqui, S. A. Heinig, J. Li, N. Price, Z. Zimmerman, S. Yuan, S. Chaudhary, N. Kitano, G. E. Arteel, A. P. Sanders, and J. I. Beier. University of Pittsburgh, Pittsburgh, PA.

Background and Purpose: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects over 30% of Western populations with disproportionate impact on lower socioeconomic communities. While early-stage MASLD prevalence approaches 100% in at-risk individuals, progression to severe forms is not inevitable, suggesting additional risk factors drive disease severity. Environmental chemical mixtures may be such a risk factor and transform manageable dietary stress into severe liver injury. "Rust to Resilience" (R2R) chemical mixtures contain legacy toxicants (lead, cadmium, arsenic) and emerging PFAS relevant to industrialized countries and of high priority concern in southwestern Pennsylvania. **Methods:** This study investigated whether R2R-mixture exposure transforms Western diet-induced metabolic stress into severe hepatotoxicity. C57BL/6J mice were fed Western or control diets for 12 weeks, with subgroups receiving R2R mixtures at 1X and 100X concentrations. Analysis included plasma biochemistry, histopathological assessment, and RNA-sequencing with integrated pathway analysis to determine molecular mechanisms of toxicant-diet interactions. **Results:** The combination of R2R-mixture exposure with Western diet escalated diet-induced liver injury, causing metabolic

dysfunction, severe inflammation, and portal expansion. RNA-seq analysis revealed dysregulation of key regulators of hepatic lipid metabolism inflammation. IHC staining for activated macrophages and endothelial and epithelial markers demonstrated a unique, lipotoxicity-associated immune response as well as portal expansion and endothelial cell damage, all hallmarks of more severe hepatic pathogenesis. These results were not replicated in control diet mice with equal R2R-mixture exposure or western diet mice with vehicle exposure, indicating that the combination of both factors leads to more severe disease progression. **Conclusions:** Western diet transformed manageable environmental exposure into severe hepatotoxicity characterized by metabolic dysregulation, activation of pro-inflammatory pathways, and endothelial cell dysfunction.

PS 3013 Utilizing Clinically Approved Epidermal Growth Factor Receptor Inhibitors for the Treatment of Acetaminophen-Induced Liver Injury

G. A. Williams, S. Jain, R. Mukherjee, A. V. Orr, and B. Bhushan. University of Pittsburgh, Pittsburgh, PA.

Background and Purpose: Acetaminophen (APAP) overdose is the leading cause of acute liver failure (ALF) in the United States. Despite this, APAP-induced liver injury (ALI) currently has only one widely accepted treatment, N-acetylcysteine (NAC), which only works within a limited time window. Epidermal growth factor receptor (EGFR) has been previously established to bolster regeneration of the liver following partial hepatectomy. Our recent work demonstrated that hepatocyte-specific deletion of EGFR leads to a surprising alleviation of ALI, indicating an injury promoting facet of EGFR. Here, we seek to investigate the therapeutic relevance of this paradoxical finding by employing clinically approved EGFR inhibitors (EGFRi), afatinib and osimertinib, with the aim of discovering novel treatment strategies for countering ALI. **Methods:** C57BL/6J mice were first administered either a moderately toxic (300 mg/kg) or severely toxic (500 mg/kg) dose of APAP. Following this, these mice were treated with afatinib, osimertinib or their vehicle (PBS) at 1 or 12 hours post APAP administration. These mice were then sacrificed at 6, 24 or 48 hours post APAP administration to investigate liver injury and regeneration. Osimertinib was also tested in combination with NAC, being given 4 hours after APAP administration, a timepoint at which NAC does not work alone. Additional analysis was conducted on publicly available single nucleus RNA sequencing and spatial transcriptomics databases. **Results:** Treatment with EGFRi significantly decreased ALI when administered 1 hour after both moderately and severely toxic doses of APAP. Of the two, osimertinib proved to be consistently more effective, reducing ALT and necrosis more than afatinib. EGFRi treatment did not impair the initial mechanisms driving APAP hepatotoxicity such as depletion of glutathione (GSH), APAP protein adduct formation and JNK activation at 6 hours post APAP. However, decreased activation of JNK and increased rate of GSH replenishment were observed in EGFRi treated mice 24 hours post APAP, potentially contributing to restricted progression of ALI. In addition to this, EGFRi treated groups displayed increased markers of autophagy and mitophagy, which are known to decrease ALI through degradation of dysfunctional mitochondria. Mechanistically, EGFRi treatment decreased activation of MTOR signaling resulting in increased levels of TFEB, a master transcriptional regulator of autophagy. These results are all consistent with our previous findings in hepatocyte-specific EGFR-KO mice. In addition to working if given 1 hour after APAP overdose, osimertinib also decreased ALI when administered either alone or, more effectively, in combination with NAC 4 hours after APAP when NAC by itself was ineffective. Furthermore, EGFRi treatment did not inhibit liver regeneration, whether given early or after injury was fully established (12 hours post APAP), as indicated by PCNA staining and immunoblotting. Lastly, analysis of single nucleus RNA sequencing and spatial transcriptomics data revealed that EGFR signaling and several EGFR ligands were significantly upregulated in human ALF patients, signifying the human relevance of our findings. **Conclusions:** Overall, our studies suggest that EGFR inhibition using clinically approved inhibitors is a viable treatment strategy for targeting ALI, significantly reducing hepatotoxicity via inhibiting mitochondrial damage and inducing autophagy, without impairing regeneration.

PS 3014 Pharmacological inhibition of MET impairs hepatocyte regeneration in a murine model of acetaminophen-induced liver injury

S. Jain, R. Mukherjee, G. A. Williams, A. Orr, and B. Bhushan. University of Pittsburgh, Pittsburgh, PA.

Background and Purpose: Hepatocyte growth factor receptor (MET) is the key driver of liver regeneration following partial hepatectomy (PHx) but remains poorly understood in the context of acetaminophen-induced liver injury (ALI). ALI is the foremost cause of acute liver failure (ALF) in the US and the Western world. Our previous studies utilized a hepatocyte-specific MET knockout (KO) mouse model to explore its function in ALI. Due to severe injury and high mortality in MET KO mice, even at moderate overdose levels where spontaneous recovery typically occurs, the direct contribution of MET to liver regeneration could not be assessed. To overcome this limitation, the present study investigates the regenerative potential of MET in ALI using a pharmacological approach with Capmatinib (CAP), a selective MET inhibitor.

Methods: Male C57BL/6J mice received either a moderate (300 mg/kg) or severe (500 mg/kg) overdose of APAP, followed by CAP (15 mg/kg) or vehicle treatment 2 hours later. Serum and liver tissue were subsequently collected at 12, 24, and 48 hr post-APAP administration to assess the extent of liver injury, regeneration and recovery. The time points utilized covered both the peak injury (12 and 24 hr) and recovery phases (48 hr) of AILI. Publicly available bulk and spatial transcriptomic data from APAP-induced acute liver failure patients were also analyzed. Lastly, freshly isolated primary human hepatocytes (PHH) were treated with APAP (10 mM) alone and in combination with CAP (0.1 and 1 μ M), and cell death was assessed using propidium iodide staining. **Results:** The moderate APAP overdose led to elevated serum ALT and centrilobular necrosis, with similar peak injury levels observed in CAP-treated mice. This similar extent of peak damage allowed us to evaluate the direct role of MET specifically in compensatory regeneration and recovery independent of injury. MET inhibition markedly reduced key cell cycle markers (p-ERK1/2, Cyclin D1, and PCNA) at 24 and 48 hr, indicating impaired regeneration with CAP treatment. Further, MET inhibition resulted in no significant difference in peak ALT levels or necrosis at 24 hr after severe APAP overdose. Both these injury parameters declined at 48 hr in vehicle-treated mice but remained markedly higher in CAP-treated mice, indicating impaired regression of injury following MET inhibition. This impaired recovery was accompanied by a reduced regenerative capacity, as evidenced by decreased expression of PCNA and Cyclin D1 at 48 hr in CAP-treated mice. Furthermore, a comprehensive analysis of publicly available bulk and single-nucleus RNA sequencing datasets demonstrated that the upregulation of proliferation and cell cycle-associated genes and pathways, indicative of an active regenerative response, was accompanied by robust activation of the HGF/MET signaling axis in APAP-induced ALF patients. Interestingly, spatial transcriptomic analysis revealed a marked elevation of HGF expression in peri-necrotic regions of APAP-induced ALF patients. Notably, pharmacological inhibition of MET exacerbated APAP-induced hepatotoxicity in primary human hepatocytes in a concentration-dependent manner, highlighting the critical protective role of MET signaling in a human model of AILI. **Conclusions:** Overall, MET inhibition using Capmatinib suppressed liver regeneration and impaired recovery following AILI especially after severe APAP overdose. These findings highlight MET's direct role in coordinating timely regenerative responses during recovery from AILI.

PS 3015 Hepatic stellate cell-specific HuR deficiency protects mice from CCl₄-induced liver fibrosis development

E. Jones, N. Eppler, Z. Xing, and Y. Zhang. University of Kansas Medical Center, Kansas City, KS.

Background and Purpose: Liver fibrosis is a progressive condition characterized by excessive extracellular matrix (ECM) accumulation and chronic inflammation resulting from hepatocellular injury. Hepatic stellate cells (HSCs) are the principal drivers of this process, transitioning from a quiescent to an activated myofibroblast-like state that produces collagen and pro-inflammatory mediators. The RNA-binding protein HuR (ELAVL1) stabilizes and regulates mRNAs involved in inflammation, stress response, and fibrogenesis, but its cell-type-specific role in liver fibrosis remains unclear. This study investigates how HSC-specific *HuR* loss alters fibrogenic and inflammatory responses during acute and chronic liver injury. **Methods:** *HuR^{fllox/flox}* mice were bred with LRAT-Cre mice to generate hepatic stellate cell-specific *HuR* knockout (*HuR^{HSC-/-}*) mice, alongside wild-type (WT) littermate controls. Male mice at least 2-months old were administered carbon tetrachloride (CCl₄) via intraperitoneal injection at 0.5 μ g/g to induce acute (single dose) or chronic (twice weekly for six weeks) liver injury. Serum alanine aminotransferase (ALT) activity was measured to assess hepatocellular damage. Liver tissue was collected 48 hours after the final exposure for histological (H&E, Picro Sirius Red), immunohistochemical (HuR, PCNA, F4/80), and immunofluorescent (HuR, SMA) analysis. Fibrogenic and inflammatory gene expression was quantified by qPCR for *Acta2*, *Col1a1*, *Adgre1*, *Ccl2*, and *Tnfa*. Single-nucleus RNA sequencing (snRNA-seq) was additionally performed on chronic injury samples to explore cell-type specific changes associated with HSC-*HuR* loss. **Results:** *HuR^{HSC-/-}* mice exhibited similar serum ALT levels to WT controls under both acute and chronic conditions, confirming equivalent hepatocyte injury. Histological assessment revealed reduced necrotic regions and diminished collagen deposition in *HuR^{HSC-/-}* mice after chronic CCl₄ treatment. Picro Sirius Red staining demonstrated less fibrotic bridging in knockout livers, while immunofluorescence confirmed loss of HuR expression in SMA-positive HSCs, validating efficient and specific deletion. qPCR analysis showed that fibrogenic gene expression (*Acta2*, *Col1a1*) was elevated following CCl₄ exposure but was significantly reduced in *HuR^{HSC-/-}* mice compared to WT. Inflammatory markers (*Adgre1*, *Ccl2*, *Tnfa*) followed a similar pattern, indicating reduced macrophage activation and cytokine signaling. Immunohistochemistry for F4/80 supported these findings, revealing dense macrophage clustering along collagen bridges in WT livers, while *HuR^{HSC-/-}* tissue exhibited markedly fewer macrophages, particularly after chronic exposure. Preliminary snRNA-seq analysis of chronic injury samples suggested transcriptional shifts consistent with altered activation of HSC, macrophages, and endothelial cells, along with dampened inflammatory signaling in *HuR^{HSC-/-}* livers. Early findings also point toward dysregulated expression of ECM-remodeling genes and immune response pathways, warranting further investigation into how HSC-specific *HuR* regulates cell-to-cell communication in fibrosis. **Conclusions:** Loss of *HuR* in HSCs reduces fibrogenic activation and inflammatory crosstalk during both acute and chronic liver injury. Despite comparable hepatocyte damage, *HuR^{HSC-/-}* mice show attenuated collagen deposition, decreased macrophage recruitment, and lower expression of fibrogenic and inflam-

matory genes. Initial snRNA-seq analyses support a model in which HuR modulates HSC activation and paracrine signaling within the fibrotic microenvironment. These findings identify HuR as a key post-transcriptional regulator of liver fibrosis and a potential therapeutic target for chronic liver disease.

PS 3016 Plasminogen and plasminogen deficiency in acetaminophen-induced acute liver injury

D. Banerjee¹, Z. Wei¹, A. Newberry¹, A. W. Strilchuk², F. Ferrareso³, C. Kastrop³, and J. P. Luyendyk¹. ¹Michigan State University, East Lansing, MI; ²University of British Columbia, Vancouver, BC, Canada; and ³Versiti Blood Research Institute, Milwaukee, WI.

Background and Purpose: Acetaminophen/paracetamol (APAP) induced liver injury is a leading cause of acute liver injury/failure (ALI/ALF). Challenging mice with a hepatotoxic dose of APAP recapitulates fundamental mechanisms and histopathological consequences of APAP overdose in humans, including alterations in blood coagulation and fibrinolysis. Prior studies report that APAP-induced liver damage is reduced in mice lacking plasmin(ogen), the terminal effector of the fibrinolytic system, but the precise link between plasminogen and APAP-induced liver injury is unclear. **Methods:** We determined the impact of APAP overdose on plasma and hepatic plasminogen levels in experimental APAP-induced ALI (300mg/kg) and ALF (600mg/kg) and tested the hypothesis that inducible plasminogen deficiency reduces APAP hepatotoxicity in mice. We used a novel siRNA approach to deplete plasminogen, and both immunohistochemistry and western blotting to measure plasminogen levels in plasma and liver. **Results:** APAP challenge in wild-type mice significantly decreased plasma plasminogen levels after 6 and 24 hours, and increased plasma plasmin-antiplasmin complex levels after 6 hours. This was paired with deposition of plasmin(ogen) within the injured liver, indicated by western blotting and immunohistochemical staining of plasmin(ogen); plasmin(ogen) accumulation was evident within areas of hepatocellular necrosis. Administration of lipid nanoparticles containing siRNA targeting plasminogen (siPlg) dramatically reduced plasma and hepatic plasminogen levels. Surprisingly, siRNA-induced plasminogen deficiency did not affect early (6h) or peak (24h) APAP-induced liver injury in mice challenged with either 300 or 600mg/kg APAP, as indicated by plasma alanine aminotransferase activity and hepatic necrosis. **Conclusions:** The results indicate that hepatic plasminogen levels increase significantly after APAP challenge in association with a reduction in plasma plasminogen concentration, but in contrast to congenital plasminogen deficiency in mice, siRNA-induced plasminogen deficiency does not inhibit APAP-induced liver damage. The results suggest a need to revisit the link between plasminogen and APAP hepatotoxicity, potentially due to differences in germline and knockdown plasminogen deficiency, as well as a need to further investigate hemostatic mechanisms in acute liver injury.

PS 3017 FXIII-B deficiency increases APAP-induced liver injury without impacting hepatic fibrin(ogen) crosslinking

C. D. Schneider¹, Z. Wei¹, K. Kangro², Y. Sang², A. S. Wolberg², and J. P. Luyendyk¹. ¹Michigan State University, East Lansing, MI; and ²University of North Carolina, Chapel Hill, NC.

Background and Purpose: Hepatic deposition of the coagulation protein fibrin(ogen) is a hallmark of acetaminophen (APAP)-induced hepatotoxicity in mice and humans. The transglutaminase coagulation factor XIII (FXIII) covalently crosslinks the majority of fibrin(ogen) deposits in the APAP-injured liver. FXIII circulates in plasma as a heterotetramer (FXIII-A₂B₂) composed of two catalytic (FXIII-A) subunits stabilized by two regulatory (FXIII-B) subunits, the latter synthesized by the liver. FXIII-A₂ is also stored intracellularly in certain cell types (e.g., platelets, macrophages). We tested the hypothesis that plasma FXIII-A₂B₂ drives hepatic fibrin(ogen) crosslinking in the APAP-injured liver. **Methods:** To test this hypothesis, we generated novel mice with a selective reduction in plasma FXIII-A₂B₂ by deleting the gene encoding FXIII-B (*F13b^{-/-}* mice). *F13b^{-/-}* mice were then challenged with APAP (300 mg/kg, i.p.) and analyzed after 24 hours. **Results:** FXIII-B was not detectable in plasma of *F13b^{-/-}* mice. As anticipated, plasma FXIII-A levels were reduced to less than 3%, while platelet intracellular FXIII-A levels were not impacted. Wild-type mice challenged with APAP developed acute hepatocellular injury indicated by centrilobular necrosis and elevated plasma alanine aminotransferase activity. Hepatic deposition of fibrin(ogen) with abundant Fibrin- γ crosslinking, a modification imposed by FXIII-A, was evident in the liver of APAP-challenged wild-type mice. Unexpectedly, FXIII-B deficiency dramatically increased APAP-induced hepatic necrosis and sinusoidal congestion, an observation that was not present in *F13a1^{-/-}* mice. This increase in injury was not attributable to an increase in APAP adduct formation. Additionally, extravascular fibrin(ogen) deposition and crosslinking (Fibrin- γ) was preserved in the APAP-injured liver of *F13b^{-/-}* mice. **Conclusions:** The results indicate that selective loss of plasma FXIII-A (in *F13b^{-/-}* mice) does not impact extravascular fibrin(ogen) crosslinking in experimental hepatocellular necrosis, suggesting a potential role of cellular FXIII-A in fibrin(ogen) crosslinking. Furthermore, the results suggest a hepatoprotective effect of FXIII after APAP overdose that is mediated by mechanisms independent of traditional fibrin crosslinking.

Poole¹. ¹Rutgers University, Piscataway, NJ; ²Michigan State University, East Lansing, MI; and ³University of North Carolina at Chapel Hill, Chapel Hill, NC.

Background and Purpose: Liver injury is associated with activation of the blood coagulation cascade. Hepatocytes express low levels of tissue factor (TF), the transmembrane receptor and co-factor for coagulation Factor VIIa (FVIIa). The TF-FVIIa complex activates the extrinsic coagulation pathway and plays a key role in hemostasis. In various settings of liver injury, such as acetaminophen overdose, hepatocyte-derived TF has been shown to drive coagulation activation. This study tested the hypothesis that hepatocyte TF drives coagulation activation following CCl₄-induced liver injury. **Methods:** In acute challenge, wild-type mice, mice with whole-body TF deficiency (LowTF), and mice lacking TF specifically in hepatocytes (HPC^{ΔTF}) were challenged once with carbon tetrachloride (CCl₄, 1 mL/kg, i.p.). Liver injury and coagulation were evaluated various times after challenge. In separate studies, to establish chronic injury, mice were challenged twice weekly with CCl₄ for 4-6 weeks, and samples were collected 24-72 h after the final challenge. **Results:** Acute CCl₄ challenge caused hepatic injury (ALT, necrosis) and robust coagulation activation, measured by plasma thrombin-antithrombin (TAT) complexes. Whole-body TF deficiency (~1% of normal) significantly reduced coagulation activation and attenuated peak hepatocellular necrosis. Interestingly, hepatocyte TF deficiency had no effect on acute liver injury. *In situ* hybridization identified cells in inflammatory foci expressing TF (F3) mRNA in the necrotic region of the CCl₄-challenged liver. Similarly in chronic CCl₄ challenge, hepatocyte TF deficiency did not impact coagulation activation or liver fibrosis, but whole-body TF deficiency significantly reduced coagulation activation and modestly decreased hepatic myofibroblast (hepatic stellate cell) activation. **Conclusions:** Together, these data suggest that TF-expressing non-parenchymal cells mediate coagulation activation during acute and chronic CCl₄-induced liver injury. Our results indicate that hepatocellular necrosis is not sufficient to trigger hepatocyte TF-dependent coagulation in all contexts; rather, coagulation activation is likely dependent on the mechanism of cell death.

H. Lee^{1,2}, S. Heo^{1,2}, S. Cho³, D. Cho², and C. Choi^{1,2,3}. ¹Department of Integrative Biological Sciences & BK21 FOUR Educational Research Group for Age-Associated Disorder Control Technology, Chosun University, Gwangju, Korea, Republic of; ²Institute of Well-Aging Medicare & Chosun University G-LAMP Project group, Chosun University, Gwangju, Korea, Republic of; and ³Department of Biomedical Science, Chosun University, Gwangju, Korea, Republic of.

Background and Purpose: Liver disease remains a significant global health concern, and drug-induced liver injury (DILI) often progresses to acute liver failure (ALF). Acetaminophen (APAP) overdose induces hepatotoxicity primarily through the formation of the toxic metabolite N-acetyl-p-benzoquinone imine (NAPQI), leading to severe oxidative stress, glutathione depletion, and subsequent hepatocyte necrosis. *Cornus kousa* (CK) is a tree widely distributed across East Asia, has recently been reported to exhibit antioxidant and anti-lipid peroxidation effects. Thus, CK is considered a potential agent for mitigating drug-induced liver damage. **Methods:** The powder of CK was obtained through hot water extraction, concentration, and subsequent freeze-drying. For the *in vivo* study, ICR mice were orally administered CK for 3 days. Following the final CK administration on the third day, APAP (400 mg/kg) was intraperitoneally injected. The mice were sacrificed on the fourth day. Serum samples were collected to assess liver function by measuring aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels. Liver tissues were analyzed for malondialdehyde (MDA) content to evaluate lipid peroxidation, and fixed tissues were subjected to hematoxylin and eosin (H&E) staining for histopathological observation of liver injury. **Results:** In the *in vivo* study, oral administration of CK resulted in decreased serum levels of ALT and AST. Furthermore, CK treatment reduced the hepatic MDA content compared to the APAP-induced injury group. Histopathological examination via H&E staining provided evidence of tissue recovery in the liver structure following CK administration. **Conclusions:** CK could be a beneficial hepatoprotective agent for the prevention and amelioration of APAP-induced liver injury *in vivo*. These findings warrant further investigation into the specific cellular and molecular mechanisms of CK within liver cells to fully understand its therapeutic potential.

Background and Purpose: Cisplatin is a chemotherapeutic drug prescribed for the treatment of solid tumors, but its use is limited in part by nephrotoxicity. Current methods of detecting cisplatin-induced acute kidney injury (AKI) are inadequate for revealing the progression from subclinical to clinical injury. Our team recently performed an untargeted aptamer-based discovery of urinary proteins in patients who received cisplatin-containing chemotherapy within the prior 48 h and identified over 800 differentially enriched proteins. **Methods:** In this study, 21 potential protein biomarkers from our previous study were prioritized for validation at the mRNA level using: 1) the human AKI mRNA dataset in the Kidney Tissue Atlas and 2) kidneys of mice treated with cisplatin. The human AKI mRNA dataset consisted of single cell kidney RNAseq data from 14 AKI cases of variable etiology and 28 healthy references. For the latter approach, total RNA was extracted from frozen kidneys of saline-treated control mice (n=5) and cisplatin (20 mg/kg, ip)-treated mice (n=7) at 4 days, and qPCR was performed for 24 genes, including 3 known kidney injury biomarkers (Kim-1, Timp-1, and Lcn-2) as positive controls. **Results:** Cisplatin treatment increased mRNA expression of all three established kidney injury biomarkers, Kim-1 (287-fold), Timp-1 (60-fold), and Lcn-2 (893-fold), in mice at 4 days. Of the 21 genes selected for potential validation, 6 were up-regulated, 2 were down-regulated, and 13 were not significantly changed in the kidneys of cisplatin-treated mice. Increased mRNA expression was observed for the apoptosis receptor Tnfrsf10b (8-fold), RNA-binding Carhsp1 (3-fold), calcium-binding S100a11 (6.5-fold), serine protease Prss22 (44-fold), and cytokines Cxcl5 (82-fold) and Ccl5 (3-fold). Notably, Tnfrsf10b, Cxcl5, Carhsp1, S100a11, and Prss22 showed significant positive correlation (Pearson r: 0.7-0.9) with the established injury markers. Decreased mRNA expression was observed for ubiquitin complex receptor Khlh13 (47% of control) and glycosyltransferase St8sia4 (42% of control). Overall, there was low concordance between the directional change (up-regulation, down-regulation, no change) between the untargeted protein biomarker analysis, the human AKI mRNA dataset, and changes in the regulation of these aforementioned genes in the kidneys of cisplatin-treated mice. Nonetheless, the upregulation of Tnfrsf10b mRNA in the kidneys of cisplatin-treated mice corresponded with increased protein levels in the urine of patients receiving cisplatin-containing chemotherapy. **Conclusions:** The lack of similarity in regulation of biomarkers between the untargeted analysis and the mRNA profiles in human and mouse kidneys likely reflects differences in the matrix analyzed, degree of injury, and regulation of the targets at the mRNA versus protein level. Nonetheless, Tnfrsf10b, a TNF-related receptor involved in apoptosis signaling, emerged as a potential novel biomarker of cisplatin-induced nephrotoxicity. Future studies aim to perform longitudinal evaluations of this and other potential kidney injury biomarkers in the entire patient cohort. Supported by NIH R25ES020721, R01GM123330, P30CA072720, and the American Society for Pharmacology and Experimental Therapeutics.

T. Krsmanovic¹, K. Jankovic¹, A. Surla¹, P. Stojakovic¹, D. Dragovic¹, G. Apic¹, and R. B. Russell². ¹Metisox, Cambridge, United Kingdom; and ²Heidelberg University, Heidelberg, Germany.

Background and Purpose: Exposure to particulate matter (PM) has been associated with diseases of the respiratory and cardiovascular systems. Owing to the dense vasculature, the kidney has also been identified as a target organ to fine particulate matter of <2.5 µm in diameter (PM_{2.5}). The mechanisms through which PM affects the tissues involved in xenobiotic removal, such as the liver and kidneys, are still unclear. The aim of this study was to determine the effect of PM_{2.5} on human kidney proximal tubular epithelial cell line (HK-2 cells), an *in vitro* model of kidney function. **Methods:** For this purpose we analyzed RNA-seq data (GSE208331) of HK-2 cells treated with PM_{2.5} for 24 hours. We used our proprietary database and software for data interpretation and visualization. We generated the database to include internally curated and various publicly available data on proteins, biologically-active chemicals, their interactions, pathways and pathologies. In order to support data integration and capture different levels of histopathological observations, we developed toxicology ontology with nearly 9,000 diseases and 800 pathology endpoints. Over 30 million references were catalogued, supporting each database entry. Molecule interactions were hyperlinked to appropriate PubMed articles, proteins were hyperlinked to corresponding NCBI Gene and UniProt Protein pages, and chemicals to corresponding PubChem pages. **Results:** From the whole genome analysis, using the cut off criteria of log₂ fold change ≥ ±2, and padj<0.05, 427 differentially expressed genes (DEGs) were identified. Our system recognized 315 DEGs, with 132 of them being upregulated and 183 downregulated. Mapping DEGs to Gene function (GO) and Signaling and Metabolic pathways clusters within our system revealed that in kidney, PM_{2.5} upregulated genes involved in response to xenobiotic stimulus/xenobiotic metabolic process, Phase I-functionalization of compounds and NFE2L2 regulating antioxidant/detoxification enzymes, and downregulated genes involved in renal sodium excre-

tion, RHOA GTPase cycle and DNA damage response. Mapping of DEGs to Organ and tissue pathologies and Diseases clusters in our system revealed that upregulated genes were associated to kidney proximal tubule necrosis, kidney apoptosis, renal hypoplasia and renal fibrosis, whereas the downregulated genes were associated with renal fibrosis and renal tubular transport disease. Vast amount of processed data in our system presents the potential for generation of valuable mechanistic hypothesis. To illustrate this we chose the renal fibrosis. Detailed interrogation of the renal fibrosis network from our proprietary database, combined with DEGs from the experimental dataset, revealed PM2.5 exposure led to upregulation of the genes involved in maintaining homeostasis in the presence of oxidative stress (HMOX1). It also upregulated complement C5a receptor 1 (C5AR1). It is known from the literature that the C5a/C5aR1 axis promotes progression of renal tubulointerstitial fibrosis in a mouse model of renal ischemia/reperfusion injury. PM2.5 exposure led to down-regulation of a WNT signaling pathway inhibitor DKK1, indicating potential activation of WNT signaling pathway. For WNT signaling pathway is known, particularly its beta-catenin route, to be a driver of fibrogenesis. Regarding DKK1 specifically, the literature shows that in animal models, enhanced expression of DKK1 had a clear suppressive effect on fibrosis. **Conclusions:** By applying bioinformatics tools on dysregulated gene set from *in vitro* model of kidney function we have shown that PM2.5 dysregulates genes/proteins involved in xenobiotic responses in kidney. In addition, we have identified potential renal system toxicities following PM2.5 exposure and generated the mechanistic hypothesis showing how PM2.5 exposure can dysregulate genes leading to renal fibrosis.

PS 3022 THY1/CD90 as a Novel Biomarker of Subclinical Drug-Induced Kidney Injury in Humans

X. Wen¹, J. Yang¹, C. Kim¹, L. Thompson², Y. Zhuang², J. Edgar³, M. Joy², and L. Aleksunes^{1,4}. ¹Rutgers University, Piscataway, NJ; ²University of Colorado, Aurora, CO; ³Memorial Sloan Kettering Cancer Center, Piscataway, NY; and ⁴Environmental and Occupational Health Sciences Institute, Piscataway, NJ.

Background and Purpose: While cisplatin is a long-standing treatment for solid tumors, clinical use is limited by kidney toxicity. THY1 (thymocyte differentiation antigen-1, known as CD90) is a small cell surface protein expressed on the brush border of human proximal tubule cells, and has been targeted experimentally to induce glomerulonephritis in rodents. In our recent untargeted proteomic assessment using aptamer-based Somascan technology, THY1 was one of the top proteins increased in the urine of 20 patients who had received cisplatin-containing chemotherapy within the preceding 48 hours. In the current study, we sought to 1) profile time-dependent changes in urinary THY1 protein levels following cisplatin infusion in a larger set of patients and 2) compare urinary THY1 excretion patterns to established kidney injury biomarkers. **Methods:** Urine samples were collected at baseline, 4-24, 24-48, 48-72 h and 10 days from cancer patients receiving their first or second round of cisplatin-containing chemotherapy (≥ 25 mg/m²; 0.5-2-h infusion, n=41). THY1 levels were measured in urine supernatant using ELISA and normalized to urinary creatinine concentrations. Patterns of THY1 secretion over time were compared to established kidney injury biomarkers, including kidney injury molecule-1 (KIM-1), trefoil factor 3 (TFF3), beta-2 microglobulin (B2M), and calbindin D_{28k} (CALB1), also measured by ELISA. **Results:** Consistent with the previous Somascan analysis findings, urine THY1 concentrations (mean $\pm$ SD) increased following cisplatin treatment, showing increases at 4-24 h (4.3 $\pm$ 6.5-fold), 24-48 h (3.0 $\pm$ 4.4-fold), 48-72 h (2.8 $\pm$ 4.7-fold) and 10 days (2.6 $\pm$ 3.5-fold), relative to baseline. THY1 was increased by at least 2-fold in 30-45% of subjects across all time points. B2M and TFF3 were increased in 63-65% and 51-60% of subjects between 4 h and 72 h with lesser change at 10 days. By comparison, less than 30% of subjects exhibited a 2-fold change in CALB1 between 4h and 72 h whereas 59% displayed elevated levels at 10 days. About 43-57% of subjects showed a 2-fold increase in KIM-1 levels between 24 hours and 10 days, while 32.5% exhibited such increases between 4 and 24 hours. **Conclusions:** Urinary THY1 levels increased significantly following cisplatin treatment, peaking within the first 24 hours and remaining elevated for up to 10 days. This pattern of increase at early time points was most similar to KIM1, B2M, and TFF3 although in a smaller subset of subjects treated with cisplatin compared to the established kidney injury biomarkers. Supported by NIH R25ES020721, R01GM123330, P30CA072720, and the American Society for Pharmacology and Experimental Therapeutics.

PS 3023 *In vitro* evaluation of drug-induced kidney injury using cell painting assay in 2D and 3D kidney models

X. Du, Z. Wu, J. Xu, and F. He. Pharmaron Beijing Co., Ltd., Beijing, China. Sponsor: S. Luo

Background and Purpose: Drug-induced nephrotoxicity remains a leading cause of clinical trial failures and post-market withdrawals, with renal proximal tubule epithelial cells (RPTECs) being particularly vulnerable due to their role in drug secretion and reabsorption. Current preclinical models for renal toxicity screening, such as 2D monolayer cultures, often lack physiological relevance, resulting in poor predictivity of *in vivo* outcomes. 3D spheroid models, which more faithfully recapitulate RPTEC polarization, tight junction assembly, and metabolic functionality, emerge as a promising alternative. However, their performance in toxicity prediction has

not been systematically benchmarked against that of 2D models. Cell painting, a multiplex fluorescence microscopy technique, captures hundreds of cellular features (including morphology, organelle distribution, and cytoskeletal architecture) to generate "phenotypic fingerprints" of drug-induced effects, enabling unbiased toxicity profiling beyond the scope of traditional viability assays. This study aims to: 1) Compare the renal toxicity predictive capacity of 2D and 3D RPTEC models using an FDA-curated compound library; 2) Integrate cell viability data (IC₅₀) with cell painting-derived phenotypic profiles to develop predictive toxicity models; 3) Assess the sensitivity and specificity of both models in distinguishing nephrotoxic from non-nephrotoxic compounds. **Methods:** Human renal proximal tubule epithelial cells (RPTECs) were cultured as a monolayer in renal epithelial growth medium (REGM) on collagen-coated plates. For 3D spheroid formation, RPTECs were seeded in ultra-low attachment plates and cultured in REGM supplemented with 2% Matrigel. A total of 24 compounds were selected from the FDA's Drug-Induced Kidney Injury (DIKI) database and nephrotoxicity-specific databases, comprising 12 known nephrotoxins and 12 non-nephrotoxins. Both 2D RPTEC monolayers and 3D spheroids were treated with each compound at 8 concentrations (ranging from 0.1 μ M to 1 mM) for two exposure durations: 24 hours and 72 hours. Vehicle controls (DMSO, $\leq 0.1\%$) and positive controls (10 mM H₂O₂) were included. Toxicity was assessed using two complementary approaches: 1) Cell Viability Assay (CellTiter-Glo, CTG Assay) were conducted and half-maximal inhibitory concentration (IC₅₀) values for each compound were calculated using non-linear regression analysis. 2) Cell Painting Assay: Cells were stained with a panel of 6 fluorescent dyes to target distinct cellular compartments: nuclei (Hoechst 33342), cytoplasm (CellTracker Green CMFDA), mitochondria (MitoTracker Red CMXRos), endoplasmic reticulum (ER-Tracker Blue-White DPX), actin cytoskeleton (Phalloidin-Atto 647N), and Golgi apparatus (Wheat Germ Agglutinin, WGA-Alexa Fluor 555). Fluorescent images were acquired using a high-content imaging system (Operetta CLS, PerkinElmer) at 20x magnification. **Results:** Cell painting revealed distinct clustering of nephrotoxins vs. non-nephrotoxins in both models. Nephrotoxins induced consistent phenotypic changes: reduced mitochondrial intensity, fragmented ER, and actin cytoskeleton disorganization—more pronounced in 3D spheroids. Good correlation showed between cell painting assay and cell viability assay. **Conclusions:** This study demonstrates that 3D RPTEC spheroids integrated with cell painting assay yield a superior predictive approach for renal toxicity relative to 2D monolayer cultures. Key findings are as follows: 1) 3D spheroid models exhibit enhanced sensitivity and specificity in differentiating nephrotoxic from non-nephrotoxic compounds. 2) The cell painting assay captures subtle phenotypic alterations that complement viability readouts, thereby augmenting the predictive accuracy of the model. The integration of 3D RPTEC spheroids and cell painting-based analysis provides a robust *in vitro* platform for the early prediction of drug-induced nephrotoxicity during preclinical development. This approach reduces reliance on animal models and facilitates more reliable clinical translation of candidate therapeutics.

PS 3024 Retrograde Ureteral Catheterization for Renal Pelvis Access. A Feasibility Study in Cynomolgus Macaques.

K. Hokamura, M. Kosugi, M. Matsushita, M. Amano, R. Fujii, A. Hama, and T. Natsume. Hamamatsu Pharma Research, Inc., Hamamatsu, Japan. Sponsor: A. Fujiwara

Background and Purpose: Preclinical testing of novel drugs for kidney disorders is hampered due to the rapid excretion of systemically delivered drugs through the kidneys. Accurate determination of therapeutic efficacy of systemically delivered test compounds is extremely difficult. A noninvasive method to deliver drugs to the kidneys in cynomolgus macaque, using clinically available equipment was developed. **Methods:** Female cynomolgus macaques were sedated with intramuscular ketamine and subsequently maintained with inhaled isoflurane. A veterinary endoscope (Karl Storz, Germany) was introduced via the urethra into the bladder, allowing visualization of the ureteral orifices. A guidewire was then inserted into the ureteral orifice, followed by the advancement of a balloon catheter along the wire. The catheter tip was positioned near the renal pelvis, and its location was confirmed using a C-arm fluoroscope (GE, USA). Upon successful placement, the balloon at the catheter tip was inflated to prevent retrograde leakage of iohexol, a non-ionic iodinated contrast agent. About 1.5 ml of contrast agent was injected through the catheter into the renal pelvis, and fluoroscopic imaging was used to assess the distribution and retention of the agent within the kidney. **Results:** Retro-ureter catheter insertion was achieved without complications in three macaques. Fluoroscopic imaging confirmed positioning of the catheter tip near the renal pelvis. Anatomical structure of the renal pelvis varied among individuals, resulting in distinct imaging patterns and possible differences between subjects of volume of compound that can be dosed. The procedure was well tolerated in all subjects, with no significant bleeding during the procedure and no postoperative hemorrhage or health abnormalities observed. The use of balloon inflation effectively prevented leakage into the ureter, ensuring exposure of contrast to most of the kidney. **Conclusions:** Clinically utilized retro-ureteral catheterization for targeted drug delivery to the kidney was successfully scaled down for preclinical use in the cynomolgus macaque. The method enables localized drug administration while preserving renal perfusion, offering a promising strategy for preclinical testing of treatments for renal disorders.

M. Ljubojevic¹, V. Micek¹, M. Pavic Vulinovic², D. Breljak¹, J. Madunic¹, and I. Vrhovac Madunic¹. ¹Institute for Medical Research and Occupational Health, Zagreb, Croatia; and ²University of Zagreb, Faculty of Veterinary Medicine, Zagreb, Croatia. Sponsor: I. Vrhovac Madunic, EUROTOX

Background and Purpose: Cisplatin, CDDP is metal based antineoplastic still widely used for treatment of solid tumors. Pronounced side effects are numerous, among which nephrotoxicity is the most limiting. Problem of fast decreased renal function either ends in fibrosis or through recovery is additionally burdened with potential of secondary renal derived neoplasms. Aim of this work was to determine the functional changes in the expression of primary NaK-ATPase pump throughout nephron tubules and cortically expressed, tertiary active organic anion transporters Oat1&3 responsible for para-aminohippurate, PAH secretion known to be decreased with CDDP treatment. Expected changes in nephron epithelial cells cytosolic structural and functional components beta-actin and alpha-tubulin of cytoskeleton, together with inducible metallothioneins, MT1&2 that respond to metal challenge were not addressed before. Also, we follow intermediate filament member, vimentin that specifically increase in proliferation of fibroblasts and possible indicate epithelial to mesenchymal transition, EMT in damaged cells. Whereas, cyclooxygenase, COX1&2 as regulating enzymes of immune system were also followed for purpose of multilayers in here presented picture of animal CDDP nephrotoxicity model. **Methods:** After a single treatment of male Wistar rats with cisplatin (i.p. dose of 5 mg CDDP/kg) the most pronounced toxicity effect occurs on the 5th day, a point of here presented results in observed protein expression changes, while distribution of some proteins were followed each day after treatment. Kidney samples from 4 animals as homogenates and total cell membranes were used for western blot, WB for cytoskeleton and membrane proteins, respectively and cryosections were made for immunohistochemistry, IHC; while expression of mRNA for analyzed proteins was determined by the end-point RT-PCR. Specific antibodies were used for WB and IHC parallel with custom-made primers for targeted proteins mRNA expression analysis. **Results:** WB results fifth day showed decrease in NaK-ATPase and transporters expression with Oat1 affected more than Oat3, that did correspond to IHC but not to end-point RT-PCR results, whereas all applied methods showed increase in cytoskeleton proteins especially in prominently damaged outer stripe of outer medulla kidney zone. Fibroblast specific vimentin together with MT1&3 showed increased expression and even change in distribution. Fibroblasts increased in proliferation and move toward damaged epithelia of outer stripe while Mt1&2 showed prominent expression in inner stripe and papilla, absent in the control. **Conclusions:** Decrease in expression of NaK-ATPase Oat1 and Oat3 correlates with disturbed renal function. Increase of overall cytoskeleton and MT1&2 together with vimentin followed by changed distribution indicates disruption of renal structure accompanied by proliferation and invasiveness of fibroblasts from papilla to the most damaged kidney zone of outer stripe but exclude EMT in repair. Late indicate increased potential of regeneration that can lead to fibrosis but also revealing importance of inner stripe and papilla in recovery response to CDDP treatment. Further research is needed of potentially new neoplasms growth in outer stripe epithelial cells regenerative process. *Funded by the European Union - Next Generation EU (Class: 643-02/23-01/00016, Reg. no. 533-03-23-0006)-Project: Evaluation of efficacy and toxicity of biologically active substances (BioMolTox).*

PS 3026 Differentiating Hepatic and Renal Toxicity Reveals Cyp-Independent Mechanisms of Acetaminophen-Induced Acute Kidney Injury

Y. Etemadi, T. A. Fields, J. Akakpo, A. Ramachandran, and H. Jaeschke. University of Kansas Medical Center, Kansas City, KS.

Background and Purpose: Acetaminophen (APAP) overdose is the leading cause of acute liver failure (ALF) in the U.S. Hepatotoxicity is initiated by cytochrome P450 2E1 (CYP2E1)-mediated conversion of APAP to the reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI), which depletes glutathione (GSH), triggers mitochondrial dysfunction, and causes necrotic cell death. Although the liver is the primary target, APAP overdose also causes substantial renal dysfunction, with acute kidney injury (AKI) occurring in more than 50% of patients with ALF, where it worsens clinical outcomes and independently predicts mortality. Despite this strong clinical association, most studies of APAP-ALF have focused primarily on hepatic injury, and the mechanisms underlying APAP-induced nephrotoxicity remain poorly defined—particularly regarding whether renal injury is a direct effect or secondary to liver injury. In addition, N-acetylcysteine (NAC), the only approved antidote, replenishes hepatic GSH and prevents liver injury but fails to protect the kidney, underscoring a mechanistic difference between hepatic and renal injury. This study investigates whether APAP-induced AKI occurs independently of ALF by using liver-specific Cyp2e1 knockout (KO) mice generated via AAV8-Cre delivery to distinguish hepatic versus renal contributions to toxicity. **Methods:** Fasted male and female C57BL/6J mice received APAP (600 mg/kg, i.p.) and were euthanized at various time points up to 48 hours post-dose. For hepatic deletion, Cyp2e1 flox/flox mice were injected with AAV8-Cre intravenously two weeks before APAP treatment and sacrificed at 24-48 hours. Hepatic injury was assessed by serum alanine aminotransferase (ALT) and necrotic area quantification in histology. Renal injury was evaluated by blood urea nitro-

gen (BUN), serum creatinine, periodic acid schiff (PAS) staining, and tubular injury markers (KIM-1 and osteopontin). Apoptosis was determined by the TUNEL assay, while CYP2E1 and osteopontin protein levels were measured by western blotting and Immunohistochemistry (IHC). APAP-protein adducts were quantified by HPLC with electrochemical detection. **Results:** In male mice, APAP overdose (600 mg/kg) caused a sharp increase in serum ALT ($\approx 10,000$ U/L), BUN (≈ 60 mg/dL) and creatinine (≈ 0.4 mg/dL), with extensive centrilobular hepatic necrosis and renal cortical damage marked by proximal tubular vacuolation and strong KIM-1 and osteopontin staining. CYP2E1 IHC revealed robust expression in the renal cortex of both control and APAP-treated males. In contrast, APAP overdose resulted in a smaller elevation in ALT (≈ 6000 U/L) and BUN (≈ 40 mg/dL) in females, where liver sections showed marked centrilobular necrosis, but renal architecture remained largely preserved. IHC demonstrated minimal KIM-1 and osteopontin staining, and TUNEL assays showed few apoptotic cells in the female kidney. No positive CYP2E1 staining was observed in the kidney in both control and APAP-treated females, and protein adducts were undetectable at 3, 6, and 24 hours, suggesting limited renal CYP2E1 expression and reduced APAP bioactivation in the kidney. In liver-specific Cyp2e1 KO male mice, hepatic injury was completely prevented, with mice surviving to 48h, confirming efficient and liver-restricted deletion of CYP2E1 as verified by IHC. Despite the absence of hepatic injury, renal damage progressively worsened over time, characterized by tubular cast formation, brush border loss, and strong induction of KIM-1, osteopontin, and apoptotic cell death at 48 hours. Interestingly, in liver-specific Cyp2e1 KO female mice, renal injury still progressed despite the absence of CYP2E1 in both liver and kidney. This was evidenced by extensive tubular vacuolation on H&E staining and strong TUNEL, KIM-1, and osteopontin staining. **Conclusions:** The persistence of AKI in Cyp2e1-deficient mice, despite absent hepatic CYP2E1, demonstrates that APAP-induced nephrotoxicity can occur independently of liver metabolism. In female mice, which do not express renal CYP2E1 and show no protein adduct formation, even after hepatic CYP2E1 deletion, kidney injury still progressed, indicating that APAP-induced AKI can occur through a CYP-independent mechanism. These findings highlight the need for kidney-targeted therapies beyond NAC.

PS 3027 A proximal tubule on-chip model for nephrotoxicity and drug safety evaluation

P. Zamprogno, G. Raggi, N. Albrecher, L. L. De Maddalena, L. Froment, J. Kamper, A. Hugli, and N. Hobi. AlveoliX AG, Swiss Organs-On-Chip, Bern, Switzerland. Sponsor: A. Stucki

Background and Purpose: Renal toxicity remains a major challenge in drug development due to the kidney's role in filtering and concentrating external compounds, which can lead to adverse effects. Renal proximal tubule epithelial cells (RPTEC) are central to drug absorption and metabolism, making them particularly vulnerable to drug-induced kidney injury (DIKI). To better mimic the kidney's complex architecture and dynamic environment, proximal tubule-on-chip systems have emerged as advanced platforms for drug screening and toxicity testing. **Methods:** This study introduces and characterizes the ^{AX}PToC model, a Proximal Tubule-on-Chip system built using AlveoliX's ^{AX}Barrier-on-Chip technology. RPTEC were cultured on a soft, porous membrane within the chip, and their differentiation was monitored over time via gene expression analysis (RT-qPCR). Barrier integrity was evaluated using Transbarrier Electrical Resistance (TER) and permeability assays. Cell morphology was examined through immunofluorescence staining, and albumin uptake via Megalin/Cubilin was assessed using fluorescently-labelled BSA. **Results:** RPTEC cultured on-chip formed a functional epithelial barrier, demonstrated by permeability to both small (10 kDa) and large (70 kDa) molecules, while maintaining low TER values, closely reflecting *in vivo* kidney physiology. Over time, RPTEC differentiated and expressed key markers such as CUBN, LRP2 (Megalin), CD13, ATP1A1 (Na/K ATPase), and transporters involved in drug metabolism and resistance (ABCC2, OAT1). Albumin uptake was confirmed through FITC-albumin assays and shown to be specific, as it decreased significantly in the presence of unlabelled albumin. Immunofluorescence revealed characteristic dome-like structures and P-Glycoprotein (MDR1) expression in RPTEC on-chip. When challenged with cancer therapeutics such as Cisplatin, the ^{AX}PToC model showed hallmarks of DIKI such as cytotoxicity and cell layer impairment. **Conclusions:** The ^{AX}PToC model successfully replicates essential features and functions of the human proximal tubule, including marker expression and transport activity. This robust and physiologically relevant system offers a promising platform for evaluating nephrotoxicity and drug safety, particularly in the context of DIKI.

PS 3028 Exosomes Secreted from Human Proximal Tubular Cells are Sources of Biomarkers for Exposure to Nephrotoxic Environmental Chemical and Drugs

L. H. Lash¹, M. Gargano¹, P. M. Stemmer², K. Lowran², R. Rosati², X. Hu³, and D. P. Jones³. ¹Wayne State University School of Medicine, Detroit, MI; ²Wayne State University, Detroit, MI; and ³Emory University School of Medicine, Atlanta, GA.

Background and Purpose: In previous work, we showed that exposure of human PT (hPT) cells to subtoxic or mildly toxic concentrations of nephrotoxicants resulted in release of proteins and metabolites associated with mitochondrial and other pathways and that these could be used as biomarkers. We further hypothesized that

hPT cells would also release exosomes and that these could serve as an enriched source of biomarkers for the same exposures. **Methods:** hPT cells were grown to approx. 80% confluence and incubated for 0.5, 1, or 4 h with either media (= Control), the trichloroethylene metabolite S-(1,2-dichlorovinyl)-L-cysteine (DCVC) [10, 50 µM], HgCl₂ [0.2, 0.5 µM], cisplatin (CDDP) [10, 50 µM], polymyxin B (PmxB) [10, 50 µM], or tenofovir disoproxil fumarate (TDF) [5, 20 µM]. Exosomes were isolated from extracellular media samples by differential centrifugation and ultracentrifugation steps and were analyzed by both metabolomics and proteomics. Metabolomics analysis was conducted by high resolution mass spectrometry coupled with ultrahigh performance liquid chromatography to determine pathways altered by the diverse exposures. Abundance of proteins released into exosomes by cells was analyzed by labeling with isobaric TMT mass tag reagents. Peptides were identified by MS2 spectra using an Eclipse Orbitrap mass spectrometer and abundances were quantified from the TMT tags in MS3 spectra using Real Time Search. Protein MS/MS data were evaluated using Proteome Discoverer 3.1 (PD) and then proteins and peptides were quantified based on the TMT reporter ion signal. Quantitative values were evaluated in a PCA plot to visualize segregation of the sample groups. Data were then submitted to a moderated t-test to detect differences between groups and proteins that were different between groups were identified. Proteome Discoverer was used to perform protein enrichment analysis and to identify biological processes and pathways altered by treatment. Reactome and GO Metabolic Pathway analyses were conducted to identify pathways altered by the exposures. **Results:** Metabolomics analyses of exosomes released from hPT cells exposed to low concentrations of the nephrotoxic environmental chemicals or clinically used drugs whose efficacy is dose-limited by nephrotoxicity demonstrated significant alterations in several pathways, many of which are associated with mitochondria. Further, many of these pathways were the same ones identified by study of the total secretome from the hPT cells. These include prostaglandin metabolism from arachidonate, fatty acid beta-oxidation, several amino acid metabolism pathways, pentose phosphate and related vitamin metabolism pathways, and glutathione metabolism. Proteomics analysis of the whole secretome confirmed the presence of exosomes by detection of 9 marker proteins and found 8 of 9 to be increased 1.3- to 3.2-fold in association with exposures. Reactome pathway analysis showed many of the same pathways altered by exposures in the whole secretome as well as additional pathways. Common pathways that were shared amongst exosomes from hPT cells incubated with the two toxicants and the three drugs included pathways derived from mitochondria, cytoskeleton, and cytoplasm for metabolism of several amino acids, pathways indicative of immune function modulation, including cytokine signaling and neutrophil degranulation, purine and pyrimidine metabolism, glutathione conjugation, signaling and metabolism of retinoic acid (vitamin A), vitamin D metabolism, biotin transport and metabolism, malate-aspartate shuttle, citric acid cycle, and keratin metabolism and differentiation of keratinocytes. **Conclusions:** These results support the overall hypothesis that mitochondria are a critical source of potential biomarkers of toxicant exposure and identify putative proteins and metabolic pathways that may serve as these biomarkers for both nephrotoxicant exposure and metabolic reprogramming for repair and regeneration. Isolation of exosomes from the secretome of hPT cells supports the hypothesis that secreted vesicles may serve as an additional and specific source of biomarkers of effect. This research was funded by NIH Grant R01-ES031584 and the CURES Grant Number P30-ES036084.

PS 3029 1,4-Dichlorobenzene Nephrotoxicity *In Vitro*: Effect of Electron-withdrawing Groups

G. O. Rankin, L. Tran, J. Sherif, J. Sherif, C. Cole, M. Jarrell, M. McCormick, and D. K. Anestis. Marshall University, Huntington, WV.

Background and Purpose: 1,4-Dichlorobenzene (1,4-DCB) is a common chemical used in mothballs and as a building block for pesticides and other commercial products. 1,4-DCB is also found in the environment as a pollutant. Exposure to 1,4-DCB in the air can cause respiratory issues, while prolonged exposure can lead to liver and kidney injury. In *in vitro* studies, 1,4-DCB was the most cytotoxic of the three dichlorobenzene isomers to isolated kidney cells (IKC) from Fischer 344 rats. The purpose of this study was to examine the effects of various electron-withdrawing groups added to 1,4-DCB on 1,4-DCB nephrotoxicity as part of a structure activity study on the *in vitro* nephrotoxicity of halogenated benzenes. **Methods:** IKCs (~4 million cells/ml; 3 ml) from male Fischer 344 rats were incubated with 1,4-DCB or a 1,4-DCB derivative (1,4-dichloro-2-nitrobenzene, 2,5-dichlorobenzoic acid, and 2,5-dichloroacetophenone; 0.25-1.0 mM) or dimethyl sulfoxide (DMSO, vehicle) for 30 or 60 minutes at 37 °C in a 95% oxygen/ 5% carbon dioxide atmosphere. The release of lactate dehydrogenase (LDH) was utilized to determine cytotoxicity. **Results:** All the examined electron-withdrawing groups produced compounds with a reduced level of cytotoxicity compared to 1,4-DCB. 1,4-Dichloro-2-nitrobenzene caused the least cytotoxicity in IKC, while 2,5-dichloroacetophenone induced the highest cytotoxicity of the tested 1,4-DCB derivatives. 2,5-Dichlorobenzoic acid produced intermediate cytotoxicity among the 1,4-DCB derivatives. **Conclusions:** The results of this study indicate that the stronger the electron-withdrawing group, the greater the reduction in 1,4-DCB derivative nephrotoxicity. Previous studies have indicated that 1,4-DCB is oxidized to form a toxic metabolite(s). Since oxidation rates would be reduced by the addition of an electron-withdrawing group, the order of decreased cytotoxicity relative to 1,4-DCB supports those findings.

PS 3030 Menthol Induced Decline in Mitochondrial Function and Autophagy in Renal Epithelial Cells

M. Valentovic, K. Brown, and E. McGuffey. Marshall University School of Medicine, Huntington, WV.

Background and Purpose: Vaping device use is increasing in teenagers and young adults. The health effects of the numerous agents released into the atmosphere during vaping is relatively unknown. Menthol is a flavoring agent contained in vaping products and detectable plasma levels of menthol have been measured following vaping. The health effects beyond the lung are not widely explored. The purpose of this project was to evaluate the effect of menthol on renal proximal tubular epithelial cells. The overall hypothesis was that menthol is cytotoxic to HK-2 cells by impairing mitochondrial function and autophagy. **Methods:** Human HK-2 cells were plated and equilibrated for 48h. Cells were exposed to a final concentration of 0-1500 uM menthol for 24h. The vehicle for menthol was water. All experiments were conducted as a minimum of 4 independent experiments with different cell passages. Cytotoxicity was assessed using the MTT assay after the 24h exposure. MTT in viable cells was converted to formazan. Upon completion of the exposure period, cells were collected, lysed and samples prepared for Western blot analysis. Differences between groups were evaluated using ANOVA followed by a post hoc test at a 95% confidence interval. **Results:** Viability was not impacted in HK-2 cells incubated with 0-200 uM menthol. Further studies examined 0-1500 uM menthol. Menthol was cytotoxic between 200-1500uM compared to vehicle control (p<0.05). Studies examined autophagy markers LC3BII and II and SIRT1 by western blot which showed no difference between groups to 0-200 uM menthol. LC3BII levels were increased by 1500 uM menthol when compared to control. Additional studies examined mitochondrial function following a 24 h exposure to menthol. **Conclusions:** In summary, menthol was cytotoxic to HK-2 cells within 24h when compared to vehicle controls. Mitochondrial impairment of basal and maximal respiration was detected at lower concentrations than impacted by MTT and cell membrane integrity. Menthol also increased autophagy. (Supported by NIH Grant P20GM103434).

PS 3031 Blocking complement as a preventative measure for kidney ischemia reperfusion injury: Insights from a human kidney-on-a-chip study

L. Gijzen¹, L. Tool¹, E. Haspeslagh², R. Annida¹, J. Delaere², R. van Vught¹, K. Budding², E. Hack², and I. van de Walle². ¹MIMETAS B.V., Oegstgeest, Netherlands; and ²Argenx B.V., Zwijnaarde, Belgium. Sponsor: S. Kundu

Background and Purpose: Delayed graft function (DGF), a prevalent complication following kidney transplantation, is often driven by ischemia reperfusion injury (IRI), with complement activation playing a key role. Despite this recognition and its significant impact on transplant outcomes, preventative treatments are currently not available. In this study, we investigated the therapeutic potential of ARGX-117, a novel humanized anti-C2 antibody, in diminishing complement-induced IRI using a human kidney on-a-chip model. **Methods:** We established a 3D kidney-on-a-chip co-culture model in the OrganoPlate platform that incorporates human renal proximal tubule epithelial cells (RPTECs) and human umbilical vein endothelial cells (HUVECs) cultured under flow and in direct contact with a collagen-I ECM gel layer. Ischemia-reperfusion (IR) conditions were established by culturing the cells under low oxygen and without perfusion flow for 48 hours, followed by restoring normoxic conditions for 24 hours representing reperfusion. **Results:** Under IR conditions, the model exhibited hallmark features of IRI, including altered RPTEC morphology, decreased barrier function, and IgM-mediated complement activation, as evidenced by C3 deposition. Furthermore, complement-driven upregulation of ICAM-1 expression on RPTECs was observed, indicative of an inflammatory response. Therapeutic intervention with ARGX-117 effectively prevented IR-induced complement activation in a concentration-dependent manner, as demonstrated by reduced C3 deposition, while preserving IgM binding. Finally, ARGX-117 attenuated the IR-induced upregulation of ICAM-1 on RPTECs, suggesting reduced inflammation and subsequent tissue damage. **Conclusions:** These findings highlight the crucial role of complement activation in IRI pathogenesis and demonstrate the efficacy of ARGX-117 using a preclinical human kidney IRI model. By preventing complement-driven inflammation and kidney damage, ARGX-117 offers a promising strategy to prevent DGF and to improve kidney transplantation outcomes. This study emphasizes the importance of advanced human *in vitro* models for preclinical evaluation of targeted therapies, paving the way for better management of transplantation-associated IRI.

PS 3032 Evaluating the NRF2-KEAP1 Responses of Melatonin in Human Kidney Proximal Tubule Cells

T. Xie, C. Kim, X. Wen, L. Aleksunes, and L. Brunetti. Rutgers, The State University of New Jersey, Piscataway, NJ.

Background and Purpose: Melatonin is an endogenous neurohormone and dietary supplement used to treat sleep disturbances. Melatonin acts as an antioxidant and reactive oxygen species scavenger, with documented protective effects against diseases in the immune, metabolic, neurological, and renal systems. We have previ-

ously reported the anti-apoptotic effect of melatonin against vancomycin-induced cytotoxicity in human kidney proximal tubule HK-2 cells. The mechanism of this protection remains unclear although preliminary studies have suggested that melatonin can promote antioxidant signaling by favoring the release of NRF2, the master regulator of oxidative stress response, from the cytoplasmic regulatory protein KEAP1. This allows NRF2 to translocate to the nucleus and activate a coordinated network of antioxidant genes. Therefore, the purpose of this study was to compare the mRNA levels of NRF2-target genes in HK-2 cells genetically manipulated to have low, normal, or high NRF2 signaling following treatment with melatonin or the prototypical NRF2 activator sulforaphane. **Methods:** Three HK-2 cell lines, empty vector (EV), KEAP1-knockdown (KD), and NRF2-KD, were generated using stable transfection with short hairpin RNAs and treated with melatonin (32 μ M) or a known NRF2 activator, sulforaphane (SFN; 10 μ M), either alone or in co-treatment with a non-cytotoxic concentration of vancomycin (VAN; 1 mM) for 24 hours. qPCR was performed to assess the expression of kidney injury biomarker KIM-1, the pro-inflammatory cytokine TNF- α , and NRF2-ARE pathway genes. **Results:** As expected NRF2 mRNA was lowest in the NRF2 knockdown cells with little difference in mRNA levels between EV and KEAP1-KD cells. Likewise, SFN induced the expression of NRF2 and its target genes NQO1 and HO-1 in EV and KEAP1-KD cells, but to a lesser extent or not at all in NRF2-KD cells. In general, melatonin and vancomycin had little to no impact on the mRNA levels of NRF2, NQO1, or HO-1 in any of the three cell lines. Notably, VAN treatment did not alter KIM-1 mRNA levels, but it did increase TNF- α mRNA by 145%. Co-treatment of cells with vancomycin and SFN, but not melatonin, mitigated the induction of TNF- α mRNA regardless of NRF2 expression. **Conclusions:** The results indicated the attenuation of kidney injury and inflammation biomarkers by sulforaphane may involve both NRF2-dependent and independent mechanisms. By comparison, melatonin had minimal impact on NRF2-KEAP1 signaling in HK-2 cells. Ongoing studies are investigating additional pathways and transporters regulated by melatonin to further elucidate its mechanisms of renoprotection. Supported by R01DK131214, T32ES007148, and F31DK141202.

PS 3033 Silica deposits in drinking water and renal biopsies from a Mexico hotspot region of Chronic Kidney Disease of Unknown etiology (CKDu)

L. D. Calvimontes Barrientos¹, S. Brindley¹, S. Santos¹, C. A. Roncal², M. Madero³, R. J. Johnson², J. M. Arreola Guerra⁴, and J. M. Brown¹. ¹Department of Pharmaceutical Sciences, Sackler School of Pharmacy and Pharmaceutical Sciences, University of Colorado, Anschutz Medical Campus, Aurora, CO; ²Division of Renal Diseases and Hypertension, School of Medicine, University of Colorado, Anschutz Medical Campus, Aurora, CO; ³Department of Medicine, Division of Nephrology, Instituto Nacional de Cardiología-Ignacio Chavez, Mexico City, Mexico, Mexico City, Mexico; and ⁴Department of Nephrology, Hospital Centenario Miguel Hidalgo, Aguascalientes, Mexico, Aguascalientes, Mexico.

Background and Purpose: Chronic kidney disease of unknown etiology (CKDu) is a worldwide epidemic primarily affecting healthy male young adults. These individuals lack traditional co-morbidities such as hypertension or diabetes. The cause of the disease remains unknown, however, current understanding suggests an environmental etiology including heat stress, particulate matter, and pesticide exposure from agricultural practices. In Aguascalientes, Mexico, a hotspot for CKDu, the disease disproportionately affects adolescents, presenting primarily with focal segmental glomerulosclerosis (FSGS). Our previous experimental and clinical studies have implicated silica particle exposure from particulate matter as a potential contributor to CKDu leading to oxidative and mitochondrial injury in the kidney. The goal of this study was to assess the presence of silica particles in renal tissue from adolescents with adaptive podocytopathy and adults with FSGS and explore possible environmental sources of silica exposure in Aguascalientes, Mexico. In addition, we examined the effect of silica particles collected from water samples in Aguascalientes on mitochondrial respiration via human renal cell models and functional assays. **Methods:** This case-control study included kidney biopsies from four groups (median age 30 years, IQR 18-42; 50.9% female): [1] adolescents with adaptive podocytopathy (n = 15), [2] adults with adaptive FSGS (n = 19), [3] adults with other glomerulopathies (n = 10), and [4] renal tissue from trauma nephrectomy controls (n = 10). We used single-particle inductively coupled plasma mass spectrometry (SP-ICP-MS) to measure silica particles in all samples. **Results:** Analysis of kidney biopsies (n=54) detected silica particles in 66% of adolescents and 65% of adults with FSGS, compared with 0% and 10% in the control groups (p < 0.01). Mean silica particle density was highest in adolescents (1.7 $\pm$ 0.4 particles/mm³ tissue) and FSGS adults (1.26 $\pm$ 0.1), versus 0.23 $\pm$ 0.04 and 0.29 $\pm$ 0.12 in disease and controls, respectively. Silica was also detected in water from non-commercial purification plants but was absent in the public water system (72,272.8 vs. 0 particles/ml, p < 0.001). Lastly, we found that silica particles disrupted mitochondrial respiration and caused oxidative stress in human renal cells. **Conclusions:** Elevated silica levels in both renal samples from affected individuals and local water sources supports silica exposure as a potential contributor to CKDu pathogenesis in Aguascalientes, Mexico.

PS 3034 Modified Albumin Elicits AKI-Like Transcriptomic Programs in Human Proximal Tubule Microphysiological Systems

A. Mahadeo, T. Bammler, J. MacDonald, C. Yeung, S. Akilesh, J. Himmelfarb, and E. Kelly. University of Washington, Seattle, WA.

Background and Purpose: Proteinuria is a key predictor of chronic kidney disease (CKD) progression, yet whether direct tubular exposure to serum proteins exacerbates injury remains debated. We have previously shown that normal human serum, rather than purified human serum albumin (HSA), activates pro-inflammatory and remodeling pathways in human proximal tubule microphysiological systems (MPS). In CKD and diabetes, albumin is subject to post-translational modifications such as carbamylation and glycation, which alter structure and bioactivity. Carbamylated albumin (CA) accumulates with uremia in advanced disease states, whereas glycated albumin (GA) arises in hyperglycemia and may engage inflammatory receptors such as RAGE. The present study aimed to determine whether these modified albumin species independently drive tubular injury and to define associated molecular pathways. **Methods:** Primary human proximal tubule epithelial cells from three donors were cultured in Nortis ParVivo microphysiological devices under continuous perfusion. Tubules were exposed for 48 h to control media, 2% pooled human serum, or 720 μ g/mL of HSA, bovine serum albumin (BSA), CA-BSA, or GA-HSA. Effluent media were analyzed for cytokines, and tubule lysates underwent bulk RNA-seq with differential expression and pathway analyses performed using iPathwayGuide. Transcriptomic profiles were then compared with Kidney Precision Medicine Project (KPMP) single-cell datasets from healthy, AKI, and CKD proximal tubule samples. **Results:** Carbamylated albumin and human serum induced transcriptional changes (516 and 157 DEGs, respectively, FDR < 0.05), whereas native or glycated albumin elicited no significant transcriptional change. Gene Ontology enrichment identified perturbation of plasma-membrane, transporter, and oxidative-stress pathways. Consistent downregulation of Metallothionein-1 family genes (MT1E/G/H/X/M/F) by CA-BSA was also observed in AKI transcriptomes. CA-BSA exposure upregulated SMURF2, FSTL1, and TNFRSF11B (osteoprotegerin) while suppressing CISH, GPC3, and FKBP5, a pattern consistent with enhanced TGF- β and cytokine signaling which was observed in AKI and CKD transcriptomes as well. While not significant, GA-HSA demonstrated a trend of MAPK-cascade activation with donor-to-donor variability. **Conclusions:** Carbamylated, but not native, albumin invokes an AKI-like transcriptional response in human proximal tubule MPS, characterized by activation of TGF- β remodeling, cytokine signaling, and metallothionein depletion. These findings suggest that post-translational albumin modifications associated with advanced kidney disease can directly perturb tubular processes, linking proteinuria to epithelial stress and fibrotic remodeling. The data provides a mechanistic bridge between modified albumin exposure and pathways driving CKD progression along the AKI-to-CKD continuum.

PS 3035 Spatially Resolved MultiOmics Reveals Localized Renal Responses to Cisplatin Nephrotoxicity

J. Akakpo¹, E. Abbott¹, B. L. Woolbright¹, A. Ramachandran¹, R. G. Schnellmann², D. P. Wallace¹, and J. Taylor¹. ¹University of Kansas Medical Center, Kansas City, KS; and ²University of Arizona, Tucson, AZ.

Background and Purpose: Cisplatin, a cornerstone in bladder cancer chemotherapy, faces a significant clinical hurdle due to cisplatin nephrotoxicity (CN). This adverse renal effect necessitates innovative therapeutic approaches to safeguard kidney function without diminishing cisplatin's anticancer potency. Our research employs a relevant bladder cancer model to elucidate the spatial metabolic alterations induced by cisplatin within the renal microenvironment, thereby paving the way for protective strategies against CN that maintain cisplatin's therapeutic efficacy. **Methods:** Male C57Bl/6J mice were induced with bladder cancer via 16 weeks of N-butyl-N-(4-hydroxybutyl)-nitrosamine (BBN) in drinking water, followed by a 3-week treatment of 9 mg/kg cisplatin weekly. Outcomes assessed included general health, survival, renal injury (as determined by plasma and kidney samples), and cancer progression (as assessed by bladder tissue). Renal injury and cancer progression were further analyzed using Desorption Electrospray Ionization-Mass Spectrometry Imaging (DESI-MSI) on 5 μ M frozen kidney sections, followed by spatially resolved cell population transcriptomics with the GeoMx digital spatial profiler. **Results:** Mice treated with BBN developed various stages of bladder cancer, including muscle-invasive bladder cancer, leading to a significant decline in survival rates due to rapid tumor growth and weight loss. Cisplatin treatment, while improving survival by reducing tumor weight and progression, also induced considerable nephrotoxicity, as indicated by elevated serum creatinine and BUN levels. Histological analysis revealed that cisplatin primarily induced tubular damage within the renal cortex. DESI-MSI further demonstrates that cisplatin disturbs the localization of specific lipids, as indicated by the regional variations of lipids like SM (d34:1) and phosphatidylcholine PC (38:4). **Conclusions:** The direct correlation between metabolite abundance and cisplatin-induced renal gene expression changes offers crucial insights into potential molecular mediators that could be therapeutically targeted to prevent CN.

M. Anthony, C. Kim, L. Aleksunes, and L. Brunetti. Rutgers University, Piscataway, NJ.

Background and Purpose: Drug-induced kidney injury affects millions of individuals annually across the globe. One particular culprit is vancomycin, a glycopeptide antibiotic, that is essential for treating serious *Staphylococcus aureus* infections. The molecular mechanisms contributing to the toxicity of vancomycin are not fully understood, but preliminary studies suggest that oxidative stress and mitochondrial dysfunction damage proximal tubule cells. As an endogenous antioxidant, melatonin offers cellular protection from oxidative damage by scavenging reactive oxygen species and enhancing cellular defense pathways. In the current study, we sought to 1) evaluate the ability of vancomycin to alter mitochondrial function in cultured human proximal tubule cells and 2) determine whether melatonin can mitigate the vancomycin-induced changes. **Methods:** Human proximal tubule epithelial cells (HK-2, N=8/treatment group) were exposed to vancomycin at pharmacologically-relevant concentrations of 0, 1, 2, 4, or 8 mM with or without concomitant treatment with melatonin (16 μ M) for 24 hours. Mitochondrial health was assessed with the Mito Stress assay performed on the Agilent Seahorse XF Analyzer. This assay measures bioenergetic parameters, including basal respiration and maximal respiratory capacity. The Bioenergetic Health Index (BHI), a quantitative measure of energy production capacity and mitochondrial stress, was calculated using the bioenergetic parameters acquired from the Mito Stress assay. A lower BHI is reflective of increased mitochondrial damage and decreased metabolic function. **Results:** Vancomycin treatment caused a concentration-dependent decrease in mitochondrial metabolic function. Compared to control HK-2 cells, the basal and maximal respiration of cells exposed to 4 mM vancomycin was reduced by 88% and 83%, respectively. Likewise, the BHI in HK-2 cells treated with 4 mM vancomycin was 44% lower than that of the control, indicating decreased mitochondrial health. The BHI of HK-2 cells treated with 8mM vancomycin was 167% lower than that of the control. Similar to vancomycin, treatment of HK-2 cells with melatonin alone reduced the basal and maximal respiration of cells between 48-61%. Together, cotreatment with melatonin further decreased both the basal and maximal respiration of cells by 29% relative to vancomycin treatment alone. By comparison, melatonin did improve the decline in BHI associated with vancomycin. **Conclusions:** Exposure of HK-2 cells to vancomycin significantly reduced mitochondrial respiration and metabolic function indicated by the decrease in basal and maximal respiration, suggesting compromised mitochondrial integrity. Despite our team previously demonstrating the ability of melatonin to protect against the cytotoxicity of vancomycin in HK-2 cells, we observed mixed mitochondrial responses to the co-treatment. Further studies using real-time monitoring of mitochondrial respiration and changes in morphology and fusion/fission are needed. Supported by R01DK131214; F31DK141202

PS 3037 AI-Driven Histology and Urinary Biomarkers to Assess Adverse Effect of Heat Stress on the Kidney in a Rat Model

J. Zhou¹, D. Verdugo¹, S. Xiang², V. Stevenson¹, Y. Yang², K. Greenbergs¹, J. Escandor¹, A. Alli¹, N. Denslow¹, and C. Vulpe¹. ¹University of Florida, Gainesville, FL; and ²University of Georgia, Athens, GA.

Background and Purpose: Chronic kidney disease of unknown etiology (CKDu) is an urgent health issue with increased mortality among farmworkers across the globe. Geographic data suggested a cluster of reported CKDu in agricultural communities from regions with hot and humid climates, like Central America and South Asia. Multiple factors, including heat exposure, have been reported to contribute to the development of CKDu, but the underlying cause(s) of the disease remain unclear. Previously, we reported that young adult male Sprague-Dawley (SD) rats that were repeatedly exposed (4 hours a day, 5 days a week) to heat stress at 35 °C with 50±10% humidity which increased core body temperature (CBT) by ~ 1 °C, comparable to the hyperthermia observed in farm workers, showed impaired growth and decreased body weight gain over a 4 week period. During each 4-hour heat exposure with free access to water, the animals lost ~3% of their body weight, despite significantly higher water intake as compared to the control. **Methods:** To further assess the effect of repeated chronic heat exposure on the kidney, we gathered urine samples in metabolic cages and measured a panel of urinary protein biomarkers for kidney toxicity (Thermo Fisher Scientific) by Luminex multiplex assay. We assessed kidney histopathology changes at 2-week intervals using customized AI and deep learning algorithms developed in the HALO AI platform (Indica Labs). We carried out a holistic assessment of rat kidney histopathologic changes, which we term Whole Slide Imaging (WSI) analysis, by combining quantitative structural analysis with functional staining-based objective quantification. **Results:** Our quantification of urinary biomarkers indicated that KIM-1, Calbindin, and NGAL were increased in the heat-exposed animals. We validated increased expression of *Calb1* mRNA in the kidney, and further demonstrated increased levels of the acute-phase protein, haptoglobin (Hp), which has been previously associated with heat stress in the liver. Furthermore, the whole slide histology analysis indicated glomerular and tubular injuries, as well as evidence of renal interstitial fibrosis in the heat-exposed animals. Specifically, we noted glomerular shrinkage and increased intratubular proteinuria, accompanied by significant intraglomerular accumulation of IBA-1 indicative macrophages and PAS+/Trichrome+ deposits in the kidney. **Conclusions:** Our present study reveals that heat stress increased urine biomarker levels and was associated with histopathological

changes in the kidney, highlighting the importance of applying different approaches in assessing renal damage, which may provide insights into understanding the cause and development of the disease. These findings may have relevance to the development of chronic kidney disease of unknown etiology in heat-stressed individuals.

PS 3038 Novel Role of Lipins in Aminoglycoside-Induced Renal Cell Death

C. M. Henry, and B. Cummings. Wayne State University, Detroit, MI.

Background and Purpose: Aminoglycoside antibiotics (AGs) remain an essential class of drugs for treating life-threatening gram-negative infections, particularly in hospital and emergency settings; however, their clinical utility is limited by dose-dependent nephrotoxicity, which can lead to acute kidney injury (AKI). Lipins are phosphatidic acid phosphatases, enzymes that convert phosphatidic acid to diacylglycerol. Recent studies have suggested novel roles for lipins in renal cell death, but their ability to mediate AG-induced nephrotoxicity has not been studied. As such, this study investigated the role of lipins in AG-induced renal cell death. **Methods:** The toxicity of AGs was studied in cultures of human renal proximal epithelial tubule (RPTEC) and human kidney-2 (HK-2) cells using MTT staining, cell morphology, and annexinV/PI flow cytometry. Autophagy was also assessed using flow cytometry and western blot analysis. The expression of lipin isoforms was determined using immunoblot analyses and lipin activity was inhibited using the non-selective inhibitor propranolol. **Results:** Exposure of RPTECs and HK-2 cell to AGs for 48 hr resulted in concentration-dependent cytotoxicity. High concentrations (8 mM) of multiple AGs produced marked morphological changes indicative of cell death, while gentamicin exhibited the greatest toxicity even at 2 mM. Quantification of MTT staining demonstrated dose-dependent toxicity across the AG panel. Annexin V and propidium iodide staining revealed increased early and late apoptosis in AG-treated HK-2 cells relative to control. Autophagy red staining demonstrated modest increases in autophagic flux following AG exposure, as compared to rapamycin, which was used as a positive control. Immunoblot analysis of LC3-II expression supported these findings, with rapamycin and tobramycin producing the most pronounced increases in LC3-II expression. Treatment of cells with propranolol increased RPTEC cell death as determined by cell morphology and MTT staining. **Conclusions:** These data show that AGs induced concentration-dependent cytotoxicity in both RPTEC and HK-2 cells via mechanisms that involved apoptosis. Select AGs induced low levels of autophagy. Propranolol increased the toxicity of select AGs in RPTEC suggesting the novel finding that lipin mediates the mechanism of toxicity of AG's.

PS 3039 Organophosphate Flame Retardants Induce Renal Cell Proliferation In Vitro

C. E. Fillmore, and B. S. Cummings. Wayne State University, Detroit, MI.

Background and Purpose: Organophosphate flame retardants (OPFRs) are widely used in consumer products as alternatives to brominated flame retardants (BFRs). Despite their increasing prevalence, the renal toxicity of OPFRs remains poorly understood. This study investigated the effects of select OPFRs—triphenyl phosphate (TPP), tris(2-ethylhexyl) phosphate (TEHP), tris(1,3-dichloro-2-propyl) phosphate (TDCPP), and tris(2-butoxyethyl) phosphate (TBEP)—on renal proximal tubule epithelial cells (RPTECs) by assessing viability, proliferation, wound repair, autophagy, and transcriptomics. **Methods:** Cell viability was assessed using MTT staining after 24 and 48 hours of OPFR exposure (5-100 μ M). Proliferation was measured by fluorescent DNA-binding dye across serial seeding densities following TPP and TEHP exposure (5 and 25 μ M). Wound healing capacity was evaluated using a scratch assay at 24 and 48 hours. Ki67 immunocytochemistry was used to assess cellular proliferation. Autophagy was examined via autophagy red staining, flow cytometry, and LC3-II immunoblotting. For transcriptomic analysis, migrating cells (those repopulating the denuded region) and non-migrating cells (those remaining after wound initiation) were harvested after DMSO or TEHP (5 μ M) treatment and processed for RNA-sequencing. **Results:** None of the OPFRs significantly decreased MTT staining at 24 or 48 hours; however, morphological alterations were observed at concentrations above 50 μ M after 48 hours. Both TPP and TEHP increased MTT staining and RPTEC number at concentrations below 25 μ M, consistent with enhanced proliferation at low seeding densities. TPP at 25 μ M inhibited wound closure in RPTEC cells, whereas TEHP enhanced wound closure after 48 hours. Ki67 staining was increased in cells located at the wound periphery following TEHP exposure, aligning with its pro-migratory phenotype. Additionally, TPP—but not TEHP—induced autophagy, as indicated by autophagy staining, flow cytometry, and elevated LC3-II levels. RNA-sequencing of migrating versus non-migrating RPTECs exposed to TEHP identified 206 upregulated and 107 downregulated genes, with enriched KEGG pathways that included cell cycle, lysosomal processes, DNA replication, and metabolic and DNA repair pathways, indicating a TEHP-driven transcriptional program supporting migration and proliferation. **Conclusions:** These findings show that OPFRs caused distinct, compound-specific effects on RPTEC growth and repair. TEHP promoted proliferation and migration, whereas TPP hindered wound repair through autophagy induction.

PS 3040 Multiple doses of elesclomol-copper is beneficial and does not trigger cuproptosis in a mouse model of Menkes disease

K. P. Maremanda^{1,2}, and V. M. Gohil¹. ¹Texas A&M University, College Station, TX; and ²University of Oklahoma, Oklahoma City, OK.

Background and Purpose: Menkes disease is an X-linked disorder of copper (Cu) deficiency, caused by loss-of-function mutations in the Cu transporter ATP7A. The disease is characterized by progressive neurodegeneration and connective tissue defects, with death occurring at three years of age. Currently, no FDA-approved drug is available for the treatment of this fatal pediatric disease. We recently discovered that an investigational chemotherapy drug, elesclomol (ES), when complexed with Cu (ES-Cu), rescues Cu deficiency, activates cuproenzymes, and prevents perinatal lethality in a *mottled-brindled* (*mo-br*) mouse model of Menkes disease. We showed that a mere two doses of ES-Cu can rescue *mo-br* mice from early mortality; however, within a few months of life, the Cu deficiency remains visible, as reflected by the decrease in Cu-dependent proteins, such as COX1, in the mitochondria. **Methods:** The current study was conducted to evaluate the feasibility of administering extra doses of ES-Cu at later stages of life to correct Cu deficiency without causing unwanted toxic effects. To evaluate this we have used mottled-brindled (*mo-br*) mouse model of Menkes disease. **Results:** Here, we report that multiple ES-Cu doses in *mo-br* mice, at various stages of growth, are beneficial in preserving the mitochondrial COX1 without triggering cuproptosis. **Conclusions:** Our results support the concept of repurposing ES for the treatment of Cu deficiency disorders.

PS 3041 Assay-Dependent Artifactual Prolongation of Activated Partial Thromboplastin Time (APTT) Observed in Cynomolgus Monkeys

K. Ishida¹, R. Boyer¹, G. de Hart¹, S. Brennan¹, P. Chitiyala¹, E. Miller¹, C. Orciani², C. Cluzel², B. Hock¹, S. J. Zoon¹, and E. Koo¹. ¹BioMarin, San Rafael, CA; and ²Charles River Laboratories, Laval, QC, Canada.

Background and Purpose: This study characterizes an assay-dependent, artifactual prolongation of activated partial thromboplastin time (APTT) observed in nonclinical safety studies of a polymer-conjugated enzyme biologic in cynomolgus monkeys. **Methods:** Two 8- and 13-week repeat-dose toxicology studies were conducted in cynomolgus monkeys. The animals received subcutaneous injections twice weekly. Study endpoints included pharmacokinetic/toxicokinetic (PK/TK) and pharmacodynamic (PD) assessments, clinical observations, body weight, clinical pathology, gross and histopathology. The 8-week study utilized a single silica-based APTT assay, whereas the 13-week study employed both silica- and kaolin-based assays. Additional *ex vivo* APTT assays were performed using plasma from naïve cynomolgus monkeys spiked with either the full biologic or the conjugated polymer. **Results:** In the 8-week study, a time- and dose-dependent prolongation of APTT was observed using the silica-based assay at Weeks 4 and 8. PK/PD effects were prominent during the first two weeks but diminished thereafter, likely due to immunogenicity, and did not correlate with APTT prolongation. No abnormalities were observed in other coagulation parameters (e.g., prothrombin time, fibrinogen), nor were there histopathological findings indicative of bleeding or coagulopathy. *Ex vivo* spiking of plasma with the biologic or polymer did not result in APTT prolongation. In the 13-week study, APTT prolongation was again observed only with the silica-based assay, while the kaolin-based assay showed no such effect. **Conclusions:** The APTT prolongation observed was specific to the silica-based assay and was not associated with any clinical or pathological evidence of hemorrhage or coagulopathy. These findings support the conclusion that the APTT changes were assay-dependent artifacts related to the silica activator, rather than true pharmacologic or toxicologic effects.

PS 3042 From Monospecific to Bispecific: Comparative Safety of T-Cell Engagers and Dual-Receptor BsAbs Versus Monospecific Agents Using Clinical Outcomes and FAERS Data

A. Nielsen¹, D. Thomas¹, and O. Barبران². ¹Elsevier, Inc., San Diego, CA; and ²Elsevier, Inc., Amsterdam, Netherlands. Sponsor: D. Thomas, International Society for the Study of Xenobiotics

Background and Purpose: **Background:** The shift from monospecific monoclonal antibodies (mAbs) to bispecific monoclonal antibodies (BsAbs) enables simultaneous engagement of two targets, allowing immune cell redirection or dual-pathway blockade. This mechanistic versatility can enhance therapeutic efficacy and overcome resistance, but it introduces unique safety challenges distinct from those of mAbs. The ability to engage two antigens drives both enhanced potency and complex adverse event (AE) profiles. As of September 2025, PharmaPendium lists 18 BsAbs approved in Europe and the United States, spanning two mechanistic classes: T-cell engagers (TCEs) and dual-receptor modulators. BsAbs range from Bi-specific T-cell engager (BiTE)-like fragments to full IgG-like constructs. This study compares the safety of TCEs and dual-receptor BsAbs against monospecific antibodies targeting similar antigens, integrating clinical regulatory and postmarketing safety data. **Methods:** Clinical data from PharmaPendium were analyzed using the *Tox Navigator* (developed in collaboration with Pfizer) to extract structured toxicity information for both monospecific and bispecific monoclonal antibodies. Postmarketing data from

the FDA Adverse Event Reporting System (FAERS) were evaluated for real-world safety signals and disproportionality. Clinical outcomes were aligned with FAERS data to triangulate safety trends. BsAbs were classified as (1) T-cell-engaging BsAbs (TCEs) or (2) dual-receptor BsAbs that modulate two signaling pathways without direct T-cell engagement. Monospecific comparators targeting the same antigens were included to enable mechanism-based safety contrasts. Adverse drug reactions (ADRs) were mapped to MedDRA terminology and aggregated by System Organ Class (SOC) and preferred terms. Endpoints included cytokine release syndrome (CRS), neurotoxicity/ICANS, cytopenias, infections, hepatic and renal dysfunction, cardiovascular events, and ocular or dermatologic toxicities. Descriptive statistics by mechanistic class, molecular format (BiTE-like vs IgG-like), target, indication, and line of therapy were applied to identify and interpret safety signals. **Results:** Integrated analyses using *Tox Navigator* revealed mechanism-consistent and class-specific safety profiles. For TCEs, safety signals aligned with T-cell-mediated toxicities, including higher frequencies of CRS and immune effector cell-associated neurotoxicity syndrome (ICANS) compared with monospecific antibodies targeting the same antigens. Cytopenia and infections were frequent, varying by timing and treatment line. Dual-receptor BsAbs exhibited safety profiles consistent with dual-pathway modulation, including overlapping toxicities such as hepatic enzyme elevations, edema, and hypertension, along with class-related cytopenias and infections. Integration of FAERS and clinical data strengthened the detection of mechanism-driven AE patterns, distinguishing inflammatory versus dual-pathway safety liabilities. **Conclusions:** This integrated framework demonstrates that TCEs exhibit inflammatory toxicity patterns (CRS, ICANS), while dual-receptor BsAbs present broader but overlapping adverse events linked to dual-target blockade. Triangulation of clinical and postmarketing data provides translational insight into mechanistic toxicities and informs risk mitigation strategies such as antibody design optimization, dose modulation, premedication, and patient monitoring. Leveraging structured datasets via the *Tox Navigator* supports evidence-based risk assessment to guide safer development and clinical use of next-generation bispecific antibodies.

PS 3043 Corrosive Exposures in Clinical Toxicology: Poison Prevention Strategies for Hydrofluoric Acid

T. Dodd-Butera¹, and H. Li². ¹Azusa Pacific University, Azusa (San Diego Regional Campus), CA; and ²Azusa Pacific University, Azusa, CA.

Background and Purpose: Both acids and bases can exert corrosive tissue effects through routes of ingestion, inhalation, dermal, and optic exposures. As with other toxic exposures, symptoms may be related to dose, route, and individual characteristics. Hydrofluoric (HF) acid is an inorganic acid and dehydrating agent that is used for industrial and automotive purposes. HF is used in metal processing and glass etching and can be found in rust removers and cleaners. The purpose of this study is to examine HF exposure and describe poison prevention strategies. **Methods:** Using the National Poison Data System (NPDS) annual reports from poison control centers in the United States (years 2018 to 2023), HF poisoning exposures and fatalities were reviewed and described. In addition, accident reports from the Occupational Safety and Health Administration (OSHA) for HF were reviewed (years 2018 to 2021). Poison prevention information was accessed from Health Resources & Services Administration (HRSA) Poison Help and the National Capital Poison Center. **Results:** During the 6 years of NPDS reports, HF exposures were reported either as a chemical acid ($N = 3,085$), or a household cleaning substance in wheel cleaners ($N = 227$) or rust removers ($N = 1,184$). Most of the HF exposures were for populations 20 years and older, 83.92%, 73.13%, and 60.6%, for the three sources, respectively. Overall, 96.92% of exposures to HF as a chemical acid and 95.15% of exposures to HF through wheel cleaners were unintentional. In contrast, only 76.44% of HF exposures through rust removers were reported as unintentional. NPDS reported HF-related fatalities steadily decreased from 2018 ($N = 5$), 2019 ($N = 2$), 2020 ($N = 2$), 2021 ($N = 1$), 2022 ($N = 1$), to 2023 ($N = 1$). Based on the OSHA Accident Reports for industrial exposures for HF (2018-2021), 11 cases were reported, including one fatality. Two cases were reported in 2018, six cases in 2019, one case in 2020, and two cases in 2021. Descriptions of these exposure cases included chemical burns, illness from inhalation, splash injuries to skin and face, injuries from an arc flash in an electrical panel, and death from falling into industrial paint remover. **Conclusions:** HF exposure was documented in chemical acids, wheel cleaners, and rust removers from annual and accident reports of the NPDS and OSHA, respectively. Unintentional exposures dominated the intent of exposures, with variations in site and routes of exposure. Due to the significant adverse health outcomes from exposure, including fatalities, preventive measures should be emphasized, reviewed, and implemented routinely with product use. In order to limit toxic exposures and promote proper handling for safe usage, consistent practices for poison prevention should include the following: keeping products in original containers, with proper labelling; placing products in locked cabinets, and away from children and cognitively disabled persons; providing appropriate protective equipment and environmental conditions in occupational settings; and accessing available resources from the Poison helpline, America's Poison Centers, and HRSA Poison Help Prevention Tips. With continuing preventative and educational efforts in both community and workplace settings, residential and occupational risks of HF exposure can be mitigated.

K. Oberoi. Clarivate, Ann Arbor, MI. Sponsor: R. Tanguay

Background and Purpose: A significant portion of disease-relevant proteins remain “undruggable” by traditional therapeutic approaches, representing a major hurdle in drug discovery. Targeted protein degradation (TPD) is rapidly advancing as a strategy to overcome this challenge, enabling the selective elimination of previously inaccessible proteins. Protein degraders have potential safety benefits due to their targeted nature but also pose risks like long-lasting toxicity from prolonged degradation and off-target effects. Pre-clinical safety data for TPD is limited due to a combination of their novel mechanism, structural complexity and evolving evaluation framework. Loss-of-Function (LoF) variants could be used as analogues to the effects of TPDs to reveal long-term consequences of reduced or absent protein function. Similarly, Knockout (KO) models especially humanized versions are playing a crucial role in anticipating and evaluating potential toxicities associated with targeted protein degraders (TPDs) such as PROTACs and molecular glues. This systematic review of literature, conferences, clinical trials, pathway maps compare the safety and selectivity of clinical TPDs against pharmacological inhibitor, as well as reported LoF and KO models. **Methods:** Meta-analysis of TPDs in development from clinical to pre-registration using Cortellis Drug Discovery Intelligence (CDDI) and OFF-X Safety Intelligence. CDDI incorporates information from journals, conferences, patents, press releases, regulatory agencies and company websites on the scientific development of drugs and targets from biological testing to launch. OFF-X monitors all adverse events (AEs) from pre-clinical, clinical and post-marketing studies from regulatory agencies, biomedical literature, congresses and scientific conferences, major clinical trial registries, company communications and pharmacovigilance databases (i.e. FAERS, JADER). To assess the potential of degraders as an alternative technology for target modulation, we utilized these databases to compare the safety profile of degraders that are in late clinical phases with traditional inhibitors and reported LoF and KO models. **Results:** There are currently 12 TPDs that were included in this analysis, four of them are in Phase 2, seven in Phase 3 and one Pre-registered. Common targets for these degraders are androgen receptor (AR), IKAROS family and Bruton tyrosine Kinase (BTK). Commonly observed safety issues across all the compared degraders included hematologic, gastrointestinal and skin disorders. Both BTK degraders and inhibitors show infections and vascular and cardiac disorders as common issues. AR pharmacologic inhibition and degradation, commonly manifests systemic gastrointestinal, metabolic and cardiovascular risk. However, no signs of hepatotoxicity have been identified with any of these degraders yet, in line with the preclinical data that has been reported for BTK and AR degraders. **Conclusions:** Observed safety issues are not unique to TPDs but are particularly relevant due to their potent and irreversible mechanism of degrading target proteins. When BTK is degraded or inhibited, it disrupts several critical immune pathways-this leads to an increased risk of infections, such as upper respiratory tract infections (URTIs). Loss of BTK function, such as in X-linked agammaglobulinemia, was also linked to increasing susceptibility to infections. AR is a systemic regulator of metabolism, cardiovascular health, and tissue homeostasis. Disrupting these pathways, potentially is leading to a cascade of metabolic, cardiovascular, and GI symptoms. TPDs that degrade transcription factors like Ikaros, which are key regulators of lymphocyte development and immune homeostasis can lead to hematologic toxicity like neutropenia and thrombocytopenia. Preclinical toxicology studies with degraders need to be designed with the aim to anticipate potential safety liabilities, including those identified with pharmacology inhibitors, to de-risk development programs. To do so, individual target evaluation, considering context-specific biology, genetics and pharmacology need to be considered to help identify mechanistic toxicity drivers.

PS 3045 Cigarette Smoking, Cytokines, and Immune Evasion in Lung Cancer

M. Shabrang, J. Akulian, and B. Vincent. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Background and Purpose: Cigarette smoking introduces a complex mixture of toxicants into the airways and remains the leading cause of lung cancer, while also contributing to the development of several other malignancies. A recent study indicates that roughly 25% of cancer patients are active smokers when diagnosed, and up to 58% maintain smoking behavior during therapy. Malignant pleural effusion (MPE) is a common complication of advanced cancers, especially lung cancer. Research indicates that crosstalk between tumor cells and the immune system contributes to the development of MPE, establishing a unique tumor microenvironment (TME) enriched in immune cells. In our preliminary studies using a personalized immunotherapy approach on an NSCLC patient from the UNC-Chapel Hill’s Carolina Center for Pleural Diseases (CCPD) biobank, we detected antigen-specific CD8⁺ T cell populations in the patient’s MPE. However, despite their presence, effective intrapleural anti-tumor immunity was not achieved, suggesting that factors within the MPE microenvironment may actively suppress CD8⁺ T cell function or impair their cytotoxic potential. A few studies describe overall elevation of immunosuppressive cytokines in pleural fluid of lung cancer patients but do not differentiate between smokers and non-smokers. Evidence from recent research suggests that, smokers exhibit significantly higher levels of pro-inflammatory cytokines in blood serum compared to non-smokers. Therefore, we sought to determine whether cigarette smoking similarly influences the cytokine profile and the immunosuppressive mechanisms within the MPE microenvironment. **Methods:** This study utilized

matched MPE fluid and plasma samples from lung cancer patients categorized as cigarette smokers or non-smokers. To examine whether smoking similarly influences the cytokine landscape in other cancers, we also obtained matched MPE fluid and plasma samples from breast cancer patients, who were likewise categorized as smokers or non-smokers. Using a Human Immune Response Panel, we quantified the levels of different cytokines, chemokines, and growth factors in matched MPE fluid and plasma samples to comprehensively profile the immune landscape and identify potential smoking-related alterations in immune signaling. **Results:** Across all MPE fluid samples analyzed, several cytokines—including IL-6, IL-10, and MCP-1 (MCAF), were consistently elevated, reflecting the inflammatory and immunosuppressive nature of the pleural tumor microenvironment. These cytokines are linked to immune regulation and T-cell suppression, such as IL-6 and IL-10 that showed the most pronounced variability between groups. These early findings suggest that MPE fluid has immunosuppressive cytokine milieu within the pleural space, potentially impairing effective anti-tumor immune responses. Ongoing analyses will expand this dataset to more comprehensively compare lung and breast cancer MPE samples between smokers and non-smokers and to better understand how smoking status influences the pleural immune landscape. **Conclusions:** Our preliminary findings reveal a distinctly immunosuppressive cytokine milieu within the MPE microenvironment, which is highly intriguing and may help explain the limited effectiveness of local anti-tumor immunity. These observations warrant deeper investigation across smoking histories and cancer types to define key immune-regulatory pathways. Understanding how cigarette smoke alters cytokine signaling within the pleural space in cancer patients, provides critical insight into the immunotoxic mechanisms driving cancer progression and impaired immune surveillance.

PS 3046 A second generation PFAS, GenX, Induces Astrocytic Activation and Metabolic Defects

A. Abu Salah¹, N. Boonpraman², D. Kim², I. Mhatre-Winters³, Y. Han³, P. Reina-Gonzalez¹, A. Anchan¹, J. R. Richardson³, S. R. Sammi², and S. Sarkar¹. ¹University of Rochester, Rochester, NY; ²Michigan State University, Michigan, MI; and ³University of Georgia, Athens, GA.

Background and Purpose: Per/polyfluoroalkyl substances (PFAS) are a group of anthropogenic chemicals, characterized by a strong carbon-fluorine bond. Owing to extensive usage in industrial and consumer products such as firefighting foams, water or stain repellents, etc., and their resistance to breakdown, PFAS are persistent in the environment, and have been detected in over 98% of the USA. Use of some PFAS, such as perfluorooctanesulfonate (PFOS) and perfluorooctanoic acid (PFOA), was discontinued in 2000, and as such, these are referred to as “legacy PFAS.” Over time, legacy PFAS have been replaced by newer (so-called ‘second generation’ or emergent) PFAS, which often have shorter chain length; however, their safety to human health and the environment is still questionable. Emergent PFAS such as GenX (Ammonium perfluoro(2-methyl-3-oxahexanoate)), also known as (HFPO-DA), was synthesized in 2009 to replace the legacy PFAS, PFOA. **Methods:** Using an iPSC-derived blood-brain barrier (BBB) model, we demonstrated that GenX readily crossed the barrier. Further, rodents exposed to GenX showed that GenX was present in mouse cortex, where it induced pronounced astrogliosis (GFAP⁺), suggesting that GenX can induce astrocytic activation. To understand the effect of GenX on glial cells, we treated astrocytic and microglial cell lines with GenX. Interestingly, GenX reduced metabolic activity and ATP production in human astrocytes, but not in microglia, indicating cell-type-specific toxicity. Mitochondrial impairment manifested as decreased basal respiration and ATP production, accompanied by A1-like astrocytic activation (C3⁺, IL-6⁺) and senescence markers (γH2AX⁺, p53⁺), phenotypes associated with neurodegeneration. **Results:** Mechanistically, PFAS have been linked to lipid dysregulation in humans. Apolipoprotein E4 (APOE4) is the primary genetic risk for sporadic AD and is expressed in ~40-65% of AD patients. Apolipoprotein E is involved in neuronal proliferation, synapse formation, and myelination, affecting cellular functions such as inflammation. Astrocytes are the main source of APOE in the brain and are also involved in lipid metabolism. GenX exposure caused marked mitochondrial dysfunction and IL-6 up-regulation in primary astrocytes from humanized APOE4, but not APOE3 mice, implicating a strong gene-environment interaction between GenX and ApoE. **Conclusions:** In summary, GenX acts as an astrocyte-specific neurotoxicant that perturbs mitochondrial metabolism, driving inflammatory and senescent phenotypes. This toxicity is strongly amplified by the APOE4 genotype, providing an interaction between environmental PFAS exposure and genetic risk factor. These findings establish a framework for evaluating emerging PFAS in the context of gene-environment interactions underlying brain aging.

PS 3047 First clinical case of N-pyrrolidino protonitazene intoxication in Brazil: detection and quantification in serum by micro-QuEChERS and LC-MS/MS

K. de Oliveira Souza, R. Lanaro, L. Costalonga Rodrigues, and J. da Costa. Universidade Estadual de Campinas, Campinas, Brazil.

Background and Purpose: Nitazenes are a class of novel synthetic opioids derived from 2-benzylbenzimidazole, several of which display potencies greater than fentanyl, raising significant concerns for public health. Their rapid emergence in

global drug markets poses a major challenge to forensic and clinical toxicology laboratories. *N*-pyrrolidino protonitazene is among the most recent nitazene analogues associated with severe opioid toxicity. In 2025, the first clinical case of *N*-pyrrolidino protonitazene intoxication was confirmed in Brazil, prompting a national alert. This study describes the analytical detection and quantification of *N*-pyrrolidino protonitazene in human serum using a micro-QuEChERS extraction procedure coupled to a liquid chromatography-tandem mass spectrometry (LC-MS/MS) system and reports the associated clinical manifestations. **Methods:** Serum aliquot (100 μ L) was extracted using a micro-QuEChERS approach. The sample was mixed with 400 μ L of acetonitrile and 100 mg of partitioning salts (NaAc:MgSO₄, 1:4 w/w), vortexed for 5 minutes (2500 rpm), and centrifuged for 5 minutes (14000 rpm). The supernatant was collected and evaporated under a nitrogen stream for 10 minutes at 40 °C. Finally, the content was reconstituted using 100 μ L of methanol. A 5 μ L aliquot was injected into an LC-MS/MS system operating in positive electrospray ionization (ESI) mode. Separation was performed with a C18 column (50 mm $\times$ 3 mm, 2.6 μ m) using gradient elution with 0.1% formic acid and 2 mM ammonium formate both in water (mobile phase A) and methanol (mobile phase B). Detection was performed in multiple reaction monitoring (MRM) mode using a certified *N*-pyrrolidino protonitazene reference standard. The estimated limit of detection was 0.025 ng/mL and the limit of quantification 0.05 ng/mL. **Results:** *N*-pyrrolidino protonitazene was detected and quantified in the patient's serum at 1.37 ng/mL. The patient had reportedly the consumption of an alcoholic beverage and one tablet before developing symptoms of severe opioid intoxication, including marked somnolence, miosis, apnea, oxygen saturation of 30%, and a Glasgow Coma Scale score of 3, indicating profound central nervous system depression. Administration of three ampoules of naloxone was required to reverse respiratory failure. Additional compounds identified in the toxicological screening included MDA, dipentylone, pentylone, ethanol, and nicotine, suggesting polydrug exposure. **Conclusions:** This case represents the first confirmed clinical detection of *N*-pyrrolidino protonitazene in Brazil. The combination of micro-QuEChERS extraction and LC-MS/MS provided an efficient and sensitive approach for detecting highly potent synthetic opioids at trace levels. The clinical course, requiring multiple naloxone administrations, highlights the pharmacological potency and toxicological risk of nitazenes. These findings were promptly communicated to the Brazilian Rapid Alert System on Drugs, contributing to the inclusion of *N*-pyrrolidino protonitazene in the national list of controlled substances. This case underscores the need for analytical vigilance and continuous monitoring of emerging synthetic opioids in forensic and clinical settings.

PS 3048 *In silico*-driven mechanistic insights into the increased sensitivity of canines to drug-induced seizures in nonclinical safety studies

L. Talecki, A. Mogas Barcons, J. Ferguson, Z. Farooq, H. Dixon, S. Tomlinson, L. Zolkiewski, K. Rockley, M. Morton, and R. Roberts. ApconIX, Alderly Edge, Cheshire, United Kingdom.

Background and Purpose: Drug-induced seizures are serious adverse events for which adequate nonclinical testing is crucial. The translatability of drug-induced seizures in canine toxicology studies is being questioned due to neurological findings at low exposures in beagle dogs which are not observed in other standard toxicology species. The lack of mechanistic and physiologic understanding behind this outcome compromises the safety window for predicted human exposure and can lead to clinical hold or attrition. Our objective was to investigate whether there are differences in ion channel function and/or expression that explain the increased sensitivity to seizure observed in dog. **Methods:** We have previously identified and characterized a panel of 15 human ion channels involved in seizure liability using *in vitro* electrophysiology (Na_v1.1, Na_v1.2, Na_v1.6, K_v1.1, K_v2.1, K_v3.1, K_v4.2, K_{Ca}1.1, K_{Ca}4.1, K_v7.2/7.3, K_v7.3/7.5, GABA α ₁ β ₂ γ ₂, NMDA 1/2A, nicotinic α ₄ β ₂, and Ca_v2.1). In the current study, we have used a suite of computational approaches to generate alignments of human versus dog protein sequences and analyze the differences in amino acids. We identified sites of drug- or ligand- binding, sites of known epilepsy mutations, residues with post-translational modifications, variants located in or near functional domains, and nonconservative amino acid changes. Based on these parameters, the canine ion channels were prioritized from highest to lowest interest for further investigation. Preliminary transcriptomic analysis of seizure-associated ion channels and their auxiliary subunits revealed their absolute gene expression levels across multiple CNS regions in humans versus dogs. **Results:** Our data indicated that the nicotinic α ₄ β ₂, K_v7.2/7.3, Ca_v2.1, K_v7.3/7.5, GABA α ₁ β ₂ γ ₂, and NMDA 1/2A channels were of highest interest after the sequence alignment analysis. Examples of the findings include the following: the nicotinic α ₄ β ₂ channel had the lowest sequence homology (89.75%) between humans and dogs and the lowest number of conserved residues at phosphorylation sites, ligand-binding and functional domains. K_v7.2/7.3 had the highest number of altered residues at pathogenic/likely pathogenic sites identified in UniProt. GABA α ₁ β ₂ γ ₂ had the lowest Blosum score (-1.0) of all the channels, meaning that its amino acid changes were on average the most unlikely to occur by chance. Expression level differences were examined in seizure- and ataxia-relevant tissues - cerebellum and spinal cord. Initial investigations of transcriptomic data showed no notable differences in spinal cord. Cerebellar expression was more varied, with human cerebellum showing the greatest increases in KCNQ2 and CACNA1A expression compared to dogs. **Conclusions:** Our initial findings provide insights into the complex question of increased seizure liability in canine toxicology by highlighting inherent differences in ion channel sequence

and expression level between dogs and humans. Next steps will be to generate cell lines expressing the relevant canine ion channels to assess relative sensitivity via automated patch clamp electrophysiology.

PS 3049 Screening Novel Radioprotective Compounds for Salivary Glands Using Microbubble Chip Array

R. Kato¹, C. Y. Chen², J. Mereness¹, and L. DeLouise¹. ¹University of Rochester School of Medicine and Dentistry, Rochester, NY; and ²University of Rochester, Rochester, NY.

Background and Purpose: Head and neck cancers (HNCs) are a group of malignancies accounting for approximately 900,000 new cases and over 400,000 deaths annually. According to the World Health Organization (WHO), HNCs are the 7th most common cancer globally. Currently, the most effective cytotoxic therapy for localized solid tumors is ionizing radiation (IR). However, this approach comes at a cost with 80% of patients experiencing some degree of salivary gland damage or permanent loss of secretory function as an off-target effect. This dysfunction decreases the production of saliva and increases the risk for infection, difficulty speaking, eating, or swallowing, which ultimately lowers quality of life. Amifostine is an antioxidant drug and the only FDA approved radioprotective compound used for clinical indications against IR therapy. This compound however, has a myriad of limitations including high doses, short half-life (~15min), high toxicity, severe side effects and low efficacy. For these reasons, its use is often not recommended. Thus, there is a critical unmet need to develop a new radioprotective compounds which will decrease the severity of off-target radiation injury. Discovery of new drugs has however, been hindered by the lack of functional salivary gland tissue models. Recently, the DeLouise lab pioneered the development of the first ever functional 3D salivary gland tissue chip array platform which was used successfully to conduct high-content screening of a Selleck Chemicals library. This screen identified 7 non-antioxidant top hits, three of which were validated in a murine model. This project seeks to investigate analogs of these hits to investigate structure function relationships, to develop more potent drugs and provide insight into their mechanism of action. **Methods:** Female SKH1 hairless mice backcrossed 6 generations with C57BL/6J mice, aged 6-12 weeks were used in this study. Only female mice were used due to known sex differences in rodent salivary glands, with female glands more accurately emulating human salivary gland structure and function. Primary murine submandibular gland cells were isolated and introduced into the salivary gland tissue chip and irradiated at 15Gy. Injury response to IR was quantified using the reduced glutathione and cell senescence assays that were developed to conduct the initial radioprotective drug screen. The established protocol was followed by conducting the glutathione assay first. Hits that showed indistinguishable radioprotection from 0 Gy controls were then tested with the senescence assay. Drug analogs were screened at 10 μ M. **Results:** In this study, drug analogs of enoxacin (fluoroquinolone antibiotic) and doripenem (carbapenem antibiotic) were tested. Structural analogs were selected primarily from the fluoroquinolone class, with the C=N 8-azaquinoline core that seems to be essential for enoxacin's radioprotective activity. In total 24 analogs were tested and 13 showed higher levels of reduced glutathione levels indicating some radioprotection. **Conclusions:** These preliminary results indicate that fluoroquinolone and carbapenem antibiotics exhibit radioprotective properties in the tissue chip and in preclinical models. On-going studies will seek to test the senescence (β -galactosidase) levels upon IR exposure to confirm radioprotection of the 13 additional hits. Moreover, understanding radioprotective mechanisms of antibiotics compounds is critical for clinical translation of these novel compounds that can have a significantly benefit to HNC patients

PS 3050 Dual roles of the Ah receptor (AHR) ligand 6-Formylindolo[3,2-b]carbazole (FICZ) in the induction of pulmonary cytochrome P450 (CYP)1A1 by hyperoxia, and the attenuation of hyperoxic lung injury in mice *In Vivo*

B. Moorthy, D. Narke, L. Wang, C. Chu, and W. Jiang. Baylor College of Medicine, Houston, TX.

Background and Purpose: Supplemental oxygen administration is frequently encountered in infants and adults with pulmonary insufficiency. Hyperoxia causes lung injury in experimental animals, and contributes to acute respiratory distress syndrome (ARDS) in adults and to bronchopulmonary dysplasia (BPD) in premature infants. In this investigation, we tested the hypotheses that (i) hyperoxia induces CYP1A1 via the formation of 6-Formylindolo[3,2-b]carbazole (FICZ), an endogenous ligand for the Ah receptor (AHR; and (ii) FICZ would attenuate hyperoxic lung injury *in vivo*. **Methods:** Adult (10 week old) wild type (WT) mice were maintained in room air or exposed to hyperoxia (> 95% O₂) for 6-48 h, and lungs were analyzed for the formation of FICZ. In a second set of experiments, WT mice were treated with FICZ (2 mg/kg), i.p., once daily for 3 days, and the animals were maintained in room air or exposed to hyperoxia (> 95% O₂) for 72 h, and lung injury was determined by histology. In a third set of experiments, WT, *Cyp1a1*-null, *Cyp1a2*-null, *Cyp1b1*-null, *Cyp1a1/1a2*-double null, *Cyp1a1/1a2/1b1* triple null, and AHR-null mice were treated with FICZ (2 mg/kg), i.p., and FICZ levels were measured in lung and liver. **Results:** FICZ was detected in mouse lungs exposed to hyperoxia at 6 h, but not at later

time points, as revealed by LC-MS/MS experiments. Further mechanistic studies showed formation of FICZ from tryptophan in the presence of Fe²⁺ and H₂O₂ *in vitro*, and also in H358 cells exposed to hyperoxia (80% O₂; 8 h). FICZ was detected *in vivo* in mouse lungs exposed to hyperoxia at 6 h, but not at later time points, as revealed by LC-MS/MS experiments. FICZ significantly upregulated CYP1A1 and CYP1B1 in lung and liver and CYP1A2 in liver at the mRNA, protein, and enzyme levels. Hyperoxia caused significant lung injury and inflammation as determined by increased lung weight/body weight (LW/BW) ratios and histology and neutrophil recruitment. FICZ treatment significantly suppressed lung injury mediated by hyperoxia. FICZ was detected in all types of mice, but the levels were significantly higher in *Cyp1a1*-null, *Cyp1a1/1a2*-double null, *Cyp1a1/1a2/1b1*-triple null, and AHR-null, with FICZ being the highest in AHR-null mice. These results suggest that CYP1A1, 1A2, and 1B1 play an important, differential role in the metabolic degradation of FICZ *in vivo*. **Conclusions:** Our results demonstrate (i) novel role of FICZ in the induction of CYP1A1 by hyperoxia via the AHR; (ii) protection against hyperoxic lung injury by FICZ; and (iii) role of CYP1A1, 1A2, 1B1, and AHR-mediated mechanisms in the metabolism of FICZ *in vivo*. Further studies could lead to the development of novel AHR agonists in the prevention/treatment of ARDS and BPD in humans.

PS 3051 Advanced 3D iPSC-derived cardiac model for improved drug-induced cardiotoxicity assessment

S. Swamy¹, S. Dhepe¹, A. R. Ribeiro², M. Seguret², K. Rajendran¹, A. Khedher², C. Cerveau², P. Bhanushali¹, A. Khanna¹, and V. Pitke¹. ¹Yashraj Biotechnology Ltd, Navi Mumbai, India; and ²4DCell, Montreuil, France.

Background and Purpose: Cardiotoxicity is a leading cause of drug attrition during development, largely due to the poor predictive capacity of traditional 2D *in vitro* models. To address this unmet need, we employed the SmartHeart® technology platform to generate a 3D co-culture system combining iPSC-derived cardiomyocytes (YBLiCardio) and human cardiac fibroblasts, which more closely mimics the *in vivo* cardiac microenvironment and enhances prediction of drug-induced toxicity. **Methods:** Cardiac fibroblasts and iPSC-derived cardiomyocytes cells were seeded on 4D plates at a 75:25 cardiomyocyte:fibroblast ratio, yielding 85,000 cells/well. Cultures were maintained for seven days before performing the experiments. Downstream analyses included microscopy, live cell imaging, flow cytometry, qPCR, calcium flux, immunocytochemistry, and western blot for cardiac markers. Cardiotoxicity drugs with known like Disopyramide, Quinidine, Nifedipine, Ibutilide, Vandetanib, Azimilide, and Bepridil—were tested and compared for toxicity in the 2D and 3D model. **Results:** Preliminary results indicate robust formation of 3D cardiac rings with viable contractile activity. Imaging and flow cytometry confirmed successful co-culture and differentiation, with cardiac markers expressed as per expected profiles. Calcium flux assays demonstrated functional responsiveness, and molecular profiles (qPCR, ICC) supported enhanced maturation and cell-cell interaction in 3D compared to 2D. Drug exposure studies revealed differential sensitivity and toxicity profiles in the 3D model. Preliminary data suggests improved predictive sensitivity of the 3D model over traditional 2D assays. **Conclusions:** The SmartHeart® technology enables the generation of complex 3D cardiac co-cultures using iPSC-derived cardiomyocytes (YBLiCardio) and human ventricular fibroblasts, substantially improving the accuracy and sensitivity of *in vitro* cardiotoxicity prediction. This approach offers a translationally relevant alternative to conventional 2D screening methods and paves the way for improved risk stratification of drugs early in the development process.

PS 3052 Investigation of the application of Hemoglobind™ to improve detection of nitrate in hemolyzed ocular fluid samples

L. Mejia-Garcia, and C. Wilson-Frank. Purdue University, West Lafayette, IN.

Background and Purpose: Nitrate toxicosis, characterized by an excess of nitrate intake, can cause significant health risks in both animals and humans. In animals, especially ruminants such as cattle, high nitrate levels can cause methemoglobinemia. This disease is characterized by its reduction in hemoglobin's oxygen-carrying abilities. This leads to respiratory distress and in severe cases death. Although ruminant animals are more susceptible to nitrate-induced methemoglobinemia, these conditions can still have dire effects on humans. In humans, specifically infants under six months, this condition is commonly known as "blue baby syndrome." The lack of oxygen in blood results in a bluish tint to the skin, especially around the eyes and mouth. If left untreated, this condition can be life-threatening. Currently testing for nitrate toxicosis in ruminants involves the use of post-mortem ocular fluid and a color-based semi-quantitative test in the form of strips. Due to the nature of this testing method the presence of high levels of hemoglobin in the samples renders inconclusive results. The post-mortem ocular fluid samples extracted can be hemolyzed, impeding the detection of nitrate. **Methods:** This study focuses on a new method to reduce the degree of hemolysis in post-mortem ocular fluid samples therefore improving the ability to test for nitrate toxicosis. A series of tests were conducted to determine if the addition of Hemoglobind™ interferes with the detect of nitrate. The study was conducted using EM Quant® Nitrate Ion Specific Test Strips, quality control samples of known concentrations of nitrate up to 100 ppm, and samples with Hemoglobind™. These were then compared using the nitrate testing strips. The procedure briefly involves one drop of ocular fluid and one drop of quality control

sample to individual strips and then incubated for approximately one minute. After incubation the strips are compared to the ppm values on the container to determine the concentration of nitrate present. After concluding that Hemoglobind™ does not interfere with the detection of nitrate, the experiment was conducted again to show repeatability. To determine the optimal ratio of ocular fluid to Hemoglobind™, a sample of ocular fluid was artificially hemolyzed and then ratios of 1 to 1, 1 to 2, and 1 to 3 were compared using the nitrate testing strips. An additional experiment was conducted using a series of 6 samples of ocular fluid in varying degrees of hemolysis to determine an optimized ratio of 1 to 2 (ocular fluid to Hemoglobind™). The last experiment conducted involved determining how much hemoglobin was removed from the ocular fluid samples using Hemoglobind™. **Results:** By utilizing Hemoglobind™ to reduce the degree of hemolysis in the samples, the detection of nitrate improved while not interfering with the detection of nitrate. Determining the percent deduction of hemoglobin was accomplished utilizing an indirect ELISA for bovine hemoglobin. A ratio of Hemoglobind™ to post-mortem ocular fluid of 2 to 1 decreases the hemoglobin levels in the ocular fluid by 45.45% to 69.07% depending on the degree of hemolysis. The higher concentration of Hemoglobind™ was shown to have no binding specificity for nitrate. **Conclusions:** This study provides a new method for improving detection of nitrate in hemolyzed ocular fluid samples in suspect cases of nitrate toxicosis.

PS 3053 Evaluation of Mutational Signatures in Rat Tumors Resulting from Chronic Inhalation Exposure to Vinyl Chloride

A. Thakar¹, K. Kanchi¹, A. Boone¹, A. Brooks¹, J. Li¹, T. Ton¹, R. Cortes¹, G. Roberts¹, R. Spurbeck², R. Sills¹, E. Tibaldi³, D. Mandrioli³, J. Li¹, and A. Pandiri¹. ¹The National Institute of Environmental Health Sciences, Durham, NC; ²Battelle, Columbus, OH; and ³Ramazzini Institute, Bologna, Italy. Sponsor: C. Rider

Background and Purpose: Vinyl chloride (VC), used to manufacture polyvinyl chloride, is a mutagen and an IARC Group 1 carcinogen linked to hepatic angiosarcoma and hepatocellular carcinoma in humans as well as in rodent models. Mutational signatures, composite patterns of somatic substitutions, can provide mechanistic insight and enable comparisons across tissues and species. The Catalogue of Somatic Mutations in Cancers (COSMIC) maintains an extensive repository of mutational signatures with established or hypothesized mechanistic bases across various cancers. Due to the inherent multifactorial nature of the human exposome, many signatures hold unresolved etiologies. Identification of mutational signatures attributable to vinyl chloride exposure is imperative for understanding carcinogenesis and advancing environmental health risk assessments related to this exposure. We hypothesized that VC-induced rat tumors harbor distinct mutational signatures relative to spontaneous tumors. **Methods:** We performed whole-exome sequencing (WES) of tumor-normal pairs (n=88) from archival (~50-year) ethanol-fixed paraffin-embedded Sprague Dawley rat tumors (hepatocellular carcinoma, hemangiosarcoma, mammary adenocarcinoma, neuroblastoma) resulting from chronic (2 years) exposure to vinyl chloride or from unexposed chamber controls, i.e. tumors arising spontaneously. Exome enriched libraries were generated using the Agilent SureSelect System and sequenced on Illumina NovaSeq. Data analysis followed a modified GATK pipeline (FastQC, BWA-MEM) with variant calling by Mutect2. Samples with <70% target coverage at 30X were excluded, leaving 32 tumors for analysis. SigProfilerExtractor v1.2.0 (rn6) was used to extract *de novo* SBS signatures. Spontaneous (n=8) and VC-exposed (n=24) cohorts were analyzed separately to assess group-specific patterns. **Results:** Signature extraction in the VC-exposed cohort of tumors identified SBS40a and SBS22a. SBS40a occurred in 11 out of 24 VC-exposed tumors, driven primarily by hemangiosarcomas (8 out of 14) with per-sample contributions >35% of total mutations in all positive cases. SBS22a occurred in 7 out of 24 VC tumors, and were distributed between tumor types (3 hemangiosarcomas, 2 mammary adenocarcinomas, 1 hepatocellular carcinoma, and 1 neuroblastoma) with per-sample contributions 10-16% of total mutations. In the spontaneous only extraction, neither signature was detected. When both cohorts were combined in one signature extraction, SBS40a was also assigned to 5 out of 8 spontaneous tumors and SBS22a to 1 spontaneous tumor. **Conclusions:** These findings suggest SBS40a as a possible signature correlated with VC exposure based on its frequency and magnitude in the VC-exposed tumor cohort, particularly in hemangiosarcomas, and its absence in the spontaneous only cohort. Because *de novo* signature extraction can be sensitive to group effects in small WES datasets, the SBS40a assignment to spontaneous tumors in the combined run is regarded as tentative pending confirmation. Ongoing work includes cross tool extraction with an orthogonal method to confirm results, per-sample refitting, and subgroup analyses by exposure status and tumor type to assess robustness. If validated, an SBS40a association could provide a genomic indicator of VC exposure with implications for toxicological mechanism and use in environmental risk assessment.

M. Ooka¹, J. Zhao¹, K. Hirota², T. Abe³, and M. Xia¹. ¹National Center for Advancing Translational Science, Rockville, MD; ²Tokyo Metropolitan University, Tokyo, Japan; and ³Tohoku Medical and Pharmaceutical University, Sendai, Japan.

Background and Purpose: Topoisomerase II (TOP2) targeting drugs are widely used in chemotherapy. Most TOP2 targeting drugs are TOP2 poisons that stabilize TOP2 on DNA, leading to a toxic intermediate known as TOP2-DNA cleavage complex (TOP2cc). Bisdioxopiperazine derivatives, such as ICRF193, act as catalytic inhibitors of TOP2 without inducing TOP2cc. Although ICRF193 has been extensively used as a research tool, it has not been approved for clinical use due to the lack of antineoplastic effects itself. Its unique catalytic inhibition profile suggests that it may serve as a potentiator or modulator when combined with other drugs. The goal of this study was to discover novel drug combinations that exploit catalytic inhibition of TOP2 for improved anticancer efficacy. **Methods:** A quantitative high-throughput screening assay was optimized for the combination of ICRF193 and a total of 2,678 compounds from the NCATS Pharmaceutical Collection (the NPC library). The NPC library was screened for cytotoxicity in the presence or absence of ICRF193 in human colon cancer cell lines (HCT116). Compounds showing a left-shifted concentration curve in the presence of ICRF193, indicative of potentiation, were selected for follow-up studies. Follow-up experiments included: (1) Cell viability assays to validate synergistic cytotoxicity, (2) DNA synthesis assays using 5-ethynyl-2'-deoxyuridine (EdU) incorporation to measure DNA replication inhibition, (3) γH2AX immunofluorescence to quantify DNA double-strand breaks, and (4) Flow cytometry for G₂/M cell-cycle arrest analysis. To assess if the compounds with similar structure have similar effect, the same experiments were performed with the clinically approved bisdioxopiperazine derivative, ICRF183, and outcomes were compared to those of ICRF193. **Results:** The primary screening identified four compounds, including etoposide, trametinib, mebendazole, and oxfendazole, that demonstrated increased cytotoxicity in the presence of ICRF193. Of these, only etoposide consistently showed strong synergistic effects with ICRF193 across all tested cell lines. In HCT116 cells, the IC₅₀ for etoposide was potentiated from 1.05 μM to 278 nM with 200 nM ICRF193. Similar shifts were observed in breast cancer cell lines, MCF7 and T47D. Although ICRF193 was expected to reduce the toxicity of TOP2 poisons, our results indicated the opposite effect at low concentrations. Further tests with higher concentrations of ICRF193 demonstrated suppression of etoposide toxicity, indicating a dual effect: enhancement of etoposide-induced toxicity at low concentrations (200 nM) and suppression at high concentrations (10 μM). Etoposide co-treatment with ICRF193 significantly enhanced γH2AX foci formation and G₂-phase accumulation, indicating increased DNA damage and checkpoint activation. Consistent with these results, EdU incorporation assay confirmed the potentiation for DNA synthesis inhibition by 200 nM ICRF193. Importantly, the similar potentiation was not observed with other TOP2 poisons, including teniposide, daunorubicin, idarubicin, or aclarubicin, suggesting a unique functional interaction between etoposide and ICRF193. We also found that ICRF183 enhanced etoposide-induced cytotoxicity. **Conclusions:** Through quantitative high-throughput combination screening, we identified a specific and reproducible synergistic interaction between the catalytic TOP2 inhibitors (ICRF193 and ICRF183) and the TOP2 poison (etoposide). At a few hundred nanomolar, these catalytic inhibitors significantly potentiate etoposide-induced cytotoxicity and genotoxicity across multiple cancer cell lines, leading to enhanced DNA damage signaling and G₂-phase arrest.

PS 3055 Sinonasal Cytokine Patterns as Biomarkers of Gulf War Exposures: A VAGLAHS veteran population study

M. Thapa^{1,2}, B. S. Gowda¹, S. K. Basak¹, E. Srivatsan^{3,1}, M. T. Labibi², A. Lim¹, W. Chen¹, M. Cappelletti⁴, K. Sullivan⁵, N. Klimas⁶, and J. T. Lee^{1,7}. ¹Greater Los Angeles Veterans Affairs Healthcare Administration, Los Angeles, CA; ²David Geffen School of Medicine, UCLA, Los Angeles, CA; ³UCLA, Department of Surgery, Los Angeles, CA; ⁴Department of Pathology, UCLA, Los Angeles, CA; ⁵Department of Public Health, Boston University, Boston, MA; ⁶Nova Southeastern University School of Medicine, Ft Lauderdale, FL; and ⁷Head and Neck Surgery, UCLA, Los Angeles, CA.

Background and Purpose: Gulf War Illness (GWI) is a chronic multisystem disease affecting one third of Veterans from the Persian Gulf War (GWV) (1990-1991). Symptoms of chronic rhinosinusitis (CRS), including nasal congestion and fatigue, are the 1st (47%) and 3rd (41%) most common complaints associated with GWI. This study examines cytokine patterns in sinus secretions of Veterans with and without Gulf War exposures and GWI. **Methods:** We analyzed sinonasal secretions from 48 GWVs (25 with GWI, 23 without GWI) compared to those of 60 non-GWVs (23 with CRS, 37 without CRS) from the Greater Los Angeles VA. A Luminex 38-plex quantified cytokine and chemokine. Kruskal Wallis testing was used and were verified with multivariable logistic regression. **Results:** Sinus secretions of GWV with GWI had elevated levels of EGF, G-CSF, IL-8, IL-10, and TNF-beta (p<0.05) compared to GWV without GWI. A subgroup of GWI with nasal polyps (n = 7) demonstrated significantly elevated levels of EGF, IL-4, IL-5, MIP-1a, and MIP-1b compared to those with GWI without nasal polyps. Among veterans with CRS, GWI patients had elevations in G-CSF, IL-8, IL-10, IL-22 and IP-10 compared to non-GWVs with CRS (p<0.05). Among patients without CRS, GWV had elevated EGF, IL-1RA, IL-6, IL-8, IP-10, MCP1, and M-CSF (p<0.05) compared to non-GWV, suggesting that Gulf War-related exposures

influence sinonasal immune activity independent of CRS diagnosis. **Conclusions:** This study demonstrates that GWV with and without GWI have distinct cytokine profiles in their sinonasal secretions that may not only assist with detection of GWI but also differentiate between exposure-related sinonasal inflammation from conventional CRS.

PS 3056 Pathology of PD-L1 blocking therapeutics in three immune-humanized mouse models

R. E. Becker¹, K. L. Gabrielson², and K. E. Howard¹. ¹USFDA, Silver Spring, MD; and ²Johns Hopkins University, Baltimore, MD.

Background and Purpose: PD-L1 is a receptor commonly found on myeloid antigen presenting cells. PD-L1 binds PD-1, found on T cells. Such therapeutics are checkpoint inhibitors (CI) drugs and are used to treat cancer. To determine if immune-humanized mice could show immune related adverse effects (irAEs), we tested two different anti-PD-L1 drugs, atezolizumab and avelumab, in three different humanized mouse models. Avelumab is an IgG1 monoclonal antibody (mAb) with a functional Fc receptor, while atezolizumab has a non-functional IgG1 Fc receptor. This study evaluates a range of doses for anti-PD-L1 drugs to assess irAEs in immune-humanized mice. **Methods:** Immune-humanized mice were made using either NOG-hIL6 or NBSGW mouse strains. Using previously described techniques, both mouse strains received one of the following tissue implants or injections: 1) thymic fetal tissue and CD34+ hematopoietic stem cells (HSC), 2) neonatal thymus tissue and CD34+ HSC (Neo-Thy), or 3) CD34+ HSC only. Following humanization, mice were randomized to receive either atezolizumab, avelumab or saline control. Mice were treated once weekly IP with either saline or low, mid or high dose of the therapeutic. Treatment for avelumab and atezolizumab was 3, 15 or 30mg/kg, and 4, 20 or 40mg/kg, respectively. Flow cytometry was performed on days 0, 14 and 21 to assess humanization progression. Necropsies were performed on day 28, with PBMC, 2/3 spleen and bone marrow collected for flow cytometry processing. Tissues collected for pathology included heart, lungs, kidneys, adrenal gland, liver, gastrointestinal tract, mesenteric lymph nodes, reproductive tract, 1/3 of spleen, brain, femur, muscle and skin. Femur and head were decalcified for 24 hours, and all were fixed with 10% formalin and processed into slides. **Results:** Both atezolizumab and avelumab treated mice showed differences in the breadth and location of inflammatory lesions based on the method of humanization. For CD34 mice, there were no findings for atezolizumab in any tissues, whereas avelumab treated mice had mild to severe granulomatous (Gran) inflammation in the spleen, with 50% having either lymphohistiocytic (L/H) or Gran. inflammation in mesenteric lymph node or bone marrow. Mice produced with fetal thymic tissue had L/H and/or Gran. inflammation in small and large intestine, spleen and lung, with some pancreatic atrophy in atezolizumab treated; and in adrenal glands, lung, spleen, and bone marrow for avelumab treated. Neo-Thy mice also had L/H and/or Gran. inflammation, including in lungs, spleen, liver, mesenteric lymph node, pancreas, and bone marrow; which was similar in distribution for both therapeutics. **Conclusions:** Immune-humanized mice, particularly those produced with human thymic tissue, could demonstrate irAEs when treated with either anti-PD-L1 therapeutic. CD34 immune humanized mice showed no irAEs when treated with atezolizumab, and those treated with avelumab only had lesions in immune organs, suggesting they are not an appropriate model for this therapeutic. While Neo-Thy mice had a wider range of organs affected as compared to fetal-tissue produced mice, this may represent a broader immune humanization of all organs than appeared to occur with fetal-tissue produced mice. Neo-Thy mice also showed inflammation in liver, pancreas, and lung; which is consistent with some severe adverse events experienced by patients. This study suggests that Neo-Thy immune humanized mice may be an appropriate model for testing a broad range of checkpoint inhibitor therapeutics. PS How to use Retention Index information (NIST) to support Mass Spectral based identifications in GC/MS.

P. Christiaens. Nelson Labs, Heverlee, Belgium. Sponsor: T. Rollins

Background and Purpose: Organic leachables surfaced by GC/MS are often identified by mass spectral matching (MSM) in which the experimental mass spectrum is matched to reference spectra contained in a spectral library. The compound is "identified" as being the compound whose reference mass spectrum best matches the experimental spectrum, which often leads to flawed identifications. A compound's Retention Index (RI) is an independent means of corroborating proposed MSM identities. A compound's analytical RI can be matched to reference RIs contained in a RI database (NIST23). The identity secured by MSM is corroborated when the experimental RI acceptably matches the reference RI of the compound proposed by MSM. Practical use of RI matching requires that acceptance criteria be established to define when an acceptable RI match has been achieved. The use of the absolute value of the difference between RI experimental and RI reference (termed $|\Delta RI|_{obs}$) is proposed as the proper characteristic for defining the goodness of an RI match. Depending on its value, $|\Delta RI|_{obs}$ can be used to corroborate (support), reject or accept the proposed identity. Acceptance criteria for supporting, rejecting, or accepting proposed identities were established using experimental values for RI secured

by Nelson Labs and reference RI values found in the commercially available NIST23 library. **Methods:** A Confusion Matrix was constructed using the available data, intending to minimize both false positive and false negative outcomes, while taking into account that false positives should have a higher weight because they have a greater impact on the outcome of a toxicological risk assessment. A full description can be found in the scientific article that was recently accepted by the PDA Journal of Science and Technology **"Use of the Retention Index to Secure Correct Identities in GC/MS"**. **Authors :** Piet Christiaens, Dennis Jenke, Jan Baeten, Philippe Verlinde, and Jean-Marie Beusen (2025) **Results:** Use of the Confusion Matrix resulted in the following outcomes: • The supporting limit is the value for $|\Delta RI|_{obs}$ below which there is a very high confidence in the proposed identity obtained via MSM. A $|\Delta RI|_{obs}$ value below the supporting limit corroborates (supports) the identity proposed by MSM. The value for the supporting limit is set at $|\Delta RI|_{obs} \leq 20$. • The rejection limit is the value for $|\Delta RI|_{obs}$ above which there is a very low confidence in the proposed identity obtained via MSM. A $|\Delta RI|_{obs}$ above the rejection limit refutes (rejects) the identity proposed by MSM. The value for the rejection limit is set at $|\Delta RI|_{obs} > 50$. $|\Delta RI|_{obs}$ values between the supporting and rejection limits neither corroborates nor refutes the proposed identity and the use of $|\Delta RI|_{obs}$ is inconclusive. This presentation reflects the content of a scientific article, written by Nelson Labs, which was submitted to the PDA Journal **Conclusions:** Chromatographic information, such as retention index, can be a very important and useful tool in the identification process and will enhance the quality of a subsequent toxicological assessment

PS 3058 Exhaustive Extractions are Exhausting: Justification of Changes in Medical Device Manufacturing through Materials Science and Toxicology

R. Bader. Cambridge Polymer Group, Woburn, MA. Sponsor: S. Street

Background and Purpose: Any manufacturing site, material, supplier, sterilization or processing change in medical device manufacturing necessitates a re-evaluation of biological safety and demonstration of biological equivalence. Biological equivalence, in turn, requires demonstration of endpoint and material equivalence. Given the challenges of generating reproducible extractables profiles, combined with the burdensome test set-up, the use of exhaustive chemical characterization to provide evidence of material equivalence can be challenging. **Methods:** Biological risk assessments for various devices with different natures and durations of contact were reviewed with a focus on those that used analytical approaches outside of exhaustive chemical characterization to demonstrate material equivalence. **Results:** Manufacturing site, supplier, and sterilization changes were justified through non-traditional methods to demonstrate material equivalence and, when combined with endpoint testing results, biological equivalence. **Conclusions:** Materials science-driven approaches utilizing non-exhaustive extraction methods were used to effectively justify changes to medical devices. A key factor in the success of these justifications was early and strategic involvement of biocompatibility experts, materials science subject matter experts, and toxicologists to assess whether the non-traditional extraction methods could still adequately support the biological and/or toxicological risk assessment.

PS 3059 Can Material Evaluations Accurately Predict Irritation Outcomes for Medical Devices?

C. M. Ruch, and P. G. Smiraldi. NAMS, Northwood, OH.

Background and Purpose: When preparing biological evaluation plans and evaluating the biocompatibility of medical devices, the ISO standards emphasize identifying biological hazards and harms to estimate patient risk. Irritation is a biological effect to be evaluated for all medical devices that come in direct or indirect contact to patients. We wanted to understand if only evaluating device materials of construction is sufficient to predict irritation responses. Given the diversity of materials and processes used to make medical devices, we hypothesized that a material evaluation alone would not be able to predict *in vivo* irritation failures. **Methods:** Thousands of biocompatibility tests have been conducted at NAMS for medical device manufacturers resulting in an extensive database of reports. The *in vivo* intracutaneous irritation test is the most common assay used to test for irritation potential. A Python script that targeted intracutaneous irritation reports was developed to mine the NAMS database. The script was used to automate an unbiased process of extracting the results from studies completed from 2019-2024. Reports with failing intracutaneous irritation results (score of >1.0) were manually reviewed and the device's materials of construction were tabulated (typically, only high-level material of construction information is reported). Each disclosed material was reviewed to determine if the materials are known to cause irritation, or tend to fail this study, were present (e.g., adhesives). **Results:** A total of 3,801 intracutaneous irritation reports were identified. Of those, there were a combined 55 failures from the polar ($n=23$) and non-polar ($n=32$) extracts (1.47% failure rate). Based on our analysis of the materials of construction: 29 (53%) failures could have been predicted. 6 of these devices had contact with intact skin only. 14 devices were used for wound care and typically included adhesive materials which have intact skin contact only. 10 (18%) failures may have been predicted. No obvious trends were identified amongst the devices. However, some aspect of each device was identified that could explain the

result (e.g., presence of an adhesive material, device was absorbable, physical form of the device). It is unclear if the result would have been predicted before performing the study. Noteworthy, most irritation scores were <1.9 , indicating a slight irritation response. 16 (29%) failures would not have been predicted. Based on the compositional information reported, no materials had an obvious irritant hazard. **Conclusions:** We performed a retrospective analysis to determine if material evaluations alone can predict failing results for the intracutaneous irritation study. Based on the evaluated dataset, irritation failures are not common; without performing any formal material assessment, the failure rate was 1.47%. Over half (53%) with failing results could have been predicted based on a materials assessment; in many instances, the intracutaneous irritation method was deemed inappropriate based on the type of patient contact (intact skin) with the suspect material. Additionally, 18% might have been predicted based on some aspect of the device, as described above. Lastly, 29% of the devices with failing results would not have been predicted. Considering the results of our study, we rejected our hypothesis. Although not perfect, material evaluations alone can predict failing results for the intracutaneous irritation study. It is anticipated that when material evaluations are combined with evaluations of the manufacturing processes (e.g., chemicals), predictions will improve. When planning medical device testing, consideration to all device components and its intended patient contact is important to ensure appropriate testing methods are selected.

PS 3060 A comparative regulatory analysis of substance-based medical device risk classification in ASEAN and EU

N. U. Hashim¹, J. Chen², N. Adjimatera², and S. Kwon¹. ¹National University of Singapore, Singapore, Singapore; and ²Reckitt Benckiser, Singapore Pte Ltd, Singapore, Singapore.

Background and Purpose: The ASEAN Medical Device Directive (AMDD), largely modeled after the EU's former Medical Device Directive (MDD) to harmonize regional requirements, has diverged from the EU framework following the introduction of the more stringent EU Medical Device Regulation (MDR). The precise impact of this regulatory divergence on the risk classification of substance-based medical devices (SBMDs) has not yet been systematically analyzed. **Methods:** We developed decision trees as analytical tools to visually map and compare the risk classification pathways for SBMDs under both the ASEAN and EU regulatory frameworks. Case studies on eye drops, vaginal lubricants, and alginate-based reflux products were conducted to identify points of divergence in the risk classification of representative SBMDs. **Results:** The risk classification outcomes of the case studies showed that the EU MDR assigned a higher risk class (Ib, moderate-high risk) to all representative SBMDs compared with their corresponding classifications under the AMDD (Class B, low-moderate risk). **Conclusions:** Our analysis showed that Rule 21 of the EU MDR, which governs SBMDs, results in higher risk classifications for the representative products examined. In contrast, the AMDD currently lacks a rule specific to SBMDs. This divergence may affect clinical evidence and technical requirements and delay global market access due to differing risk classifications of SBMDs. Continued collaboration between ASEAN and the EU on classification criteria is essential to reduce regulatory burdens arising from these differences.

PS 3061 Scientific Confidence in the Monocyte Activation Test: A Human-Relevant Pyrogenicity Test for Medical Devices

A. Bettmann, J. Brown, and A. J. Clippinger. PETA Science Consortium International e.V., Stuttgart, Germany.

Background and Purpose: Pyrogenicity is an important safety consideration in the evaluation of medical devices. This response is mediated by immune recognition of foreign substances, leading to cytokine release and hypothalamic modulation of body temperature. Pyrogens are broadly classified as endotoxins, which are primarily lipopolysaccharides (LPS) from gram-negative bacteria, and non-endotoxin pyrogens (NEPs), which include a diverse array of biological and chemical agents. Historically, the Rabbit Pyrogen Test (RPT) has been the standard assay for detecting pyrogens; however, regulatory agencies are encouraging transition to the use of more human-relevant and quantitative methods. The Monocyte Activation Test (MAT) is a quantitative *in vitro* assay using human peripheral blood mononuclear cells (PBMCs) that offers a reliable and mechanistically relevant approach. As such, there is interest in conducting case studies to further demonstrate that the MAT is capable of detecting both endotoxin and NEPs in medical devices. Additionally, there is a growing scientific consensus that so-called material mediated pyrogens (MMPs; listed in Annex G of ISO 10993-11:2017) are not relevant to the pyrogenicity testing of medical devices, which our data supports. **Methods:** Following discussion at a 2018 workshop, we evaluated six sets of dental bone screws ("spider screws") to assess the MAT's ability to detect both endotoxins and NEPs on device surfaces within this narrow context of use. These samples were spiked with known pyrogens (LPS, HKSA, R848) or MMPs. Devices were tested with and without dry-heat depyrogenation, multiple spike controls, and dilution series (LPS/HKSA/R848 dose-responses) to assess spike recovery and to distinguish microbiological contamination from material-mediated effects. Additionally, seven MMPs listed in ISO 10993-11:2017 Annex G were tested using the MAT to determine their potential to elicit a pyrogenic response. Testing was conducted by MAT BioTech using pooled PBMCs from four

donors. Cytokine release was quantified via enzyme-linked immunosorbent assay (ELISA), using an IL-6 standard to generate a four-parameter logistic curve. After data analysis, the scientific confidence framework outlined in the 2024 Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) report, *Validation, Qualification, and Regulatory Acceptance of New Approach Methodologies*, was used to evaluate the MAT for detecting surface pyrogens on medical devices. **Results:** The results demonstrated that of the six spider screw batches tested, five were found to be free of contamination, while batch 2 showed pyrogenic activity due to a microbiological source, which was successfully eliminated through dry heat treatment. Most batches showed acceptable spike recovery ranges after increasing PBMC incubation volume, though batch 1 and batch 3 exhibited outlier results that require further investigation. Overall, the testing confirmed that the MAT is effective for detecting surface pyrogens on dental bone screws. Additionally, none of the seven MMPs listed in ISO 10993-11:2017 Annex G elicited a pyrogenic response in the MAT. These findings, along with using the scientific confidence framework outlined in the 2024 ICCVAM report, support the MAT's suitability within this context of use. The test exhibits biological relevance to humans and strong technical characterization. Moreover, it has undergone extensive independent review, establishing the MAT as a fit-for-purpose new approach methodology (NAM) for surface pyrogenicity testing of medical devices. **Conclusions:** Based on the study findings, the MAT demonstrates strong suitability for detecting both endotoxins and non-endotoxin pyrogens on medical device surfaces, and these results should be considered for regulatory acceptance in place of the RPT. The absence of pyrogenic response from the seven tested MMPs further supports the growing consensus that these substances are not relevant to pyrogenicity testing. Evaluated through the 2024 ICCVAM scientific confidence framework, the MAT proves to be a biologically relevant, reproducible, and valid approach. These results reinforce the MAT's role as a fit-for-purpose NAM for ensuring the safety of medical devices and support a shift toward more ethical, accurate, and mechanistically sound approaches in medical device pyrogenicity testing.

PS 3062 Case Based Insights When Assessing Carcinogenicity Risk in Biological Safety Evaluation

X. Dai, J. Weng, S. Wu, M. Lewis, E. Rufer, R. Shulfer, and M. Kamberi. Abbott Laboratories, St. Paul, MN.

Background and Purpose: ISO 10993-17 provides a framework for evaluating the risk of chemicals released from medical devices, including specific guidance for assessing carcinogens, both known and suspected. The US NTP, IARC, and ECHA published lists of carcinogens. However, many of listed chemicals are based on exposure scenarios irrelevant to devices. This creates challenges in characterizing cancer risk under clinical use condition. To illustrate the complexities of TRA for carcinogens in devices, here are case studies evaluating some device related chemicals identified as carcinogenic by those organizations to demonstrate a fit for purpose approach to refine TI with the context of clinical relevance. **Methods:** Published data on chemicals associated with materials and manufacturing were reviewed against 3 major carcinogens databases, US NTP Report on Carcinogens, IARC Monographs, and EU CMR substances. Five common chemicals in devices were selected: Co in stainless steel alloys; Ni in Nitinol; DEHP, a plasticizer in PVC; tetrahydrofuran (THF), a solvent & polymer precursor; benzophenone, a photosensitizer & plastic stabilizer. A comprehensive literature review was conducted to assess the carcinogenicity risk of these chemicals, focusing on the applicability, reliability, and quality of publicly available data and using key criteria: exposure route, cancer site/type, mode of action and genotoxicity evidence to establish TI values for the carcinogenicity endpoint. **Results:** These chemicals were classified carcinogenic potential by US NTP, IARC, and EU CMR: Ni as a known human carcinogen by NTP, Group 1 by IARC, & Category 1A under CMR; Co as reasonably anticipated to be a human carcinogen (RAHC) by NTP, Group 2A by IARC, & Category 1B under CMR; DEHP as RAHC by NTP, Group 2B by IARC, but not classified under CMR; THF & benzophenone as Group 2B by IARC, not listed by NTP; benzophenone as Category 1B, while THF not under CMR. Both Ni and Co are endogenous elements and trace nutrients consumed daily through diet. Ni intake from food is estimated at 100-300 µg/day for adults. It functions as a cofactor in metalloenzymes. Co also plays a vital biological role with median blood conc. around 0.39 µg/L and recommended daily intake up to 0.03 mg/kg bw. Carcinogenicity associated with Ni and Co is primarily linked to inhalation of their insoluble salts, not oral exposure to soluble ones. Lifetime oral intake of soluble Ni salts in rodents showed no increased cancer incidence at doses up to 0.75 mg/kg bw/d. Similarly, Co carcinogenicity was observed only in inhalation studies, with increased lung tumors in rodents exposed to Co powder or sulfate salts. Given the route specific nature of these findings and the lack of evidence for carcinogenicity via systemic exposure, Ni and Co are unlikely to be carcinogenic in cardiovascular devices. DEHP, THF, and benzophenone are not classified as known human carcinogens. Available evidence suggests that their carcinogenic effects in animals occur through non-genotoxic mechanism. For all three chemicals, cancer TI values could not be established using the slope factor or TD₅₀ approaches outlined in ISO 10993-17 due to limited data. Alternative scientifically justified approaches were applied to reflect their non-genotoxic carcinogen mechanism with dose- and duration-dependent effects. For DEHP, a TI of 2.02 µg/kg bw/d was derived using the benchmark dose lower confidence limit for a 10% response (BMDL₁₀) based on hepatocarcinogenesis data in rats. A TI of 71.65 µg/kg bw/d for THF was established from the POD using the lowest NOAEL identified in 2-year inhalation carcinogenicity

studies from rodents and a TI of 5 µg/kg bw/d for benzophenone was derived from the chronic tolerable daily intake established by EFSA. **Conclusions:** These case studies highlight the importance of TRA using a scientifically robust, context specific framework. Variability in carcinogenic classifications across regulatory databases along with differences in exposure routes and mechanisms of action emphasize the application of specific risk assessment. Extractables that are either endogenous or act via non-genotoxic mechanisms challenge the applicability of traditional cancer risk methods (slope factor or TD₅₀). Justifiable approaches offer a more appropriate basis for evaluating cancer risk. It is critical to conduct TRA integrating key factors, including exposure route, bioavailability, mechanistic relevance, and clinical context.

PS 3063 The Influence of Extractable and Leachable (E&L) Study Design on Biocompatibility Outcomes of Skin Patch Devices used in Ambulatory ECG Monitoring

G. Cnossen¹, K. Chatani², R. Koning², R. Nguyen³, and J. Wong³. ¹Philips, Cambridge, MA; ²Philips, Drachten, Netherlands; and ³Philips, Murrysville, PA.

Background and Purpose: This presentation examines how the design of extractable and leachable (E&L) studies impacts chemical characterization and biocompatibility of a wearable skin patch ECG device (SPD). The biocompatibility evaluation plan (BEP) ensures SPD safety prior to clinical studies and market release. As a single-use, skin-contacting device with an ECG sensor, SPD enables noninvasive heart monitoring under clinical supervision in home and healthcare settings. Our risk assessment shows SPD's skin-contacting components present low biocompatibility risk for use up to 30 days. **Methods:** Following ISO 10993-1, we performed physical and chemical characterization of SPD materials, leveraging supplier data and tests on the finished product. SPD is designed for prolonged (24 hours to under 30 days) intact skin contact, not for mucosal or compromised surfaces. Key biological endpoints included cytotoxicity, skin irritation, and skin sensitization per ISO 10993-1:2025 were conducted alongside a material assessment of patient-contacting components. The E&L study design is in accordance with the ISO 10993-18 to simulate skin contact through saline solution extraction of patient contacting components. Two temperatures were chosen: 37±1°C to match typical skin conditions, and 50 ±1 °C to represent an exaggerated scenario. The extraction periods included 3 days (72 hours), 14 days (336 hours), and 30 days. The 72-hour interval complies with ISO 10993-12 standards, while the 14-day period mirrors actual patient wear time. Extended time points were selected to better understand the chemical profiles of extractables during prolonged use. The ratio of surface area to saline solution varied according to the material's structure and the thickness of its layers. Compound identification was done via Gas Chromatography - Mass Spectroscopy (GC-MS). Extraction took place at 37°C for 24 hours, with one SPD used for every 10 mL of 0.9% saline solution. **Results: Chemical Characterization** No compounds above detection limits were found in saline extracts, except in one SPD's 336-hour extract at 37°C, containing cosmetic-related compounds from manufacturing. ICP-MS showed approximately 5 µg silver per SPD migrated every 24 hours from conductive tracks. **Biological Testing** Initial cytotoxicity and irritation responses were observed under ISO 10993, with no skin sensitization detected. Additional cytotoxicity tests on the patient contacting parts, Transfer Adhesive, Hydrogel, and Non-woven components, clarified causes of test failures. The Hydrogel's properties likely caused pH and osmolality shifts, and the potential silver migration from non-patient contacting part, contributing to the cytotoxicity results. Additional primary skin irritation patch test, more clinically relevant for SPD, showed passing results. Hydrogel's established safety, relevant testing outcomes, and SPD's intended intact skin usage together support SPD's low biological risk and biocompatibility. **Conclusions:** Understanding the composition of medical device materials and their potential leachable compounds, alongside biological safety testing results, offers predictive insight into possible toxicological risks to patients. Our material characterization and safety assessments demonstrate that SPD's skin-contacting components pose minimal risk over a 30-day period, supporting their safe application in ambulatory ECG monitoring.

PS 3064 A Proposed Framework for the Useful Life Evaluation of Breathing Gas Pathway Medical Devices: An Integral Component of Whole Lifecycle Assessments for Biocompatibility

J. Wong, R. Nguyen, S. Zheng, and D. Faulk. Philips, Murrysville, PA.

Background and Purpose: This poster presents a comprehensive yet streamlined study design framework for the useful life evaluation of breathing gas pathway devices intended for healthcare applications. The proposed framework provides for a consistent, risk-based approach to aging evaluations across diverse medical device types and use environments. These life-cycle evaluations span the entire service life of the device, from initial design through clinical therapy delivery, to ensure continued safety, performance, and regulatory compliance. Breathing gas pathway devices are typically complex and integrated with medical electrical equipment. Examples of these therapeutic systems include positive airway pressure (PAP) devices, ventilators, respiratory drug delivery devices, oxygen concentrators, and associated accessories (e.g., tubing, filters, and patient interfaces like masks). **Methods:** In accordance with ISO 10993 and ISO 18562 guidance, these medical devices can be evaluated for biocompatibility and safety throughout their entire life cycles. This may include

simulated real-time and/or accelerated aging studies designed to replicate real-world use conditions in both home and clinical environments (per ASTM F1980-21, IEC 60601-1). This proposed framework incorporates environmental exposure conditions, transportation and storage variables, and reprocessing cleaning and disinfection methods employed throughout the device's operational life. **Results:** A proposed structured framework for evaluating the whole life cycle of breathing gas pathway devices is presented, incorporating considerations for patient interface, electro-mechanical components, and device functionality. This framework considers the functional lifespan of critical to safety (CtS) components and materials, particularly those with potential toxicological risks, potential for material degradation, or patient exposure pathways, per ISO 10993 and ISO 18562 standards. **Conclusions:** Before market release, breathing gas pathway medical devices should undergo biological risk assessment, which can include aging studies. These aging studies should demonstrate acceptable results for biocompatibility, therapeutic performance, and material stability, all of which should pose negligible patient risk. These studies and datasets help meet global regulatory expectations and demonstrate conformance with international standards governing breathing gas pathway medical devices.

PS 3065 Chemical Class Emission Trends of Volatile Organic Substances Emitted from Breathing Gas Pathway Devices under ISO 18562-3:2024

K. D. Shimshock, D. Buchanan, R. Nguyen, M. Stang, and J. Wong. Philips Respironics, Murrysville, PA.

Background and Purpose: Volatile Organic Substances (VOS) released from breathing gas pathway devices constitute potential inhalation risk depending on the chemical hazard properties of the gas, emission magnitude and persistence over time. VOS emission can be evaluated under the ISO 18562-1:2024 and ISO 18562-3:2024 framework to assess potential patient exposure and establish tolerable exposure limits. The VOS emission decay curve proposed under ISO 18562-3 guidance demonstrates a typical decay curve graph, showing in theory that VOS emission from breathing gas pathway devices decreases over time. While this is widely supported by research on indoor and outdoor air pollution monitoring, no specific data on emission trends have been published on breathing gas pathway devices. An in-depth understanding of gas pathway medical device emission profiles and chemical class emission trends can assist in material selection, thereby ensuring confidence in patient safety throughout the device's lifespan. The purpose of this study is to characterize emission profiles of VOS across different chemical classes from multiple gas pathway components and determine if their emission trends are validated against the expectation of typical decay curve per the standard. **Methods:** ISO 18562-3 VOS emission tests were conducted by a third-party lab on multiple breathing gas pathway device components, constructed primarily of polycarbonate and silicones. Air was monitored continuously and sampled from the heated breathing gas stream across four discrete timepoints (0 hour, 24 hours, 72 hours, and 168 hours) under controlled conditions within the test chamber. Four representative chemical classes were selected for VOS emission trends across the multiple components tested. These classes were siloxanes (cyclic and linear), saturated hydrocarbons (aliphatic alkanes C9-C18), aliphatic aldehydes, and phenolic antioxidants. Class-summed concentrations across the four timepoints were modeled for each device and chemical class using nonlinear least-squares-fit to the first order exponential decay equation, given by: $C(t) = C_0 + A * e^{-kt}$. **Results:** The VOS emission concentrations across the four timepoints for each chemical class demonstrated a clear decay in emission, albeit with marked differences in decay profile. Modeling results indicate that Cyclic Siloxanes declined in a first-order (exponential) pattern over 168 hours. Linear siloxanes declined more rapidly than cyclic siloxanes over the same time period, yet exhibited an exponential profile during the early emission phase, consistent with first-order decay kinetics. Emissions of saturated hydrocarbons (aliphatic alkanes, C9-C18) and aliphatic alkanes declined more sharply than those of siloxanes, with a pronounced drop observed by the 24-hour timepoint. As a result, the emission pattern did not conform to first-order decay kinetics over the 168-hour period. Phenolic Antioxidants showed delayed release and gradual loss, indicating partial first-order decay after emission onset. **Conclusions:** This study demonstrates that decay profiles of volatile organic substances (VOS) emission can vary by chemical class. Furthermore, not all chemical classes exhibited first-order decay patterns over the 168-hour period, which may be partly attributed to the selection of sampling timepoints. Incorporating chemical class-specific decay patterns into toxicological risk assessments may enhance exposure estimations, inform material selection to minimize patient risk, and improve alignment with ISO 18562 framework. Future work could expand decay-based modeling across a broader range of compounds to strengthen medical device safety evaluations.

PS 3066 Determination of a medical device parenteral non-cancer TTC based on *in silico* ADME

T. Builee¹, S. Bond², R. Bachorz³, V. Lukacova³, V. Levelut⁴, M. A. Hahn⁵, and M. K. Peterson⁶. ¹Solventum, Saint Paul, MN; ²Jordi Labs, Mansfield, MA; ³Simulation Plus, Inc., Research Triangle Park, NC; ⁴NAMSA, Chasse-sur-Rhône, France; ⁵Eurofins Medical Device Services, Lancaster, PA; and ⁶Gradient, Leavenworth, WA.

Background and Purpose: Threshold of toxicological concern (TTC) values are commonly used in toxicological risk assessment of medical device (MD) constituents when there is inadequate toxicity information. Builee et al. (2025) publicly made available oral non-cancer TTC values based on a curated database (Db) of MD constituents in an open-use format. The utility of the oral non-cancer TTC values can be further advanced by considering the absorption, distribution, metabolism, and elimination (ADME) properties of each constituent. Given that computer models are a valid alternative to experimental procedures, the ADMET Predictor® (AP) (from Simulations Plus, Inc) was leveraged to develop parenteral TTC values. AP is an artificial intelligence/machine learning (AI/ML) platform used in pharmaceutical development for the prediction of toxicokinetics and other endpoints. The purpose of this poster is to present a parenteral non-cancer MD TTC value for the >30 days exposure duration based on bioavailability adjustments. **Methods:** The MD Db of Builee et al. (2025) provided the source of chemical descriptors (chemical name, CAS No., Simplified Molecular-Input Line-Entry System [SMILES]) and duration-specific oral NOAELs. The chronic duration NOAELs representing 180-day to 2-year *in vivo* studies were used in this analysis. The HTPK module, a part of ADMET Predictor® 13 suite (Simulations Plus, Inc), calculated the intestinal absorption factor percentage based on SMILES entry covering the period of 24 hours after exposure. The species used in the AP model was matched, when possible, to the species in which the NOAEL was obtained. The computationally predicted intestinal absorption results were grouped into four categories: <1%, ≥1%-50%, 50%-90%, and ≥90%, with corresponding bioavailability factors (BAFs) of 100, 10, 2, and 1 (Masuda-Herrera et al., 2022). These BAFs were further used to adjust oral NOAELs into parenteral point of departures (pPOD). The lowest 5th percentile pPOD was evaluated using a log-normally fitted cumulative frequency distribution. A modifying factor of 100 (10 each for intra- and interspecies adjustment) was applied to the lowest 5th percentile pPOD to obtain the parenteral non-cancer TTC derivation. Statistical analysis and visualization were performed using standard Python scientific libraries, including NumPy (v1.26.4), SciPy (v1.14.1), and Matplotlib (v3.10.6). **Results:** The parenteral TTC value was determined from a set of 130 constituents of the MD Db. The correlation with AP by species match was approximately 95%, indicating high similarity between the toxicity study and ADME prediction species model. The distribution of predicted BAF scores was highest in low (≥1%-50%) to mid (≥50-90%) bioavailability groups. The cumulative distribution lowest 5th percentile pPOD was 0.64 mg/kg/day for the >30-day exposure duration. After applying uncertainty factors for interspecies extrapolation (10) and intraspecies variability (10), the resulting pTTC was 6.4 µg/kg/day. **Conclusions:** A non-cancer MD TTC value for the parenteral route of exposure was derived from *in silico* predictions for intestinal absorption and assigned bioavailability adjustment factors. The parenteral TTC value of 6.4 µg/kg/day obtained for the exposure duration >30 days is 6.4 times lower than the oral non-cancer TTC value derived by Builee et al. (2025) for the same exposure duration (i.e., 41 µg/kg/day). The derived pTTC replaces the default 10-fold route-to-route uncertainty factor recommended in ISO 10993-17:2023 with a more precise, data-driven adjusted value. This work constitutes an advancement in the use of non-cancer MD TTC values for the toxicological risk assessment of MD constituents for exposure scenarios other than the oral route.

PS 3067 Identification of Chemicals of Endocrine and Reproductive Concern in Medical Device Extractables and Leachables Datasets

C. Meakin, and L. Borton. Gradient, Boston, MA.

Background and Purpose: Medical devices are composed of a wide range of materials that have the potential to release chemical constituents during patient use. Although the biocompatibility evaluation framework outlined in ISO 10993 provides guidance for assessing various toxicological risks, there is currently no requirement by the U.S. Food and Drug Administration (US FDA) or ISO 10993-1 to specifically evaluate medical device extractables and leachables for potential endocrine-disrupting compounds (EDCs). While reproductive toxicants are evaluated in accordance with 10993-17, not every device manufacturer is required to conduct ISO 10993-17 assessments. Evaluation of reproductive risk in sensitive populations like individuals who are pregnant or may become pregnant are typically limited to reproductive devices. In contrast, the European Union's Medical Device Regulation (MDR) mandates consideration of substances with endocrine or reproductive toxicity potential when present above defined thresholds. Additionally, for pharmaceuticals, ICH S5 (R3) requires the assessment of developmental and reproductive toxicity regardless of the duration of exposure for small molecule pharmaceuticals, highlighting the recognized importance of evaluating these endpoints even for short-term patient use. As awareness grows regarding the potential for low-level chemical exposures to contribute to adverse endocrine or reproductive outcomes, there is an increasing need to characterize the presence and prevalence of such compounds in medical device extracts. By cross-referencing chemical constituents with endocrine disrupting properties or reproductive toxicity potential identified from regulatory lists

with robust, published lists of medical device extractables, we aimed to identify the frequency and distribution of these compounds in medical device materials in a 'real-world' setting. **Methods:** Compounds with endocrine-disrupting potential were identified using the European Chemicals Agency (ECHA) Substances of Very High Concern (SVHC) list, while reproductive toxicants were identified from the ECHA Annex VI Classification, Labelling, and Packaging (CLP) list. These substances were then screened against two published medical device extractables datasets: (1) extractables database reported by Builee *et al.* (2025), and (2) a compiled dataset of extractable chemicals submitted by 13 medical device manufacturers, consulting firms, and analytical laboratories at contract research organizations by Borton *et al.* (2025). **Results:** Screening of medical device extractables identified multiple compounds with known or suspected endocrine-disrupting and reproductive toxicity potential. Specifically, 16 unique EDCs and 102 unique reproductive toxicants were present across both datasets. A majority of the identified compounds were classified as reproductive toxicants 1B, and four compounds, 1,2-Dibromo-3-chloropropane, Carbon Monoxide, Ethylene glycol diethyl ether, and Warfarin, were identified as a potent Class 1A reproductive toxicants. Additional identified compounds included bisphenol A, B, and S and various per- and polyfluoroalkyl substance (PFAS) such as Perfluoroheptanoic acid (PFHpA) and Perfluorodecanoic acid (PFDA). **Conclusions:** Our results indicated that screening of chemical constituents from two representative medical device databases identified multiple compounds with potential endocrine-disrupting or reproductive toxicity concerns. While the clinical relevance of these findings is dependent on actual exposure levels, the presence of such compounds underscores the need for systematic consideration of reproductive and developmental toxicity endpoints during medical device biological and toxicological risk assessment. Current ISO 10993-1 and ISO 10993-17 risk assessment frameworks can address reproductive and developmental toxicity if these hazards are recognized; however, the absence of a requirement to proactively screen for these compounds creates a systematic gap when the device can be used in individuals that are pregnant or may become pregnant. These findings highlight the importance of incorporating reproductive and developmental toxicity considerations into medical device toxicological risk assessments as a point of departure (POD) especially for devices with up to 30 days of use.

PS 3068 A Systematic Approach to Evaluating the Biological Safety of Reusable Medical Devices: A Case Study on Vascular Surgical Tool

G. Hung, K. Das, and L. Dao. Getinge Center of Excellence Advanced Materials Science and Biocompatibility, Merrimack, NH. Sponsor: G. Hung, Society for Risk Analysis

Background and Purpose: Reusable medical devices pose biological safety risks that must be evaluated over their lifecycle, particularly considering repeated reprocessing cycles involving soiling, cleaning, and sterilization. ISO 10993-1:2018 Clause 4.8 states that: "For re-usable medical devices, biological safety shall be evaluated for the maximum number of validated processing cycles by the manufacturer." The Getinge Vascular Graft Tunneler Instrumentation (VGTI), constructed from surgical-grade stainless steel, is designed for repeated use when properly maintained shows no significant signs of wear. This study provides an insight into of applicable approaches for assessing biocompatibility of reusable surgical tools from the perspectives of material characteristics, biological testing, and chemical characterization. **Methods:** VGTI devices underwent 1X, 7X, and 100X validated reprocessing cycles to replicate simulated-use conditions prior to testing. Topography, morphology, and physicochemical Characterization were conducted in accordance with ISO/TS 10993-19 to identify surface features, defects, or contaminants that could influence the chemical composition in support of understanding the biocompatibility of the material. Chemical characterization of the 1x product was also performed under exaggerated extraction conditions, followed by a toxicological risk assessment to evaluate potential patient exposure to extractables during intended use. Biological tests were conducted in accordance with ISO 10993-1 testing standards. The biological safety risk of reusable VGTI was evaluated considering all available data and overall interpretation. **Results:** The applied analytical methods employed in this study demonstrated a systematic model for evaluating biological safety of reusable medical devices. The rationale for selecting reprocessing cycles and identifying the end-of-life point was provided. All sample preparations and testing processes met international standards or validated procedures in order for a satisfactory biological risk assessment. SEM and EDS analyses showed no impurities, particulates, or contaminants on the device surfaces. Toxicological risk assessment indicated negligible risks associated with the potential leachable levels expected from the intended use of the VGTI products. Total organic carbon levels showed no statistically significant difference between 7X and 100X reprocessed devices. All biological testing met the passing acceptance criteria and comparison across different reprocessing cycles was provided. Overall, this study establishes a structured framework for evaluating biological safety risks associated with reusable devices. **Conclusions:** This study demonstrates that comprehensive material, chemical, and toxicological evaluations can effectively assess the biological safety of reusable medical devices throughout their validated reprocessing lifecycle. Although this study is limited to one device type and certain reprocessing conditions, this framework can be extended to other reusable instruments leveraging a similar applicable approach. This integrated

analytical approach—combining surface characterization, biological testing, and extractables and leachables analysis—offers a robust strategy for demonstrating the biological safety of reusable surgical tools.

PS 3069 Importance of extraction vessel shape in medical device testing: a GeneTox case report

A. A. Aggarwal, E. Meco, J. Krumpholz, S. Gollamudi, H. Fayed, and M. Brady. Labcorp, Bedford, MA. Sponsor: S. Gollamudi, American College of Toxicology

Background and Purpose: The *In-vitro* Chromosomal Aberration Test (CAT) identifies substances called clastogens. Clastogens directly cause DNA breakage. The CAT assay plays an instrumental role in the assessment of genotoxic potential of a new medical device. Since medical devices are constructed using varying materials, their fluid extracts must first be prepared to dose, making extraction a critical factor for biological testing and risk assessment of a new device. Each device is extracted at specific temperatures / conditions as per International Organization for Standardization (ISO) guidelines. Per ISO, extraction vessels are specified to be clean, inert, closed with least dead space, but their shape is not considered. Here, we present a case report where the *shape* of the extraction vessel made a significant difference in the results (positive vs. negative) for Chromosomal Aberration Test (CAT) of a new medical device. **Methods:** Two Chromosomal Aberration Test - Confirmation Assays were conducted using Chinese Hamster Ovary (CHO) cells. The device was an implantable absorbable powder, with prolonged human contact. Extractions were performed in Ham's-F12 media at 37±1°C/72±2 hours, using 0.2g/mL ratio and extracted beyond its absorptive capacity. The vessel used for the first assay was a clean glass flat-bottomed jar and a sterile plastic conical centrifuge-tubes were used for the second assay. Post-extraction, the extracts were kept at ambient-room temperature for at least 8 hours and used within 24 hours. Cells were exposed (>20 hours) without metabolic activation and dosed at 100%, 50%, 25%, 12.5%, and 6.25% concentrations. A negative control (Hams-F12 media) and positive control (Mitomycin C/MMC, 0.5 µg/mL) were prepared parallelly. Two-hundred metaphases per condition were analyzed and Chi-square (χ^2) was performed to evaluate statistical significance ($p \leq 0.05$). **Results:** The device partially dissolved forming a biphasic extract. The biphasic extract had a diffused border with the flat-bottomed jar, whereas the conical flask extract had a well-defined border for dosing. Assay validity was confirmed with significant increase in aberrations noted in positive control compared to the negative control ($p=0.000$). The device extracted in the flat-bottomed jar induced a significant increase in aberrations versus the negative control ($p=0.000$, clastogenic), but the test article extracted in the conical centrifuge-tube did not ($p>0.411$, non-clastogenic). Notably, the clastogenicity observed with the flat-bottomed jar extract exceeded even the positive control (37% vs. 23% respectively). **Conclusions:** Under similar extraction conditions and solvent, our results show that the *shape* of the extraction vessel can produce a clastogenic (positive) versus a non-clastogenic (negative) response. This case report gives insights into whether the *shape* of the extraction vessel should be another factor to consider when performing extractions of absorbable powder-based medical devices which result in a biphasic extract. Further investigations of devices with similar characteristics should be carried out to evaluate the scope of our results.

PS 3070 Inorganic Gas and Particulate emissions from Medical devices evaluated under ISO 18562

J. Hummel. Resmed, Sydney, Australia.

Background and Purpose: The ISO 18562 series of standards references inorganic gases, stating that some regulators may require evaluation of them. However, there is limited guidance on how and when to test, or otherwise assess these inorganic gasses. This lack of clarity can lead to inconsistencies in evaluation approaches and regulatory expectations. This work collates the most common sources of inorganic gases in the gas pathway of medical devices - electric motors and electronic sensors - and for each presents a high-level analysis of their risks and considerations from a toxicological perspective. The integration of electric motors and sensors into medical gas pathways introduces potential sources of inorganic emissions, including carbon monoxide (CO), carbon dioxide (CO₂), ozone (O₃), nitrogen oxides (NO_x), and also particulates. Understanding the mechanisms and triggers for these emissions is critical for toxicological risk assessment and ensuring device biocompatibility. This work is intended to provide regulators and manufacturers alike with an awareness of the engineering and science outside of, but intersecting with the field of toxicology, and how they affect the need and validity of such testing. This is to avoid both needless tests, as well as false test results. **Methods:** Inorganic gas and particulate emissions were systematically categorised using theoretical analysis and literature review. This categorisation was based on their generation mechanisms and operational triggers in common electric motor and sensor designs. Risk of inorganic gas and particulate emissions was evaluated based on component construction, operational dynamics, and material properties. For components with the potential to produce emissions, first-principles analysis was applied to derive considerations for medical device testing configurations. **Results:** Emission mechanisms were primarily associated with unintentional spark generation within electrical circuits, which can produce inorganic gases and particulates. Additional non-spark sources were

identified as high-temperature sensors and components that emit ultraviolet light, both of which can facilitate the formation of inorganic species. Importantly, brushed DC and universal motors as well as sensors that produce particulate emissions, may not have an inherent worst-case emission point, requiring characterisation of the entire life and all use cases, an assessment that extends beyond the start-of-life testing typically performed to comply with ISO 18562-2:2024. Brushed DC and universal motors, which use either a split-ring commutator or slip-rings, were found to present the highest emission risk due to spark formation and mechanical abrasion, both of which generate inorganic gases and particulates. The point of maximum emission varies between each implementation, and no single worst-case configuration can be universally defined. In contrast, brushless DC, induction, synchronous, stepper, and linear motors—all of which have passive rotors—by their innate design do not generate inorganic gases or particulates. Bearing selection also influences particulate generation. While all bearings facilitate relative motion, not all have the mechanical abrasion required to produce particulates. Bushings and seals both have directly contacting surfaces that rub, creating the mechanical abrasion that can lead to particulates. However, shielded and open ball bearings do not produce particulates. Gas sensors must interact with the gas to perform their function, but this rarely results in a toxicologically significant alteration of the gas stream. Pressure sensors, acoustic, and mass flow sensors, by their inherent design, do not produce inorganic gases or particulates. All other forms of gas sensors that were considered were found to theoretically produce trace quantities of inorganic gases. Although such emissions are expected to be below detection limits in most configurations, they still warrant empirical verification. **Conclusions:** Through appropriate selection of sensors and motor designs, the need to conduct testing for inorganic gases can often be entirely avoided. However, some sensor and motor designs can exhibit highly variable emission profiles, and testing without careful selection of parameters and device conditioning may underestimate patient risk.

PS 3071 Relevance on the Dose-Based Threshold of 120 µg/d for non-targeted analyses of non-absorbable implantable medical devices based on ISO 10993-17:2023 framework.

A. Dibao Dina¹, and P. Smiraldo². ¹NAMSA Clinical and Consulting Services GmbH, Obernburg am Main, Germany; and ²NAMSA, Northwood, OH.

Background and Purpose: ISO/TS 21726:2019 provides guidance for the application of the Threshold of Toxicological Concern (TTC) to assess biocompatibility of medical device constituents. The TTC is used to determine the Dose-Based Threshold (DBT) for the Analytical Evaluation Threshold (AET) prior the testing and to assess constituents lacking toxicological data during the Toxicological Risk Assessment (TRA). Selecting an appropriate DBT is critical to generate a conservative extractables profile for the subsequent TRA. Nevertheless, it is equally important to not select a DBT too stringent, since the non-targeted analysis may: 1) be associated with technical issues, such as obtaining an extract both compliant with the AET and compatible with the analytical instruments; 2) significantly increase the number of peaks to interpret and toxicologically evaluate, which leads to additional time and costs for the stakeholders, and 3) lead to an overly conservative assessment not relevant to assess the device's safety. In this poster, we demonstrate that the use of a DBT of 120 µg/d for non-absorbable implantable medical devices is relevant and sufficiently conservative, using the currently applicable regulatory framework.

Methods: A hypothetical non-absorbable implantable medical device (e.g. orthopedic implant or cardiovascular stent) was considered, with the assumption that a single device is used. According to the ISO 10993-18:2020, an exhaustive extraction is required. According to ISO 10993-17:2023, this exhaustive extraction allows to determine the Total Quantity (TQ) of constituents extracted from the device. Assuming release kinetics data are not available, the TQ can be used to calculate worst-case estimated exposure doses (EED_{max}) during acute (≤ 1 d), subacute (2 - 30 d), subchronic (31 - 365 d) and chronic (≥ 366 d) exposure periods, based on the fewest number of exposure days for each time period (respectively 1, 2, 31 and 366 d). Assuming a DBT of 120 µg/d was applied for the non-targeted analysis and an unrealistic Uncertainty Factor (UF) of 1 was used for the AET calculation (UF is typically higher for non-targeted analyses, which leads to detecting lower concentrations), the lowest concentration that can be detected would be 120 µg/device, which corresponds to a TQ of 120 µg in this example based on a single device. Two sets of values were used to justify that this TQ is of negligible toxicological risk: 1) The Toxicological Screening Limit (TSL), applicable to identified compound. The TQ was compared to TSL_{30d} (120 µg) and TSL_{366d} (600 µg). 2) The TTC, applicable when toxicological information is assessed to be inadequate or absent for an identified constituent. The EED_{max} expressed in µg/d, for each exposure period was compared to: TTC = 120 µg/d, for the acute (≤ 1 d) and subacute periods (2 - 30 d); TTC = 20 µg/d, for the subchronic period (31 - 365 d); TTC = 10 µg/d, for the chronic period (1 - 10 y); TTC = 1.5 µg/d, for the chronic period (> 10 y). **Results:** For all exposure periods, the TQ or EED_{max} were found to be lower or equal to the TSL or TTC, which means that the constituent can be judged to be of negligible toxicological risk and no further risk evaluation is recommended to address genotoxicity, cancer, systemic toxicity (acute, subacute, subchronic, chronic), or reproductive or developmental toxicological risks. Since the TQ is the lowest value that can be detected using a DBT of 120 µg/d, using a lower DBT is not necessary. **Conclusions:** A DBT of 120 µg/d is appropriate for non-absorbable implantable medical devices that are exhaustively extracted, considering the ISO 10993-17:2023 framework. The other TTC values from the ISO/TS 21726:2019 can be used either during the TRA or to select an appropriate

DBT prior non-targeted analysis of absorbable devices, repeatedly/single-use non-absorbable devices or devices that were extracted using exaggerated or simulated-use conditions. Before using this DBT, it is crucial to: 1) gather information on the device's composition, to ensure that compounds excluded from the TTC approach (e.g. Cohort of Concern) are not present and 2) ensure that an appropriate UF is applied for the AET calculation, since it adds a safety margin to detect potential substances of concern (such as Carcinogenic, Mutagenic and Reprotoxic 1A/1B substances or Endocrine Disruptors).

PS 3072 *In vitro* sensitization assessment of medical device extracts: Prevalidation results of GARDskin Medical Device for potential inclusion in ISO 10993-10

A. Forreryd, P. Alfrén, R. Gradin, and H. Johansson. Senzagen AB, Lund, Sweden.

Background and Purpose: Biocompatibility testing is essential to ensure the safety of medical devices (MDs), confirming their compatibility with biological systems and minimizing adverse effects. Along with cytotoxicity and irritation, skin sensitization is a key toxicological endpoint that must be assessed for all devices. While the former endpoints can be partly assessed *in vitro*, skin sensitization testing still largely relies on animal-based methods such as the Guinea Pig Maximization Test (GPMT) to meet regulatory requirements. For neat chemicals, significant progress has been made with the development, validation and regulatory integration of New Approach Methods (NAMs) into globally harmonized OECD Test Guidelines (TGs) 442C-E. These assays are increasingly replacing animal testing in several industry sectors. However, MD testing presents unique challenges due to the complex nature of polymeric materials and extractable profiles, and the regulatory adoption of NAMs in this field has been limited. To address this gap, the International Organization for Standardization (ISO) released Technical Specification (TS) 11796, providing guidance for evaluating the applicability of candidate NAMs for MD testing. The present study describes the adaptation and prevalidation of the OECD-validated GARD[®]skin assay for assessing skin sensitization potential of MD extracts in line with ISO 10993-12 and ISO TS 11796. **Methods:** To enable compatibility with MD testing, the GARDskin protocol was modified to include a pre-sample extraction step using polar (saline) and non-polar (olive or sesame oil) vehicles according to ISO 10993-12. A feasibility study followed by a prevalidation study was conducted under ISO TS 11796 to evaluate the method's reliability and applicability. In the feasibility study, silicone (MED-2000) and thermoplastic polyurethane (TPU) materials were spiked with skin sensitizers (n=4) and extracted in both polar and non-polar vehicles to serve as medical device surrogates (n=6). The prevalidation study consisted of two parts. Part 1 (GS MD method, n=16, 3 replicates): The original GARDskin Medical Device protocol was applied. Negative control material (MED-2000) was extracted in both vehicles and spiked with a panel of sensitizers and non-sensitizers. Part 2 (GS MD 0.5% method, n=29, 1 replicate): The same protocol was applied with one modification — extracts were tested at a final in-well concentration of 0.5% (reduced from 10%) to calibrate the classification threshold and compensate for the much higher sensitivity of *in vitro* assays compared to *in vivo* methods. **Results:** The feasibility study confirmed the ability of the GARDskin Medical Device protocols to correctly identify sensitizers from solid material extracts. All spiked materials (n=6) were correctly classified as sensitizers, with no false positives for un-spiked medical grade materials or extraction vehicles. Results from Part 1 of the prevalidation study demonstrated 100% reproducibility (16/16), with 94% concordance (15/16) with animal data and 88% concordance (14/16) with GARDskin data on respective neat chemical testing. With a further expanded test chemical range (n=29), Part 2 of the prevalidation study demonstrated 97% concordance (28/29) with animal data and 86% concordance (25/29) with GARDskin classifications. **Conclusions:** The GARDskin Medical Device prevalidation results demonstrate that the method is functional, reproducible, and highly accurate for assessing the skin sensitization potential of medical device extracts. The method fulfils the performance criteria to advance to an inter-laboratory ring trial, in accordance with ISO TS 11796, to further evaluate transferability and robustness prior to potential inclusion in ISO 10993-10 for *in vitro* sensitization testing.

PS 3074 Applicability and Performance of Open-Source and Paid-Access Computational Genotoxicity QSAR Models for Medical Device-Derived Extractables

A. Luthin, S. Thomas, A. Holth, O. Kinsky, A. Stornetta, and S. Huebert. Boston Scientific, Saint Paul, MN.

Background and Purpose: Under ISO 10993-17, toxicological risk assessments are performed on medical device extractables generated in accordance with ISO 10993-18. Such datasets are often complex and used to address systemic toxicity endpoints in lieu of animal studies. Limited availability of robust toxicological data for compounds requires use of alternative approaches, such as quantitative structure-activity relationships (QSAR), to predict toxicological endpoints. Historically, risk assessments conducted with open-source models may have resulted in conservative evaluations as out-of-domain constituents can prompt the selection of worst-case Threshold of Toxicological Concern (TTC) values. To better support the toxicological evaluation of medical device constituents, seven genotoxicity QSAR models

were evaluated for their applicability and prediction accuracy to device extractables. Genotoxicity was selected since one of the most pressing risk assessment needs is reliable data to select TTC. A comprehensive list of medical device-related constituents, both rare and common, was generated and a comparative analysis of the performance of these open-sourced and paid-access QSARs tools is presented here. **Methods:** A representative list of 120 medical device-related organic constituents was created from Boston Scientific's internal database of ~1200 medical device extractables, derived from >150 unique devices. The full list was ranked by frequency of occurrence in device risk assessments with the top 50 compounds (from 30-75 devices) and bottom 50 compounds (from <5 devices) chosen for further analysis. Additionally, 25 compounds identified in the internal database with literature-reported genotoxic, carcinogenic, or mutagenic hazards were included, resulting in a list of 120 compounds after duplicates were removed. Seven QSAR models for bacterial mutagenicity were assessed using this list to determine inclusion within each model's applicability domain. Out-of-domain compounds were further evaluated to identify any gaps in training sets specific to medical device extractables. Lastly, the accuracy of each prediction within the domain was compared with experimental data for genotoxicity from the European Chemicals Agency database. **Results:** For common, rare, and genotoxicity-related medical device extractables, open-source QSAR tools produced 48-63% in-domain calls, whereas paid-access QSAR models yielded about 91-93% in-domain calls. Siloxanes and antioxidants were among the most common extractables in this dataset but were often out of domain of open-source tools. Rare extractables were generally in domain of paid models but were in domain of only 1 of 5 open-source models. All models demonstrated high genotoxicity prediction accuracy with open-source models achieving 88-97% and paid models 95-98% accuracy compared to experimental data. Additionally, there were instances of unexpected predictions (e.g., phenol [CAS 108-95-2]), which appeared inconsistent with experimental data. Expert review identified phenol as a probable non-mutagenic genotoxicant in the literature, based on negative bacterial mutation and positive chromosomal aberration experimental results. It was predicted to be negative by bacterial mutation models, which aligns with these observations. Following the analysis of this dataset, a tiered process flow was created for genotoxicity prediction of medical device extractables to assess future data-poor compounds. **Conclusions:** Although both open-source and paid QSAR genotoxicity models cover many rare and common medical device-related compounds, larger gaps were observed in open-source training sets. When predictions could be made, accuracy was high for all models. A tiered approach is recommended, starting with open-source models and moving to paid models, as needed. Some common device extractables (e.g., siloxanes) remain outside many model domains, highlighting an area for QSAR improvement. As demonstrated by the phenol case study, constituents with non-mutagenic mechanisms of genotoxicity can result in false negatives using this tiered process flow. Moving forward, increased inclusion of medical device-related compounds in training sets would broaden usability of these programs and help bridge gaps in evaluation of medical device safety while using highly preferred non-animal approaches.

PS 3075 Solvent selection for leachables test in the condensate for gas pathway masks

G. Chandrayan¹, P. Duineveld², D. Faulk³, J. Wong³, and R. Nguyen³. ¹Philips, Pune, India; ²Philips, Drachten, Netherlands; and ³Philips, Murrysville, PA.

Background and Purpose: Tests for leachable in condensate are a critical part of biocompatibility assessment for gas pathway devices where patient exposure to leachable is credible. According to ISO 18562-4:2024, aqueous extraction is generally considered adequate for patient interface masks. Further, recent feedback from regulatory bodies highlights that for devices positioned close to the patient, such as patient interface masks, it is foreseeable that biological secretions from patients such as saliva, sweat, and mucus, may interact with device materials. This interaction could result in leachable compounds, which may then be reintroduced to the patient. As a result, it is recommended using water plus semi-polar and/or non-polar solvents to account for potential exposure of the inner mask surfaces with biological secretions of the oral and nasal cavities. This study was therefore designed to identify physiologically relevant solvent systems that closely replicate these biological fluids, thereby improving the accuracy and clinical relevance of Extractable and Leachable (E&L) extraction studies for face masks. **Methods:** The solvent selection was guided by Hansen Solubility Parameters (HSP) method, which describe dispersive (δ_D), polar (δ_P), and hydrogen bonding (δ_H) interactions. The chemical composition of mucus, saliva, sweat, and water was analyzed to determine their solvation characteristics. Candidate solvents were evaluated based on their HSP proximity to biological fluids. **Results:** Mucus and saliva, characterized by moderate polarity and strong hydrogen bonding capacity, showed the closest match with 20% ethanol in water (Semipolar solvent) (δ_D : ~16.0, δ_P : ~13.0, δ_H : ~26.0 MPa^{1/2}). This solvent improved extraction of semi-polar leachable while maintaining physiological relevance. PBS and saline effectively simulated the ionic strength of sweat but exhibited limited solvation power for hydrophobic compounds. Higher ethanol concentrations (>30%) led to over-extraction beyond realistic exposure conditions. Also, solvent composition of ethanol/water mixtures remained stable during extraction, with no evidence of ethanol loss or selective polymer absorption, supporting their consistency as simulating solvents. **Conclusions:** Based on HSP correlation and compositional similarity, 20% ethanol in water was identified as an optimal semi-polar solvent

for E&L extraction from face masks. It provides a balanced representation of mucus, saliva, sweat, and water environments, enabling more realistic and comprehensive detection of leachable from condensate.

PS 3076 Temporal Profiling of VOS Emissions: Accelerated Aging and Reprocessing of Breathing Gas Path Medical Devices for Biological Safety Assessments

S. Zheng, R. Nguyen, and D. Faulk. Philips, Murrysville, PA.

Background and Purpose: Volatile organic substance (VOS) emissions are a key determinant of the biological risk profile for breathing gas path medical devices. Recent updates to ISO 10993-1:2025 and ISO 18562-1:2024, have amplified focus on lifetime evaluation of breathing gas path devices as a part of the biological safety assessment. Here, we present VOS emission profile from a breathing gas path device over its useful life and additional considerations on the impact of exaggerated and clinically relevant reprocessing methods on the VOS output. **Methods:** Breathing gas path medical devices composed of polymer and metallic material classes were accelerated aged to their intended useful life, following methods outlined by ASTM F1980-21. A subset of aged devices underwent cleaning and disinfection (C&D) reprocessing following either clinically relevant or exaggerated cycle counts based on device IFUs. All aged breathing gas devices' VOS emissions were quantified using methods described in ISO 18562-3 at defined time points across the device's useful life. Emitted compounds were categorized into chemical classes and toxicologically evaluated using methods described in ISO 10993-17:2023. **Results:** Across all devices, both the number and concentration of emitted compounds decreased significantly over the simulated lifetime. Quantitative analysis demonstrated that dominant chemical classes, i.e., alkanes, organosilicon compounds, carbonyl compounds, and benzoyl derivatives decreased by 97.97%, 76.64%, 77.37%, and 89.14%, respectively, from initial (t = 0 year) to final (t = 5 year) time points. No new chemical classes were generated at the end of the device's useful life compared to initial testing. The dominant classes of chemicals detected were traceable to the materials of construction of the device, and all new compounds remained well within health-based thresholds for the intended population. For devices that received exaggerated C&D reprocessing methods (i.e., cumulative exposure to C&D agents after aging), VOS emissions were largely unchanged in chemical class composition, except for one hospital disinfecting method, where a respiratory sensitizer was identified in the VOS emission testing following an exaggerated cleaning approach. Confirmatory testing verified that the sensitizer was reduced to below quantifiable levels when clinically relevant reprocessing cycles were applied. **Conclusions:** VOS emissions significantly declined throughout the device's useful life, and exaggerated reprocessing had limited impact on chemical class composition. However, for C&D agents with the potential to cause respiratory sensitization, verification studies should be designed to ensure clinically relevant use-case scenarios are considered. These findings suggest that, with comprehensive material characterization and stability assessment, initial post-manufacture VOS emission testing can reliably inform biocompatibility risks across the full useful life of breathing gas path medical devices.

PS 3077 PFAS-Free Coverlay Material Change Assessment in SpO₂ Sensors: Biological Equivalence via E&L Study

M. Mo¹, K. Chatani², R. Koning², G. Cnossen², and J. Wong³. ¹Philips, Cambridge, MA; ²Philips, Drachten, Netherlands; and ³Philips, Murrysville, PA.

Background and Purpose: This presentation describes how an extractable and leachable (E&L) study, combined with cytotoxicity screening, enabled expedited biocompatibility assessment following a sudden material change in an SpO₂ sensor's (SS) intact skin contacting coverlay. In addition to adults, the intended population includes sensitive groups such as pregnant women and pediatric patients, with prolonged exposure (i.e., a typical use scenario of 7 days, up to 29 days). The coverlay was switched to a proprietary PFAS-free alternative, making immediate determination of biological equivalence challenging. To address this urgent supply chain disruption and ensure continued critical patient care, a fast-tracked biological and toxicological risk assessment was conducted. **Methods:** The overall approach was to establish biological equivalence in accordance with ISO 10993-18. The evaluated endpoints included physical and chemical characterization, cytotoxicity, irritation, and sensitization, as specified in ISO 10993-1. The risk-based assessment began with hazard identification, utilizing supplier-provided technical and regulatory compliance documentation, as well as public databases such as FDA, ECHA, and PubMed. To further establish chemical equivalence and to identify potential chemical hazards, the E&L study design was designed per ISO 10993-18, extracting the final finished SS coverlay with neat 2-propanol (100% IPA) at 50±1°C (an exaggerated condition), due to its affinity for both polar and non-polar compounds. SS extracts were collected at 0, 24, 48 and 72 hours to assess kinetic profiles (ISO 10993-12). Compounds identified Gas Chromatography-Mass Spectroscopy (GC-MS) were derived from triplicate extracts. The subsequent toxicological risk assessment was conducted in accordance with ISO 10993-17. **Results:** The new PFAS-free coverlay base resin, polyester (PET), is considered safe for intact skin use. There are no other differences in colorants, curing, or dispensing agents, all of which have previously been deemed biocompatible. To evaluate the new component, i.e. an undisclosed flame retardant (FR), the

SS exaggerated E&L profile was assessed as the worst-case exposure at 50±1°C, compared to the maximum operating temperature of 41°C. The study showed that no compound was released above the limit of quantitation (LOQ). The worst-case FR exposure estimation, based on the LOQ and assuming 100% dermal absorption, resulted in 7-day and 29-day exposures of 24.1 µg/day and 99.9 µg/day, respectively. A point of departure of 1,000 mg/kg/day (NOAEL or No-observed adverse effect level, for developmental and reproductive toxicity) was selected for the FR. The calculated margins of safety (MoS) were well above 1 (>600,000 for 7 days, and >150,000 for 29 days) based on the respective estimated exposure duration. The final finished SS extract met ISO 10993-5 requirements, with a grade 2 mild reactivity. The lack of quantifiable E&L's further supports the low toxicity risk as indicated by the mild cell reactivity. This screening also addresses any potential new manufacturing hazards. Biological equivalence with the predecessor was established given the chemical, material, physical and endpoint equivalence assessed above. Passing *in vivo* skin sensitization and irritation test results further supports the risk-based approach per the ISO 10993 series and the FDA's "3Rs" principle to replace, reduce, and/or refine animal use in testing when feasible. **Conclusions:** The SpO₂ sensor with the PFAS-free overlay is biologically equivalent to its predecessor. Therefore, the sensor is biocompatible if used as intended. The E&L and risk assessments demonstrated that the PFAS-free alternative does not introduce new or increased biological risks in the final device, supporting its safe and timely adoption.

PS 3078 Alternative Positive Control Material for the XTT and MTT Cytotoxicity Test ISO 10993-5 for Medical Devices

C. Kalimtzi, R. Koch, M. Bobiak, and G. DeGeorge. MB Research Laboratories, Spinnerstown, PA.

Background and Purpose: Cytotoxicity testing is a key endpoint to be addressed during the biological risk assessment of medical devices. The XTT and MTT Cytotoxicity Tests are widely accepted quantitative methods recognized by regulatory agencies when performed in accordance with International Organization for Standardization (ISO 10993-5: Biological Evaluation of Medical Devices Part 5: Tests for *In Vitro* Cytotoxicity). In these biocompatibility tests, a positive control material that produces a cytotoxic response must be tested in parallel. Currently, the standard recommends a polyurethane film containing zinc diethyldithiocarbamate (ZDEC) or zinc dibutylthiocarbamate (ZDBC) as a positive control material; however, these materials have a limited availability. Previous work identified hypoallergenic silk tape as a suitable positive control material for use in the MEM Elution Cytotoxicity Test, a qualitative method. The purpose of this study was to evaluate whether Hypoallergenic Silk Tape can also serve as a suitable positive control material for the XTT and MTT Cytotoxicity Tests, which are quantitative in nature. **Methods:** Six independent runs of XTT cytotoxicity tests and six independent runs of MTT cytotoxicity tests were performed. Each run included six concentrations of the positive control, tested in sextuplicate. Extracts were prepared in accordance with ISO 10993-12: Biological Evaluation of Medical Devices Part 12: Sample Preparation and Reference Materials. The extraction medium consisted of Eagle Minimum Essential Medium (without phenol red) supplemented with 10% fetal bovine serum, 4mM Glutamax™, 100 IU/ml penicillin, and 100 µg/ml streptomycin (EMEM-PR10). Hypoallergenic Silk Tape was extracted at a surface area-to-volume ratio of 6 cm²/ml (for material thickness < 0.5 mm). Negative control (high-density polyethylene, to assess background cellular response) and vehicle control (extraction solvent only, to evaluate possible confounding effects due to the extraction vessel, vehicle, or extraction process) were prepared. All extraction vessels were incubated for 24 hours at 37°C under continuous agitation. This temperature allowed for maximal extraction, while remaining below the softening temperature of the test samples, and without adversely impacting the chemistry and/or stability of the serum and other constituents in the extraction solvent (culture medium). The outer 36 wells of each 96-well plate were each filled with 100 µl of EMEM PR10. The remaining 60 central wells were seeded with 100 µl of L929 mouse fibroblast cells at a density of 1 x 10⁵ cells/ml (1 x 10⁴ cells/well). Plates were incubated for approximately 24 hours at 37°C in a humidified atmosphere containing 5% CO₂ to allow formation of a sub-confluent monolayer. Within 24 hours of extraction preparation, the positive control extract was assessed at six concentrations, 100% (neat) and, 50%, 25%, 12.5%, 6.25%, and 3.13% (v/v) in EMEM-PR10. Each concentration was applied in sextuplicate and incubated for 48 hours at 37°C and 5% CO₂ for 48 hours. Following incubation, cell viability was assessed using XTT or MTT assay, according to standard procedures. **Results:** Viability reduced to < 70% of the blank is considered a cytotoxic effect. In the XTT cytotoxicity assay, cell viability decreased to below 70% following exposure to 100% and 50% concentrations of the positive control extract of Silk Tape. A clear dose-dependent response was observed. The average cell viability following treatment with the negative control and vehicle control was 96.8% and 97.9%, respectively, which is the expected response of these materials in the test system. In the MTT cytotoxicity assay, cell viability decreased to below 70% following exposure to 100%, 50%, and 25% concentrations of the positive control extract of Silk Tape. A clear dose-dependent response was observed. The average cell viability following treatment with the negative control and vehicle control was 98.2% and 105.3%, respectively, which is the expected response of these materials in the test system. **Conclusions:** Hypoallergenic Silk Tape was determined to be cytotoxic under both testing conditions and was shown to meet the positive control requirements of the XTT and MTT cytotoxicity tests as described in ISO 10993-5.

PS 3079 Passivation, Electropolishing and Anodization as Surface Residue Mitigation Steps for Biocompatibility Risk Management in Medical Device Manufacturing—A Retrospective Analysis

K. Godlewska¹, C. Graham², M. Frohbergh³, S. Kalyan³, R. Viswanadha², and P. Hasgall¹. ¹Zimmer Switzerland Manufacturing GmbH, Winterthur, Switzerland; ²Zimmer Inc., Warsaw, IN; and ³Exponent, Menlo Park, CA.

Background and Purpose: Medical device biocompatibility evaluation per ISO 10993 is a risk management approach that involves a manufacturer evaluating existing relevant data from all sources, such as raw materials, process flow information, clinical history, etc., to identify any gaps in the data supporting biological safety. Reviewing all available data facilitates a comprehensive assessment for determining if new testing is required. This optimizes the manufacturer's resources, ensures the ethical use of animals per ISO 10993-2, and promotes timely, economic access of device technologies to healthcare providers and patients. Included in the hazards that can lead to biocompatibility risks are manufacturing material or processing aid residues that can remain on a device following manufacturing and become sources of clinical leachables. However, manufacturing processes often have built in steps that modify the surface of devices and intrinsically remove these residues which, in turn, can mitigate the risks stemming from surface residues. Passivation, electropolishing and anodization, which are chemical or electro-chemical processes employed on metallic devices to increase corrosion resistance (passivation, electropolishing, and anodization), reduce surface roughness (electropolishing), and impart a color (anodization), are examples of surface modifying processes that have the potential to mitigate manufacturing material residues on the device surface from previous manufacturing steps. However, there is a paucity of reports providing empirical evidence supporting that these processes can effectively mitigate medical device surface residues to toxicologically insignificant levels. **Methods:** A retrospective review of a medical device manufacturer's library of ISO 10993-18 extractables test data was performed to correlate the quantity and type of extractable identified on devices to the types of surface modification processes performed on the devices and the manufacturing materials used. The goal of this analysis was to determine if passivation, electropolishing, and anodization effectively remove manufacturing material residues from upstream manufacturing steps. It was also aimed at determining what, if any, limitations apply when considering these processes as biocompatibility risk mitigation steps. **Results:** Extractables test data from 112 devices with different surface modifications were reviewed. The passivation, electropolishing, and anodization subsets (18, 9, and 13 devices, respectively) were amongst the groups demonstrating the lowest total device residue burden, when considering both the per device surface area median residue amounts and range of residue amounts across all devices in each subgroup. When considered individually, all extractables identified on electropolished and anodized devices that were able to be plausibly traced to manufacturing materials were associated with manufacturing materials used in the surface modifying steps or operations thereafter. Most extractables identified on passivated devices were able to be plausibly traced to manufacturing materials from the passivation step or subsequent operations. Some extractables were linked to materials used before passivation, but these were associated with in-process cleaning prior to passivation and/or were present at toxicologically insignificant levels. As part of the review, factors impacting the effectiveness of passivation, electropolishing, and anodization as surface residue mitigation steps were also identified. **Conclusions:** Passivation, electropolishing, and anodization can be used within defined limitations to support the mitigation of upstream manufacturing material surface residues in biocompatibility risk management. When applied appropriately considering these limitations, biocompatibility risks from residues stemming from manufacturing materials used prior to these surface modification steps can be considered negligible. Importantly, taking advantage of these steps often already built into manufacturing processes can reduce and possibly eliminate the need for animal testing and optimize resource management and device time to market.

PS 3080 Worst-case Selection in Medical Device Toxicity Risk Assessment

S. Wu, J. Hakimi, S. Dubin, J. Weng, M. Lewis, S. Mimche, J. Wilsey, S. Citrowske, E. Rufer, R. Shulfer, and M. Kamberi. Abbott Laboratories, St. Paul, MN.

Background and Purpose: According to ISO 10993-17:2023 (Clauses 8 and 5.1.3), toxicological risk assessments for medical devices shall consider worst-case use scenarios. Factors relevant to worst-case exposure include the rate or extent of constituent release, the predictable maximum number or quantity of devices a patient may be exposed to, and the lowest body weight of the exposed population. Traditionally, worst-case devices are selected based on the largest surface area or mass. However, this method may not be appropriate when different device sizes are used across diverse patient populations. **Methods:** To address this complexity, we introduce the concept of the worst-case estimated exposure dose for medical devices (WCEED), derived from the maximum estimated exposure dose (EEDmax) of constituents for a given clinical scenario in ISO 10993-17. A formula is proposed to calculate WCEED, and three case examples are presented to demonstrate its application in toxicological risk assessment. **Results:** 1. Formula for worst-case medical devices selection in toxicity risk assessment $WCEED = N \times (\text{mass or surface area})$ of a device / BW_L Where: WCEED = worst-case estimated exposure dose for medical devices, the unit is g (or cm²)/kg body weight. The greatest value is the worst -case

scenario N = the maximum number of devices that may be used in a patient simultaneously. The number shall align with instructions for use in each patient's population. BW_L = lowest body weight of patients under the device use condition Note: patients < 6 months will be excluded from older patients due to special considerations. 2. Example A. Device A1 is identical to A2 (each device weight is w) and a maximum 2 devices can be applied in a patient. A1 can be applied in adults only (60 kg), A2 in adults and children (20 kg). $2w/60$ is less than $2w/20$, thus A2 used in children is the worst-case scenario. 3. Example B. same process aid changes in devices B1, B2, B3, and B4. They are long-term tissue-contacting implant devices. Maximum device quantity in a patient are 2 for all the devices. In Devices B1, B2, B3, and B4, patient-contacting mass of process aid is 0.4, 0.5, 1.2, and 1.4 g, respectively. Lowest patient body weight is 20, 20, 60, and 60 kg, respectively. WCEED is 0.04, 0.05, 0.04, and 0.047 g/kg body weight. Therefore, Device B2 in 20 kg patient is the worst-case scenario. 4. Example C. Same process aid changes in devices C1, C2, C3, and C4, all of which are long-term blood contacting devices. Patients are ≥ 6 months old. In devices C1, C2, C3, and C4, patient-contacting mass of process aid 15.6, 12.8, 4.8, and 7.7 g, maximum device quantity per patient is 1, 2, 1, and 2, and the lowest body weight is 60, 10, 6, and 10 kg, respectively. Therefore, WCEED is 0.26, 2.56, 0.8, 1.54 g/kg body weight, respectively, and device C2 in 10 kg patient is the worst case scenario. **Conclusions:** This quantitative approach to worst-case device selection is effective in diverse clinical scenarios and a scaling factor (SF) may be applied to approximate worst-case exposure when the worst-case device was not selected a priori. An advantage of that is that one could, if they so choose, derive distinct worst case exposure scenarios for different patient populations, all based off an E&L study. It provides a systematic and transparent method that complements ISO 10993-17 guidance, enhancing the rigor and clarity of toxicological risk assessments.

PS 3081 Toxicological Risk Based Particulate Acceptance Criteria for Medical Device Manufacturing

S. Parvez, A. Sharma, J. Tessier, and S. Dutta. Intuitive Surgical, Sunnyvale, CA.

Background and Purpose: FDA (Food and Drug Administration) and USP<790> require medical devices to be essentially free of visible particulates (VP, size $\geq 0.1\text{mm}$) and limit their occurrence. However, particulates are unavoidable in manufacturing environments, originating from intrinsic sources (e.g., manufacturing, assembly, packaging) and extrinsic sources (e.g., fibers, skin cells, atmospheric dust). While manufacturers employ cleanroom protocols, inspections, and quality controls, complete elimination of particulates remains difficult. This challenge is exacerbated by stringent acceptance criteria, often adapted from USP<788> for injectable products—without regard for device-specific factors like contact duration (short, prolonged), type (blood, tissue, skin), manufacturing processes, and materials. Consequently, unwarranted non-conformances and product rejections occur. This work proposes a toxicological risk-based approach to setting particulate acceptance criteria for medical device manufacturing. The approach guides manufacturers in establishing practical acceptance limits based on existing guidelines and toxicological safety thresholds, aiming to minimize undue rejections without compromising patient safety. **Methods:** We present a risk-based methodology, validated against safe toxicological limits for common chemicals, including systemic toxicants and carcinogens. Leveraging USP<788> our method extrapolates VP thresholds and introduces "Equivalence Surface Area" (ESA) to account for variability in particulate shape/size, focusing on total surface area (SA) versus particulate count. Exposure risk (dose) is estimated to be using the heaviest likely material (e.g., stainless steel) as a worst case, ensuring broad safety for all material types lighter than stainless steel. The calculated maximum dose is then compared against established Toxicity Screening Limits (TSL, ISO 10993-17) and mutagenicity guidelines (ICH M7 R1). If exposure is below these thresholds, the ESA is deemed acceptable, and can be used for setting visual inspection plan, reducing unnecessary non-conformances. **Results:** This proposed approach is demonstrated here using a real-world example. We extrapolated the acceptable VP count from USP<788> subvisible particulate (SVP) guidance, which limits (600 particulates $>0.025\text{mm}$). We compared SA of VP and SVP (SA of 0.1 mm VP $\div$ SA of 0.05 mm SVP = 4). This yields a VP count of 150 (600 $\div$ 4). The allowable surface area threshold for total VP on a device is thus 1.5 mm^2 ($150 \times 0.01\text{ mm}^2$). For the worst-case exposure (mass) calculation—stainless steel (density 8mg/mm^3), total SA of 1.5 mm^2 and thickness of 0.010 mm resulted in mass equal to $120\text{ }\mu\text{g/device}$ (Mass=Density*SA*Thickness). This amount meets TSL and ICH M7 R1 impurity criteria, indicating an acceptable risk from particulate exposure. Thus, adopting a total acceptable criterion of 1.5 mm^2 per device provides a protective threshold. Manufacturers may use this approach to derive their own acceptance criteria for particulates based on the nature of device contact, material types, and manufacturing complexity. However, it is also important to consider particulate shape and size for cardiovascular devices, as these factors may increase clinical risk and should be reflected in the acceptance criteria after clinical inputs. **Conclusions:** The proposed approach offers a robust, pragmatic solution to particulate challenges in medical device manufacturing. By integrating toxicological risk assessment, ESA-based thresholds, and established guidelines (USP<788>, ISO 10993-17, ICH M7 R1), manufacturers can implement acceptance criteria that balance real-world risk and patient safety. This approach addresses the limitations of particulate count metrics, considers material and device-specific variables, and reduces unnecessary non-conformances and supply interruptions, while also proactively incorporating toxicological principles into particulate evaluation rather than

addressing safety concerns only after issues arise. **The views, interpretations, and conclusions expressed in this abstract are solely those of the authors and do not necessarily reflect the official policies or opinions of their employer.**

PS 3082 Tailored E&L Strategies for Hyaluronic Acid Medical Devices: A Foundation for Toxicological Risk Assessment

H. Gehrke¹, S. Baur¹, S. Holzmayer¹, and M. Doerkes². ¹Eurofins Medical Device Testing Munich GmbH, Robert Koch Straße 3a, Munich/Planegg, Germany; and ²Eurofins Medical Device Consulting Services GmbH, Robert Koch Straße 3a, Munich/Planegg, Germany. Sponsor: H. Gehrke, EUROTOX

Background and Purpose: Hyaluronic acid (HA)-based products are widely used in medical applications such as intra-articular injections, ophthalmic solutions and dermal fillers. Although they differ significantly in form and function from traditional solid medical devices (e.g., implants or catheters), they are nonetheless classified as medical devices under applicable regulatory frameworks. This classification is based on their primary mode of action, which is physical rather than pharmacological for example, by providing lubrication, hydration or mechanical support. Due to their gel-like, non-solid nature, HA-based products pose unique challenges for chemical characterization and subsequent toxicological risk assessment. Standard extractables and leachables (E&L) methodologies, following ISO 10993-18 requirements, developed for solid polymeric or metallic devices are often not applicable. Therefore, tailored extraction and evaluation strategies were developed for the analysis of E&L compounds from HA-based products. **Methods:** Due to the varying textures of the HA-based products, different approaches were applied. For highly liquid gels, the medical device was dissolved in 0.9% saline and directly injected. For more viscous gels, the HA-based product was first enzymatically digested using hyaluronidase. Prior to analysis the calculation of the analytical evaluation threshold was performed (AET) for each method. The resulting solution was then directly injected into analytical systems. Furthermore an extraction of the HA-based products with isopropanol and/or n-hexane was performed. In addition, multiple analytical techniques were employed to characterize volatile, semi-volatile and non-volatile E&L compounds, as well as elemental impurities, including headspace GC-MS, GC-MS, UHPLC-HRMS, and ICP-MS. The identification of the E&L and HA-derived compounds was performed by using a customized multi-dimensional database combined with detailed analysis of fragmentation patterns for individual compounds. Complementarily, a toxicological risk assessment was performed in accordance with ISO 10993-17. **Results:** In total, seven different HA-based products were evaluated. One major challenge, besides the extraction procedure, in the analysis of the HA-based medical devices is that the product itself as well as the degradation products and additives are detectable by GC-MS and UHPLC-HRMS. A total of 113 compounds exceeded the applied AET in UHPLC-HRMS analysis, while 637 compounds were detected by GC-MS. Using a tailored in-house database combined with fragmentation pattern analysis, most detected compounds were assigned as product-derived or product-related. In addition, compounds such as acetyltributylcitrate (CAS 77-90-7), a common plasticizer, and 3-acetamidofuran (CAS 59445-85-1), identified as a manufacturing contaminant, were detected in some products. ICP-MS analysis revealed the presence of elements including phosphorus (P), silver (Ag), and tungsten (W) in certain samples. No compounds above the respective AET were detected in headspace analysis. All substances detected in amounts exceeding the applicable AET value were further subjected to the toxicological risk assessment. **Conclusions:** The chemical characterization and toxicological assessment of HA-based products is particularly challenging especially when focusing on the "standard" extraction-based procedures developed for medical device evaluation. However, using a combination of customized work-up procedures, including direct injection, enzymatic digestion and/or apolar solvent extraction, a complete E&L analysis can be achieved for these complex systems. The database-driven identification approach combined with the detailed analysis of fragmentation patterns enabled the assignment of most detected compounds across all analytical platforms and samples. This established approach ensures the analytical investigation and toxicological risk assessment of HA-based products, thereby strengthening the overall biological risk assessment of these medical devices.

PS 3083 Setting the Benchmark for Hemocompatibility: Advanced Testing for Transfusion Devices according to ISO 1135

T. Gehring, M. Müller, and H. Gehrke. Eurofins Medical Device Testing Munich GmbH, Robert-Koch-Straße 3a, Planegg, Munich, Germany. Sponsor: H. Gehrke, EUROTOX

Background and Purpose: In addition to the horizontal standards for hemocompatibility testing like ISO standard 10993-4, there are several vertical standards addressing the need of individual types of devices. The ISO standard 1135-4/-5 provide a comprehensive framework for the hemocompatibility analysis of transfusion equipment used in medical settings. These standards ensure that the equipment is safe and effective for blood transfusions, minimizing the risk of adverse reactions in patients. While ISO 1135-4 focuses on transfusion equipment that operates with gravity feed, ISO 1135-5 addresses transfusion equipment used with pressure infusion apparatus. In 2025, these two guidelines were revised and the relevant sections

on the testing for hemocompatibility were replaced mentioning testing of hemolysis, coagulation and platelet activation and complete blood count in accordance with ISO 10993-4. However, our experience shows that regulatory bodies still prefer testing with separate blood components planned for administration mimicking clinical settings. Since the design of such a study has various pitfalls, we outline general considerations that should be taken into account. **Methods:** The design of this kind of study is tailored to the individual customer taking the real-world conditions into account. Thus, the following points should be taken into account: different flow rates, VTBI (volume to be infused), maximal time of use of the sets, etc. Further, the number of separate donors used should be determined based on the planned risk assessment and statistical analysis. The purely experimental procedure involves simulating clinical application of the test item. The corresponding blood product is connected to the transfusion device and the flow-through is performed based on the relevant parameters of the test design (VTBI, flow rate, etc.). Baseline values are taken prior to testing and are compared to samples taken after passage through the transfusion set. **Results:** When evaluating the hemocompatibility of transfusion equipment in accordance with ISO 1135-4 and -5, two critical assessment parameters are considered: retention and damage/activation of blood components in samples taken after passage through the transfusion set. Depending on the blood product used, different factors are considered for evaluation. For retention, the relevant constituents total hemoglobin, platelet count and Factor VIIIc are monitored. In parallel, the degree of hemolysis, platelet activation (e.g. β -Thromboglobulin release) and coagulation activation (e.g. formation of thrombin-antithrombin (TAT) complexes) are determined to assess the damage and activation. The different endpoints are determined using Cell counter, ELISA and/or chromogenic assays in samples taken prior to and after passage through the transfusion device allowing determination of the effects of tested test items. Our experience shows that the correct design of such a study strongly influence the regulatory acceptance and scientific weight. In general, it is recommended to discuss the planned design with regulatory bodies before execution of such studies because in the past, the analysis of effects on further plasma proteins such as Protein S and C, vWF protein and the Complement system was requested. **Conclusions:** The recent revisions of ISO 1135-4 and -5 align hemocompatibility testing requirements more closely with ISO 10993-4, emphasizing standardized endpoints such as hemolysis, coagulation, platelet activation, and complete blood count. However, regulatory expectations often extend beyond these guidelines, favoring study designs that replicate clinical conditions using separate blood components. This approach introduces significant complexity, requiring careful consideration of flow rates, VTBI, duration of use, and donor variability to ensure robust and scientifically meaningful results. Ultimately, a well-designed, clinically relevant study enhances both compliance and confidence in the safety and performance of transfusion equipment.

PS 3084 Refining Medical Device Chemical Safety Risk for Pediatric Patients: A Theoretical Case Study Considering Children Growth Trajectory

X. Dai, Z. Xia, J. Weng, E. Rankin, C. LaSalle, S. Zhang, E. Rufer, S. Citrowske, R. Shulfer, and M. Kammeri. Abbott Laboratories, St. Paul, MN.

Background and Purpose: Chemical toxicity is a critical component of device risk assessment. The ISO 10993-17:2023 introduces new tools to harmonize risk evaluation, including assumed exposure durations. It also provides specific guidance for pediatric population, acknowledging their unique physiological vulnerabilities with very conservative default body weight assumptions: 3.5 kg for infants (<1 yr) and 10 kg for children (>1 yr to ≤ 16 yrs), but not reflecting normal growth trajectory. Percentile charts published by WHO and US CDC, along with default values derived from survey data published by regulatory bodies for risk assessors (US EPA, Health Canada, EFSA, US ATSDR), offer a more representative basis for pediatric population. This case study explores how conservatism in ISO 10993-17 may overestimate risk and proposes a weight of evidence approach incorporating realistic pediatric growth to refine risk. **Methods:** Pebax, a thermoplastic elastomer composed of flexible polyether and rigid polyamide segments, is widely used in devices. The polyamide derived from lactam monomers forms the hard segment, while polyether (polytetrahydrofuran or PTHF) constitutes the soft segment. Barium sulfate is often added to materials to impart radiopacity. Lactams, PTHFs, and barium are published extractables from Pebax based devices in literature. A theoretical patient exposure scenario of these chemicals was analyzed, including 3 pediatric age groups: newborn to <6 months, 6-12 months, and ≥ 12 months. For each group, 3 assumed exposure durations within a 1-yr period were considered: ≤ 1 d, 2-30 d, and 31-365 d. The TRA followed ISO 10993-17 framework was conducted, involving a systematic review of adverse effects from chemical exposure. Key steps included the calculation of EED_{max} incorporating default body weight values from ISO 10993-17, US EPA, Health Canada, and EFSA, establishing TI for systemic harm-related toxicity endpoints, and determining and comparing MOS for each scenario. **Results:** Due to the lack of short term toxicity studies (≤ 1 d and 2-30 d), PODs for TIs were conservatively derived from longer duration subchronic toxicity studies. For infants aged ≤ 6 months, an additional UF of 3 was applied to chemicals primarily eliminated via hepatic metabolism or renal excretion, lactams and PTHFs, but not barium, which is not metabolized through those pathways. Newborn to <6 Months: For durations ≤ 1 d and 2-30 d, MOSs were only impacted by the additional UF of 3. For the 31-365 d duration, MOSs were not only inversely proportional to the default body weight values but also significantly impacted by the growth trajectory. The use of age specific default values (1-3

m, 3-6 m, and 6-11 m) by US EPA, Health Canada, or EFSA provided up to 8-fold higher MOS than by ISO 10993-17, reflecting the rapid growth trajectory in this age group. 6-12 Months: MOSs for ≤ 1 d and 2-30 d were only affected by the use of default body weight, due to less body weight variability within a month. For the 31-365 d duration, MOSs were again inversely related to default body weight. The inclusion of age specific subgroups (6-11 m and 1 to <2 yrs) refined to 2.6-fold higher MOS to account for continued growth during this period. ≥ 12 Months: Across all 3 exposure durations, MOSs were associated with body weight assumptions. In some subgroups, MOSs were up to 6-fold lower when using ISO 10993-17 defaults compared to defaults by agencies. **Conclusions:** This case study highlights the layered conservatism inherent in current practice, especially for pediatric population. Our findings demonstrated that the combination of conservative assumptions, e.g. reliance on subchronic toxicity data for short term exposure, additional UF to account for immature toxicokinetic, and assumed complete oligomer breakdown, collectively result in significantly overestimated risk. Especially, the default values specified in ISO 10993-17 are intentionally protective but do not reflect actual pediatric growth trajectories, potentially compounding overall conservatism as MOS is sensitive to body weight assumptions and exposure duration in pediatric. Incorporating age specific data from regulatory agencies enables more accurate pediatric exposure estimation by considering growth trajectories and age subgroups, supporting balanced, evidence based device safety decision and aligning with broader regulatory practices.

PS 3085 Defining the Chemical Space of Extractable and Leachables Found in Medical Devices

C. S. Barousse, C. Chatman, D. Patwardhan, M. Eppihimer, and A. Powell. US FDA, Silver Spring, MD.

Background and Purpose: The threshold of toxicological concern (TTC) is a risk assessment tool that establishes exposure levels for chemicals, below which there is a low probability of adverse health effects. It is especially useful for chemical constituents that have limited toxicity data available. Application of the TTC is not appropriate for Cohort of Concern (CoC) chemicals because CoCs are a class of highly potent, mutagens and carcinogens that pose a significant health risk at low exposures. The TTC has been applied to assess the safety of chemical constituents across multiple industries including food, pharmaceuticals, and medical devices, but to date there is no standardized list of CoCs specific to medical devices, which in turn leads to inconsistencies in assessing potential risk. To elucidate which chemical constituents, including cohorts of concern, are relevant to the chemical space of medical devices, extractable and leachables (E&L) profiles with the corresponding toxicological risk assessment from regulatory submissions were collected and curated into a single database. **Methods:** Data-mining and computational methods were utilized to compile extractable and leachable reports and corresponding toxicological risk assessments included in regulatory submissions from an internal FDA data repository. A combination of keyword searching and manual review of 4,000+ premarket notification (510(k)s) and premarket approval (PMAs) submissions was conducted to identify ones that included E&L testing and matching toxicological risk assessment. Extractable leachable testing included non-targeted and targeted analysis in the dataset. A document scraping Python script was applied to optimize data transfer from a multitude of layouts of chemical characterization and toxicological risk assessment reports to a consistent format. Subsequently, all outputs were reformatted and collated. **Results:** Extractable and leachable profiles and toxicological risk assessments from submissions were collated into a single database, referred to hereafter as ELTRA. The dataset contains 27,852 entries and consists of 3,227 unique compounds that are identified by name and at least one other identifier (i.e. CASRN). Where available, the following fields were populated: material of device, analytical technique (e.g. GC-MS), solvent of analytical technique (e.g. hexane), confidence level of identification (e.g. confident), chemical formula, retention time, mass, concentration, whether TTC was applied, whether the toxicological screening limit (TSL) was applied, tolerable intake (TI) calculation, and margin of safety (MoS) calculation. 30.5% of the entries have the MoS calculation field populated. ELTRA was compared to other lists of known toxic chemicals, or potential CoCs: Cheeseman et al. (1998) and WHO IARC Monographs on the identification of carcinogenic hazards to humans. Out of the 701 potential CoCs listed in the Cheeseman paper, 33 were found in ELTRA, out of the 621 Group 1, 2A, and 2B carcinogens identified by IARC, 49 were found in ELTRA, and 6 potential CoCs found in ELTRA were listed in both the Cheeseman paper and IARC Monographs. 68.5% of the submissions mined for data included at least one potential CoC. **Conclusions:** By leveraging the variety of medical devices that are reviewed by the FDA for chemical characterization, biocompatibility, and toxicology, this works establishes a foundational survey of the medical device chemical space and CoCs pertinent to medical devices specifically. This work can help inform the chemical space relevant to medical device.

M. Annunziato, R. Rathnayake, K. Patel, J. Kim, E. Miller, and S. Wickramasekara. US Food and Drug Administration, Silver Spring, MD. Sponsor: *B. Oktom*

Background and Purpose: Medical devices contain various chemical components including polymer additives, processing aids, and manufacturing residues that may migrate and pose safety concerns to patients. Extractables and leachables (E&L) analysis serves as a basis for identifying these compounds and enabling comprehensive toxicological risk assessment (TRA) of medical devices. Conventional non-targeted liquid chromatography-mass spectrometry (LC-MS) approaches utilizing high-resolution mass spectrometry (HRMS) deliver precise mass measurements and detailed fragmentation patterns. However, these methods frequently encounter difficulties with spectral interpretation due to matrix complexity and inadequate chromatographic resolution of structurally related compounds. The integration of ion mobility spectrometry (IMS) with HRMS provides an additional dimension of separation based on molecular collision cross-section (CCS), which correlates with ion geometry, size, and charge distribution. This study proposes criteria for integrating IMS into E&L analyses and highlights its promising role in advancing future chemical identification methodologies. **Methods:** Twelve different polymer materials were extracted using water, isopropyl alcohol, and hexane as solvents to ensure wide range of compound recovery across a broad polarity spectrum. Extracts were analyzed using Agilent 6560 IM-QTOF LC-MS system in data-independent acquisition (DIA) mode to collect comprehensive MS/MS spectra across all precursor ions. This reduces the data-dependent acquisition (DDA) limitations that may miss low-abundance or co-eluting compounds. Using PNNL PreProcessor software, all ions IM/MS mobility-aligned fragmentation data were converted into a standard LC-MS DDA file format for downstream analysis in Agilent Mass Profiler and Qualitative Analysis software. **Results:** IMS provided clear improvements in resolving poorly separated LC peaks, particularly in complex polymer extracts where traditional LC-MS/MS often struggles to distinguish overlapping or co-eluting compounds. Our data demonstrated that in the case of separating isobaric and co-eluting species, IMS enhanced resolution and reduced the likelihood of false identifications. Drift-time alignment further improved spectral clarity by filtering out background ions and unrelated fragments, resulting in cleaner and more accurate MS/MS data. These translated into higher identification confidence where IMS-DIA identified more compounds than DDA, supported by increased fragmentation coverage and the ability to confirm assignments using CCS values. **Conclusions:** IMS-enhanced HRMS combined with DIA improves E&L chemical identification by increasing sensitivity, selectivity, and reliability through enhanced spectral clarity, fewer misassignments, and broader ion coverage. Incorporation of CCS measurements provides a robust structural descriptor that further increases specificity and confidence in identifying compounds within complex extract matrices. Collectively, these capabilities deliver a more comprehensive and dependable approach for non-targeted chemical identification.

PS 3087 **Solvent properties and the effect on extraction kinetics from silicone rubber**

J. Hill, M. Alam, and K. Sapkota. US FDA, Silver Spring, MD. Sponsor: *A. Powell*

Background and Purpose: The properties of silicone have led to its broad usage as a material of construction in medical devices. The safety of these devices is evaluated based on the extractable chemicals collected and analyzed according to ISO 10993-18:2020, and assessed for their toxicity based on ISO10993-17. ; However, the selection of extraction solvent and conditions can present challenges for silicones since as these materials swell to more than 200% of their initial size and experience fast extraction kinetics. The excessive swelling may result in device damage which is not indicative of the real-world performance. Furthermore, the expedited extraction kinetics may offer an opportunity to use data-driven selection of shorter extraction intervals. This work addresses data-driven extraction intervals for silicone devices while addressing how solvent properties affect the kinetic of extraction by comparing extraction kinetics of several solvents with varying characteristics. The extraction kinetics are analyzed in the context of multiple solvent metrics such as polarity, dielectric constant, and Hansen solubility parameter. **Methods:** This study used extractions from silicone rubber and assesses siloxane species at 3, 6, 10, 24, and 72 hours as well as extractions at 6 and 7 days with solvents selected for their polarity, solubility parameters, and dielectric constant. The extracts were analyzed using gas chromatography mass spectrometry (GC-MS) at each time interval to assess the depletion of extractable levels. **Results:** Extractions were completed in 10 hours regardless of the solvent strength. Polarity, Hansen solubility parameter (HSP), and the dielectric constant were all used to assess the relationship between the extraction power of the solvent and the kinetics. While the total extracted quantity of high abundance siloxanes varied with solvent choice, the extraction kinetics were constant after the initial 3-hour extraction cycle. **Conclusions:** The extraction of silicone rubber may be more affected by the number of extraction cycles rather than longer extraction times. Solvent selection may affect the total amount of extractable siloxanes observed but the results suggest the extraction kinetics are similar for different solvents.

PS 3088 **Developmental Lead Exposure and Sex-Specific Glutamatergic Pathways Underlying Convergent Anxiety-Like Phenotypes in Adult Zebrafish**

S. J. Bhuiya, W. A. Tamagno, and J. Freeman. Purdue University, West Lafayette, IN.

Background and Purpose: Lead (Pb) is a pervasive environmental neurotoxicant and a recognized developmental origin of health and disease (DOHaD) toxicant, capable of reprogramming neural circuitry and behavior at concentrations well below current regulatory thresholds. Early life represents a uniquely sensitive window in which perturbations to neurotransmitter homeostasis may produce long-term neurobehavioral vulnerabilities. This study investigated the hypothesis that developmental Pb exposure alters anxiety-like behavior and glutamatergic signaling in a sex-dependent manner late in life in adult zebrafish. **Methods:** Wild-type (5D) zebrafish (*Danio rerio*) embryos were exposed to 0, 0.01, 0.1, or 1 ppb ($\mu\text{g/l}$) Pb acetate from 1 to 72 hours post fertilization (hpf) (embryogenesis) in groups of 50 larvae per plate. At 72 hpf, zebrafish were rinsed of the Pb exposure solution and allowed to mature with no additional Pb exposure in system water. At 1 year of age, behavioral assessment was conducted using the Light and Dark Preference Test (LDT). After behavioral testing, adult brains were dissected for molecular analysis of key regulators of glutamatergic signaling. Targets quantified included gamma glutamate cysteine ligase (GCL), phosphate-activated glutaminase (PAG), glutamine synthetase (GS), vesicular glutamate transporter 1 (VGLUT1), excitatory amino acid transporter 1 (EAAT1), and glutamate dehydrogenase (GDH). All outcome analyses were completed by sex. **Results:** In the behavior assessment, Pb exposure reduced anxiety-like responses across sexes, including prolonged permanence in the clear zone and reduced exploratory movement. Pb exposed zebrafish also displayed disrupted decision-making behaviors, characterized by fewer cautious exploratory transitions between light and dark zones, indicating altered evaluation of environmental threat. These phenotypes were most pronounced in 1 ppb treatment group for both sexes but was more prominent in females. At the biochemical level, distinct sex-specific patterns emerged despite convergent behavioral outcomes. In females, Pb exposure reduced VGLUT1 while elevating PAG, GS, and EAAT1. These changes suggest weakened antioxidant buffering, impaired synaptic packaging, and a maladaptive recycling loop in which excess glutamate is inefficiently cleared and packed but continually generated. In contrast, males exhibited increased VGLUT1 and EAAT1 consistent with enhanced synaptic glutamate packaging and shunting into glutamine as a compensatory detoxification mechanism. GDH and GCL activity was not affected in either sex. **Conclusions:** Functionally, these disruptions implicate multiple nodes of glutamatergic regulation. PAG drives conversion of glutamine to glutamate with upregulation potentially exacerbating excitotoxic potential. GS catalyzes the reverse reaction, detoxifying glutamate by conversion back to glutamine. In this study sex-specific elevation suggests differing compensatory pressures. EAAT1 mediates glial uptake of synaptic glutamate. Increase of EAAT1 in both sexes may reflect an adaptive change to compensate for the excessive amount of extracellular glutamate. Finally, VGLUT1 governs vesicular packaging of glutamate with downregulation in females compared to elevation in males highlighting fundamental sex differences in synaptic protection. Taken together, these findings demonstrate Pb acts as a DOHaD neurotoxicant disrupting glutamatergic homeostasis in the developing brain which results in sex-specific biochemical mechanisms. Although the biochemical pathways diverge with impaired buffering and recycling in females compared to enhanced packaging and shunting in males, behavioral impacts are similar in both sexes with reduced anxiety-like phenotypes and impaired decision-making observed. This work underscores the importance of considering sex as a biological variable in developmental neurotoxicology and provides mechanistic insight into how environmentally relevant Pb exposures may establish lasting vulnerability to neurological diseases and disorders.

PS 3089 **Developmental Pb exposure affects neurotransmitters distributions in the brain exerting late-in-life neurotoxic effects**

W. A. Tamagno, G. Sumner, N. Tucci, K. S. Chelladurai, C. R. Ferreira, and J. L. Freeman. Purdue University, West Lafayette, IN.

Background and Purpose: The Developmental Origin of Health and Disease (DOHaD) paradigm emphasizes that early-life environmental exposures shape long-term health outcomes, particularly in the nervous system where critical windows of vulnerability define susceptibility to neurotoxicants. Lead (Pb) is a pervasive environmental contaminant with no safe exposure threshold, and increasing evidence suggests that even parts-per-billion concentrations can disrupt neurodevelopment and predispose organisms to late-life neurological impairments, including cognitive decline and neurodegenerative disease-like phenotypes. **Methods:** In this study, we applied a combination of behavioral and neurochemical approaches to evaluate the persistent effects of developmental Pb exposure in zebrafish (*Danio rerio*). Embryos were exposed from 1 to 75 hours post-fertilization (hpf) to 0, 0.01, 0.1, or 1 ppb Pb, reflecting environmentally relevant concentrations. At one year of age, adults were subjected to a battery of validated behavioral tests including the Y-maze (spatial memory), novel object recognition test (NORT; recognition memory), novel tank test (NTT; anxiety-like behavior), social preference test (SPT; sociability), and shoaling test (group interaction). After behavioral assessments, brains were collected, cryosectioned, and analyzed using desorption electrospray ionization mass spectrometry imaging (DESI-MSI) to investigate the spatial distribution of key neurotransmitters and metabolites, with a particular focus on the glutamatergic system. **Results:**

Results revealed striking and sex-dependent impairments. Pb-exposed zebrafish displayed altered distributions of glutamate, glutamine, acetylcholine (ACh), and dopamine (DOP), indicating dysregulation of excitatory, cholinergic, and dopaminergic signaling. Females exhibited an anxiogenic-like phenotype in the NTT, whereas males showed a clear antisocial phenotype in both the SPT and shoaling test, suggesting sex-specific vulnerabilities in socio-emotional processing. In cognitive domains, both sexes demonstrated impaired recognition memory in the NORT, while spatial memory deficits were consistently observed in the Y-maze across exposure groups. Notably, glutamatergic neurotransmission appeared particularly disrupted, aligning with the hypothesis that Pb interferes with excitatory pathways critical for learning, memory, and long-term synaptic plasticity. **Conclusions:** These findings support the concept that low-dose Pb exposure during early embryogenesis produces persistent, multilevel alterations detectable in adulthood, long after the exposure period has ended. By integrating high-resolution neurotransmitter imaging with behavioral phenotyping, our study reveals that Pb disrupts the spatial organization of key neuromodulators in the brain, which may underlie the observed impairments in cognition, emotional regulation, and social behavior. The sex-dependent effects further highlight the importance of considering biological sex as a determinant of neurotoxic outcomes. Developmental Pb exposure, even at parts-per-billion levels, has profound and enduring effects on brain chemistry and function. Altered glutamatergic, cholinergic, and dopaminergic distributions detected by DESI-MSI strongly suggest mechanistic links between neurotransmitter dysregulation and behavioral phenotypes consistent with early-onset cognitive decline and neurodegenerative-like conditions. These results expand the DOHaD framework by demonstrating how trace-level Pb exposures during critical windows of development can reprogram neural circuits and predispose organisms to long-term neurological dysfunction. Our findings underscore the urgent need for stricter environmental Pb regulation and highlight the utility of zebrafish as a translational model for identifying molecular and behavioral biomarkers of neurodegenerative risk associated with early-life toxicant exposure.

PS 3090 Inflammation-induced metal dyshomeostasis increased susceptibility to manganese toxicity in HMC-3 microglia cells

K. A. Shapiro¹, A. T. Kramer¹, and F. E. Harrison^{2,1}. ¹Vanderbilt University, Nashville, TN; and ²Vanderbilt University Medical Center, Nashville, TN.

Background and Purpose: Manganese (Mn) is a trace metal that plays an important role in antioxidant defense and glutamate synthesis in the brain. Over exposure to Mn can result in accumulation within the Central Nervous System (CNS), resulting in neurotoxicity. It is well established that Mn exposure results in increased neuroinflammation, predominantly driven by microglia, the first responders of the CNS. In contrast, the role of inflammatory stimuli in altering Mn transport and Mn-induced neurotoxicity is less known. This is important to understand because changes in metal transport and increased neurotoxicity may play a detrimental role in contributing to neurodegeneration. Therefore, the purpose of this study is to determine how inflammatory stimuli influence the neurotoxic effect of Mn on microglia, while providing a mechanism to explain the potentiated effects. **Methods:** The HMC-3 cell line is a human-derived *in vitro* model for microglia. Cells were used between passage 9-19 in this experiment. HMC-3 cells were exposed to Mn (50 μ M MnCl₂), Lipopolysaccharide (LPS) (100 ng/ml), or a co-exposure (Mn and LPS) for 4-HR or 24-HR. RNA was collected at both timepoints for synthesis to cDNA and use in RT-qPCR experiments. RT-qPCR housekeeping genes were GAPDH and 18S. RT-qPCR experiments assessed changes in inflammatory markers (NF- κ B, Casp1, NLRP3, IL-1 β , IL-6, TNF α), metal importers (DMT1, Zip8, Zip14), metal exporters (Fpn1, Znt10), and metal storage (H-FTN, L-FTN). At both timepoints, live cell assays were conducted to look at metabolic activity (MTS), oxidative stress (ROS-glo), and viability (LDH-glo). At the 24-HR timepoint, protein was collected for mass spectrometry analysis (ICP-MS). 2-Way ANOVA and Fisher's LSD test were used to determine statistical significance. **Results:** Inflammatory marker gene expression was increased following the LPS exposure, with a more pronounced effect seen in the co-exposure with LPS and Mn. There was no effect of Mn on metal importer expression at either timepoint. At 4-HR, LPS treatment was associated with a transient decrease in expression of genes related to metal import, while at 24-HR there was a robust increase. In contrast, in the 4-HR co-exposure metal importer gene expression generally increased, while at 24-HR there was a decrease in expression. Additionally, While Mn single exposure caused an increase in metal exporter expression, LPS and the co-exposure resulted in a decrease in expression at 4 and 24-HR. Genes related to storage increased with the single exposure to Mn and LPS, and the co-exposure at both timepoints. ICP-MS analysis at the 24-HR timepoint showed that the co-exposure resulted in a greater increase in intracellular Mn compared to the single exposure to Mn and LPS. Moreover, increased neurotoxicity was observed with the co-exposure at both timepoints as seen with MTS, ROS-glo, and LDH-glo assays. **Conclusions:** LPS single exposure impacts metal transport dynamics by increasing expression in genes related to metal import and storage at 24-HR. Moreover, there is a greater effect of the co-exposure on changes in metal transport compared to either single exposure scenario indicating a potential for metal dyshomeostasis to increase microglial susceptibility to Mn toxicity. The changes in metal transport, within the co-exposure, work together to ultimately increase metal accumulation in cells. Changes in metal transport and increased metal accumulation were associated with cytotoxicity in the HMC-3 cells as seen through increases in oxidative stress, inflammation, and decreased metabolic activity. This data indicates that LPS

increases susceptibility to Mn exposure ultimately leading to increased cellular toxicity. Moreover, this study shows that inflammation can drive metal accumulation in the CNS. This new perspective could further explain the link between metals, inflammation, and neurodegeneration.

PS 3091 Regional Kinetics of Human Brain Manganese Clearance Measured by Quantitative Magnetic Resonance Imaging Relaxometry

Q. Wang¹, C. Hsu^{1,2}, H. Monsivais^{1,3}, C. Knight¹, and U. Dydak¹. ¹Purdue University, West Lafayette, IN; ²Hospital of the University of Pennsylvania, Philadelphia, PA; and ³The University of Texas MD Anderson Cancer Center, Houston, TX.

Background and Purpose: Excessive environmental Manganese (Mn) exposure can cause chronic manganese poisoning, a neurotoxic condition resembling Parkinsonian disorders, with symptoms including motor deficits, dystonia, rigidity, speech, and mood disturbances. Understanding not only the accumulation but also the clearance kinetics of Mn in the human brain is critical for assessing neurotoxic risk and recovery potential. Magnetic resonance imaging (MRI) is currently the only modality capable of providing *in vivo* noninvasive measurement of brain Mn burden. Due to the paramagnetic properties of Mn, the longitudinal relaxation rate ($R_1 = 1/T_1$) increases proportionally with Mn concentrations. Previously, we developed a whole-brain Mn-mapping approach to detect subtle but significant changes in individual welders by comparing their MRI contrast data against the normative map from controls. In this study, we followed welders who adopted powered air-purifying respirators (PAPRs), enabling a longitudinal assessment of Mn clearance. By further extracting regions of interest (ROIs) from major brain structures, we quantified regional washout rates to characterize the spatial dynamics of Mn clearance across the brain. **Methods:** As a part of a large imaging study on welders, 6 welders who had adopted PAPRs and 37 non-welding factory controls from a U.S. truck manufacturer were recruited, along with 12 university controls with no Mn exposure history. All participants provided written informed consent to participate in the study. MRI data were acquired using a 3T Siemens Prisma scanner. Welders were scanned prior to initiating PAPR use and again at 1-2, 4, 6, 8, and 12 months after PAPR use. Controls were scanned once. Quantitative brain T1 relaxometry maps were reconstructed to assess Mn-related relaxation changes and then converted to R_1 ($=1/T_1$) maps. ROIs were extracted from major brain structures, including the globus pallidus, putamen (anterior and posterior), caudate nucleus, and frontal white matter. For each ROI, mean z-scores relative to the control cohort were computed across time points. Slopes of z-score change were estimated to quantify regional washout rates, with values indicating the rate of movement toward normative values over time. Statistical significance was assessed using linear mixed-effects models with false discovery rate (FDR) correction for multiple comparisons. **Results:** The longitudinal analysis of R_1 revealed a significant effect of time on Mn deposition reduction across ROIs ($p < 0.0001$), and a significant ROI $\times$ time interaction ($p = 0.047$), indicating regional variability in clearance dynamics. Variance-standardized slopes ($SD \cdot month^{-1}$) showed that the globus pallidus exhibited the fastest recovery, with z-scores decreasing at 0.30 SD per month toward normative values. Frontal white matter and anterior putamen also demonstrated significant washout after FDR correction, though at more modest levels. In contrast, the posterior and caudate nucleus showed slower and less consistent recovery. **Conclusions:** Mn clearance in the human brain is regionally heterogeneous following reduced exposure. The globus pallidus showed the fastest and most robust Mn clearance, with frontal white matter and anterior putamen also demonstrating significant recovery, while the caudate nucleus and posterior putamen exhibited slower, non-significant changes. These findings are consistent with prior nonhuman primate data, which also reported preferential Mn accumulation and regionally variable clearance within the basal ganglia. Future work will use subject-specific prediction maps, derived from controls with each welder's age and sex, to generate voxel-wise z-scores. Using a regional brain atlas, this approach will enable more precise characterization of Mn clearance kinetics across brain structures. Overall, this study provides the first *in vivo* evidence of regional Mn clearance dynamics in the human brain and underscores their potential relevance for understanding and monitoring metal-related neurotoxic disorders.

PS 3092 Manganese Exposure Reveals Sex Differences in Stress-Induced Drug Seeking

N. K. Aregbe¹, and F. Harrison². ¹Vanderbilt University, Nashville, TN; and ²Vanderbilt University Medical Center, Nashville, TN.

Background and Purpose: Manganese (Mn) is an essential trace element that serves as a cofactor for several biological pathways. Optimal Mn exposure follows a hormetic curve, where both deficiency and overexposure cause neurological dysfunction. Overexposure may occur through occupational sources, drinking water, or air pollution. Chronic Mn exposure, even at subtoxic levels, leads to accumulation in dopaminergic brain regions, disrupting dopamine homeostasis. Dopamine, a key neurotransmitter released by dopaminergic neurons, is central to reward-seeking behavior through the mesolimbic pathway. When this pathway is dysregulated, the brain's ability to process and respond to rewards is compromised, forming the underlying mechanism of addiction. The mesolimbic pathway, which projects dopamine

from the ventral tegmental area (VTA) to the nucleus accumbens, hippocampus, amygdala, and cortex, is central to the brain's reward circuitry. However, its susceptibility to Mn exposure and role in drug-seeking behavior are poorly understood. This study investigates how chronic dietary Mn exposure affects dopaminergic activity and drug-seeking behavior. **Methods:** Six-week-old C57BL/6J mice were placed on either a control diet (70 ppm Mn, n=36; 18 males, 18 females) or a high-Mn diet (2400 ppm Mn, n=36; 18 males, 18 females) for six weeks. After dietary exposure, mice completed a behavioral battery including conditioned place preference (CPP), forced swim, and open field activity. CPP was conducted in a two-compartment chamber with restricted access between sides. During the pretrial, each mouse's chamber preference was recorded. Mice then received alternating IP injections of cocaine (10 mg/kg) on the nonpreferred side (afternoon) and saline on the preferred side (morning) for four days. On the CPP test day, mice had open access to both compartments without drug administration to assess conditioned preference. Daily testing continued until extinction, followed by a 10-minute forced swim test to induce stress, after which CPP was reassessed to measure reinstatement of drug-seeking behavior. After CPP, all mice underwent open-field testing to measure cocaine-induced hyperactivity. Each mouse received an IP saline injection, followed 30 minutes later by cocaine at 5 mg/kg and 10 mg/kg to assess Mn effects on cocaine-induced hyperactivity. Following behavioral testing, cortical and striatal tissues were collected for molecular analysis. RNA from striatal tissue was converted to cDNA for RT-qPCR using GAPDH and 18S as housekeeping genes. Genes of interest included metal ion importers (Zip8, Zip14, DMT1), exporters (Fpn1, Znt10), and the dopamine transporter (DAT). HPLC quantified cortical dopamine metabolites, and ICP-MS validated Mn accumulation in high-Mn versus control mice. **Results:** During CPP extinction, no significant behavioral differences were observed between high-Mn and control mice of either sex. Similarly, open field testing revealed no group differences in cocaine-induced hyperactivity. However, during stress-induced reinstatement, females exhibited stronger reinstatement of preference for the cocaine-paired environment than males, regardless of diet. This suggests Mn exposure did not broadly alter CPP behavior but highlighted increased female vulnerability to stress-induced relapse. Gene expression analyses showed a general trend toward higher Mn importer expression (Zip8, Zip14, DMT1) in high-Mn males, while exporter expression (Fpn1, Znt10) remained stable across groups. ICP-MS confirmed increased Mn accumulation in high-Mn mice, and HPLC revealed elevated dopaminergic metabolites in high-Mn males. **Conclusions:** These findings refine our understanding of how chronic, subtoxic Mn exposure influences reward circuitry and relapse-related behaviors. While Mn did not cause broad changes in cocaine-conditioned preference or locomotor activity, the pronounced female-specific reinstatement effect indicates potential sex-dependent vulnerability to relapse. The molecular profile, with increased importer but unchanged exporter expression, suggests Mn accumulation may sensitize striatal neurons to altered homeostasis even without major behavioral changes. Together, these results indicate that chronic Mn exposure interacts with sex and stress to reveal hidden vulnerabilities, with implications for environmental neurotoxicology and addiction biology.

PS 3093 Mixed Metal Oxide Exposure Drives Astrocytic Activation *In Vitro* and *In Vivo*

A. Anchan¹, R. Strazdins², A. Shah¹, P. Reina-Gonzalez¹, A. Abu-Salah¹, M. Sobolewski-Terry¹, and S. Sarkar¹. ¹University of Rochester School of Medicine & Dentistry, Rochester, NY; and ²Queensland University of Technology, Brisbane City, Australia.

Background and Purpose: Approximately 50 million people worldwide are affected by neurodegenerative diseases (NDD), with this number predicted to double in the next 50 years. Metal imbalance is a key characteristic of many of these NDDs, which may potentially be driven by environmental metal exposures. Epidemiological studies have implicated metals such as iron (Fe) and manganese (Mn) in NDD pathophysiology. However, human exposures to metals are rarely singular; rather, people are exposed to complex metal mixtures. The role of metal mixture in driving NDDs is underexplored. Astrocytes have been repeatedly associated with metal exposure-associated NDDs. These cells play a key role in metal homeostasis in the brain, but metal overexposure can push astrocytes from homeostatic to a pathological state. In this pathological state, astrocytes can directly or indirectly damage surrounding neurons, leading to cell death and further promotion of pro-inflammatory activity in the brain, both key features of many NDDs. This astrocytic reactivity has been highlighted in traditional models of metal exposure, which utilize individual soluble metal exposure, such as MnCl₂ and FeCl₂ (i.e., metal chlorides). However, occupational human metal exposure studies done in welding sites have characterized the metal particles in the air, which workers are exposed to, as metal oxides. These are insoluble and potentially participate in different interactions between astrocytes and biochemical processes. Additionally, these studies have rarely considered the implications of metal mixtures, further limiting our understanding of the role of mixed metal oxide exposures in neurodegeneration. **Methods:** First, to understand the astrocytic response to mixed metal exposure, we conducted both *in vitro* and *in vivo* studies utilizing occupationally relevant metal exposures. We were able to show that the characteristics of the astrocytic response depended on oxidation state of the metal - metal oxides versus metal chloride exposures. Exposure to metal oxide mixtures resulted in increased mitochondrial deficits and inflammatory markers in comparison to the metal chloride mixture exposure. This highlights the importance of replicating human exposures by matching both the chemical species and mixture composition, as these factors seem to modify astrocytic responses. Second, we explored the

effects of mixed metal oxide inhalation on neurodegeneration. We developed a novel sub-acute exposure model that was capable of recapitulating the characteristics of welding inhalation exposures. Exposure to mixed metal oxides in our rodent model led to astrocytic activation in a region-specific manner, which was demonstrated in both small animal MRI and immunohistochemistry (IHC). Furthermore, these regions can be functionally associated with the behavioral alterations we have characterized. **Results:** This work has demonstrated a cell-specific vulnerability of astrocytes to mixed metal oxide exposure and the regional sensitivity in inhalation exposures. **Conclusions:** This project is an important step in promoting the study of the neurodegenerative consequences of complex metal mixtures, as well as the consideration of chemical speciation in astrocytic metal handling and senescence induction. These are essential questions in developing translationally relevant models and furthering our understanding of the role of environmental metals in neurodegenerative diseases and aging.

PS 3094 Low Concentrations of Hexavalent Chromium in Drinking Water Induce Oxidative Damage in Endothelial Cells: Using a Toxic Aging Coin to Assess Cr(VI) Impacts on the Blood-Brain Barrier

W. Buchanan¹, S. T. Vielee¹, H. Lu¹, and J. P. Wise, Jr.². ¹University of Louisville School of Medicine, Louisville, KY; and ²Department of Pharmacology and Experimental Therapeutics, University of Toledo, Toledo, OH.

Background and Purpose: Hexavalent chromium [Cr(VI)] is a widespread environmental pollutant that was recently identified as the #1 chemical hazard in drinking water in the U.S. Cr(VI) contaminates drinking water from geogenic sources (e.g. ultramafic bedrock), industrial effluents, and aging cast iron or steel water pipes. The WHO and EPA have established maximum contaminant levels (MCLs) for total Cr at 0.05 and 0.1 mg/L, respectively. While Cr(VI)'s health effects have been identified in other peripheral tissues, significant knowledge gaps exist regarding its neurotoxicity. Compounding this, we are facing an aging crisis, with 20% of the U.S. population projected to be geriatric (65+) by 2030, yet we have a poor understanding of how geriatric exposures contribute to health outcomes. To combine aging and toxicology research, we use a Toxic Aging Coin approach to investigate: 1) how age impacts toxicity (*heads*), and 2) how chemicals accelerate aging (*tails*). We recently reported Cr selectively accumulated in the hippocampus of rats exposed to levels of Cr(VI), especially middle-aged and geriatric females, and induces essential metal dyshomeostasis with distinct age and sex differences. Here, we investigate how Cr(VI) damages the blood-brain barrier (BBB), a critical structure to protect the brain parenchyma. Within the BBB, endothelial cells create tight junctions that permit selective transport of key materials into the brain while preventing penetration of noxious materials. Astrocyte end-feet provide further structural and functional support. The BBB naturally becomes leakier with age and chronic inflammation and/or oxidative damage can accelerate BBB deterioration. We hypothesize that Cr(VI) damages the BBB by inducing oxidative damage in endothelial cells. **Methods:** We exposed Sprague-Dawley rats (both sexes) from three ages (3-, 7-, and 18-months-old) to low concentrations of Cr(VI) in drinking water (0.05 and 0.1 mg/L) for 90 days. After 90 days we harvested the brains and one hemisphere was preserved to assess BBB integrity and protein expression in the dorsal hippocampus by immunofluorescence (i.e., Tissue Plasminogen Activator [tPA], and glial fibrillary acidic protein [GFAP]). GFAP marks astrocytes and can indicate astrocyte activation. tPA converts plasminogen to plasmin, a serum protease linked to inflammation, and decreased tPA expression is linked to aging. 8-hydroxy 2'-deoxyguanosine (8-OHdG) was used to assess oxidative damage in endothelial and astrocytic nuclei. Female rats were selected for tPA analyses and male rats were selected for 8-OHdG expression analysis. Protein expression and 8-OHdG levels were quantified via ROI analyses and data were reported as fold-change relative to control. **Results:** tPA expression was significantly decreased in the hippocampus of young female rats, middle-aged female rats exposed to 0.1 mg/L, and geriatric female rats. GFAP expression around capillaries was significantly increased in middle-aged female rats exposed to 0.1 mg/L but significantly decreased in geriatric female rats. Preliminary data indicate that Cr(VI) induces a concentration-associated increase in 8-OHdG levels in endothelial cell nuclei of young and geriatric male rats. **Conclusions:** Cr(VI) likely damages the BBB in the process of entering the brain. Cr(VI) induces changes in GFAP expression at the capillary level with distinct age differences, with increased expression in middle-aged females and decreased expression in geriatric females. Decreased tPA expression suggest BBB dysfunction and may indicate an accelerated aging. Additionally, increased 8-OHdG levels in endothelial nuclei of male rats indicate Cr(VI) induced oxidative DNA damage, which can contribute to genomic instability if left unrepaired. Together, these results indicate accelerated BBB aging. Future directions will further examine and clarify Cr(VI)'s effects on the BBB, including assessment of 8-OHdG levels in both endothelial cells and astrocytes in female rats. Support from R21ES033327 (JPWJr), T32ES011564 (STV), University of Louisville Summer Research Opportunity Program (WJB).

PS 3095 *In vivo* repressor screen identifies dopaminergic and glutamatergic neurons as targets of manganese toxicity

A. Melkote¹, S. Grant¹, M. Bernstein², T. Jursa³, C. A. Taylor¹, S. Hutchens¹, W. Shawlot¹, L. S. Zweifel², R. A. Gonzales¹, D. R. Smith³, and S. Mukhopadhyay¹.

¹University of Texas at Austin, Austin, TX; ²University of Washington, Seattle, WA; and ³University of California at Santa Cruz, Santa Cruz, CA.

Background and Purpose: Manganese (Mn) is an essential micronutrient, but in excess, it is neurotoxic. Under conditions of over-exposure, Mn builds up in the basal ganglia of the brain and induces motor deficits, but the specific neuronal targets of Mn are unclear. Knockout studies have revealed that selective loss of the Mn efflux transporter SLC30A10 in dopaminergic or glutamatergic, but not GABAergic, neurons leads to increased Mn in targeted neurons and early-life motor deficits in mice. These findings indicate that the activity of SLC30A10 in dopaminergic or glutamatergic neurons is required to protect against Mn toxicity. **Methods:** Knockout studies raised the hypothesis that Mn targets dopaminergic and glutamatergic, but not GABAergic, neurons of the basal ganglia. To definitively determine the neuronal targets of Mn, we generated dopaminergic-, GABAergic-, or glutamatergic-specific Slc30a10 knockin mice to selectively increase Slc30a10 in targeted neurons. Knockin of Slc30a10 was driven by Cre recombination and targeted to the mROSA 26 locus. Knockin mice and control littermates received Mn treatment from birth and were run through neurobehavioral assays at early-life time-points. Metal level analyses were performed using ICP-MS and laser-ablation ICP-MS. **Results:** Results showed that neuron-specific Slc30a10 knockin mice have increased expression of Slc30a10 in targeted neurons and have attenuated Mn levels in targeted neurons after Mn exposure. Behavioral assays revealed that dopaminergic- and glutamatergic-, but not GABAergic-specific, Slc30a10 knockin mice are protected from early-life Mn-induced motor deficits after exposure compared to control littermates. **Conclusions:** These findings show that Mn targets dopaminergic and glutamatergic neurons of the basal ganglia to induce motor disease.

PS 3096 Arsenic Exposure Increases Anxiety-Like Phenotypes in Female Mice and Decreases Microglial Responsiveness to Pathogens

L. Wang¹, L. Zhao¹, J. Flores¹, A. Adeleke¹, M. Bell², K. Tseng¹, and R. M. Sargis¹.

¹University of Illinois Chicago, Chicago, IL; and ²DePaul University, Chicago, IL.

Sponsor: R. Sargis, Endocrine Society

Background and Purpose: Anxiety afflicts more than 300 million people worldwide and is associated with a 3-fold higher risk of dementia. Until recently, efforts to clarify disease etiology have often neglected environmental drivers that are increasingly linked to neuropsychiatric and neurocognitive disorders. Arsenic (As) is a common environmental toxicant that is strongly associated with anxiety and cognitive impairment. However, the mechanisms by which As contributes to neurobehavioral dysfunction remain incompletely understood. **Methods:** Using a battery of behavioral tests and hormonal assessments, our studies examine As-induced behavioral changes in female mice exposed from adolescence to early adulthood. This included open field, light/dark box, fear conditioning, and acute restraint. We also examined how As disrupts microglial function in SIM-A9 cells while in the presence or absence of inflammatory challenges. **Results:** As increased anxiety-like behavior during cued fear conditioning; moreover, As increased corticosterone secretion during acute restraint, indicating a hyperactivation of the hypothalamic-pituitary-adrenal (HPA) axis. In addition, As attenuated pro-inflammatory cytokine expression in microglia challenged with an inflammatory stimulus. This effect was consistent whether the stimulus was lipopolysaccharide, interferon-gamma, or tumor necrosis factor-alpha, though the magnitude of change differed. **Conclusions:** As exposure induces an anxiety-like phenotype in female mice through disruption of the HPA axis. As also causes inhibition of normal microglial responses to pro-inflammatory stimuli. Studies are underway to decipher the mechanisms of As-induced neurotoxicity using brain slice electrophysiology and other approaches in order to empower interventions to address the deleterious impacts of this common threat to human health.

PS 3097 A Quantitative Cell Painting Assay to Evaluate Organoid Viability and Morphodynamics During Acute Metal Exposure

R. Mohapatra^{1,2}, H. Zhao^{1,2}, and L. Smirnova^{1,2}. ¹Johns Hopkins University Center for Alternatives to Animal Testing (CAAT), Baltimore, MD; and ²Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.

Background and Purpose: Developmental neurotoxicity from exposure to heavy metals is a significant public health concern, and there is still much to be learned about their full neurological risk profiles and mechanisms of action. Microphysiological systems, such as organoids, are powerful *in vitro* models that recapture organ cytoarchitecture and higher-order functions. As such, they are highly valuable for toxicological screening and mechanistic studies. However, their increased cost and technical complexity often limit throughput compared to traditional cellular assays. *MortaLIVE* is a commercially available, biologically inert fluorescent dye that simultaneously detects both live and dead cells in live cell cultures, enabling viability monitoring over time. Our goal was to optimize the use of this cell

painting dye for organoids and assess whether *MortaLIVE* could provide not only an efficient measure of organoid viability over time but also be integrated with other functional assays to increase experimental output from a limited number of samples. We therefore conducted an acute exposure study using neural organoids treated with cadmium (Cd), hexavalent chromium (Cr), a Cd+Cr mixture, and lead (Pb) to assess the utility of *MortaLIVE* in complex *in vitro* models. **Methods:** Following 8 weeks of culture, human iPSC-derived neural organoids were attached to a glass-bottom black plate and exposed for 72 hours to a concentration range (from 0.32 μ M to 50 μ M) of each metal (n=4 per condition). Viability was assessed using the Yokogawa high-content live-imaging platform following treatment with *MortaLIVE*. In parallel, neural functionality in the form of neurite and glial outgrowth from the organoids was quantified by live-tracking high-contrast cell projections. Both viability and outgrowth results were validated using previous *in vitro* assays established at our lab: resazurin reduction for cytotoxicity and immunostaining with neuronal and glial markers for neurite and glial migration. **Results:** Concentration-response curves were generated for all metals with *MortaLIVE*, and the results were consistent with the resazurin assay. Acute metal exposure produced a dose-dependent increase in cytotoxicity. The relative neurotoxicity of the metals followed the trend Cd+Cr > Cd > Cr > Pb. Use of this *MortaLIVE* cell painting assay presents an advantage over classical viability/cytotoxicity assays such as a resazurin reduction assay or LDH release as: (a) it is not terminal, cells can be washed and further cultured and (b) one organoid per replicate is needed, while at least 10 organoids per replicate would be necessary to reach sufficient sensitivity in a resazurin-based assay. In addition, labeling of the organoids allowed neurite and glia outgrowth to be tracked in real time and quantified from the same samples. Interestingly, the Cd+Cr mixture appeared to exhibit a less-than-additive effect on both cytotoxicity and outgrowth impairment. The interaction between these two metals in neurological systems merits further exploration. **Conclusions:** We developed and validated a *MortaLIVE*-based assay that enables rapid assessment of cell viability and functionality in organoid models. Because the dye is biologically inert and preserves sample integrity, it also permits quantification of morphological features and subsequent use of samples in additional functional assays. Although demonstrated here in neural organoids, this approach is broadly applicable to other microphysiological systems.

PS 3098 Metabolic disruptions in the cerebellum of welders co-exposed to Manganese and Iron

J. A. George, N. Shin, C. G. Lee, C. Knight, K. Witkowiak, J. Park, D. Foti, and U. Dydak. Purdue University, West Lafayette, IN.

Background and Purpose: Exposure to welding fumes, containing Manganese (Mn) as well as Iron (Fe), is a well-established neurotoxic risk. Mn neurotoxicity has been associated with motor dysfunction, with higher exposure relating to worse Unified Parkinson's Disease Rating Scale (UPDRS) scores. While most studies have focused on the basal ganglia, the cerebellum, central to motor control and coordination, may also play a role in motor impairment. Using short-TE semi-LASER (sLASER) magnetic resonance spectroscopy (MRS), we examined associations between metal exposure and cerebellar metabolites: N-acetylaspartate (NAA), myo-inositol (mIns), glutamate (Glu), total creatine (tCr), and choline (Cho) as biomarkers of neuronal integrity and energy metabolism. Glu was of particular interest, as Mn disrupts astrocytic glutamate transport and glutamate-glutamine cycling, leading to excitotoxic dysregulation. Given Mn and Fe's shared transport and regulatory pathways in the brain, we hypothesized that cumulative Mn/Fe exposure alters cerebellar metabolism and contributes to motor dysfunction in welders. **Methods:** As part of a larger imaging study, 45 welders and 22 factory controls were recruited from a U.S. truck manufacturing facility. ¹H MRS was acquired on a 3 T Siemens MAGNETOM Prisma using sLASER (TE/TR = 35/2000 ms; 64 averages) with a 35x25x25 mm³ volume of interest (VOI) in the right cerebellar lobe. Spectra were processed and quantified using Osprey and LCModel; metabolite fits with SD% > 15% were excluded. Motor function was assessed with UPDRS-part III, from which rigidity and tremor composite scores were derived. Personal air sampling informed cumulative metal exposure indices (CEI) for lifetime (since age 18; Mn_{cumul}, Fe_{cumul}). Group differences were tested with Wilcoxon rank-sum tests; multivariable linear regressions examined correlations between exposure, metabolites, and motor outcomes. **Results:** Cumulative Mn and Fe exposures were significantly higher in welders than controls (Mn_{cumul} (mg/m³-yr): 1.12 ± 1.80 vs 0.10 ± 0.10, p < 0.001; Fe_{cumul} (mg/m³-yr): 7.52 ± 11.60 vs 0.80 ± 0.80, p < 0.001). Despite these exposure differences, cerebellar metabolite levels differed only in mIns between groups (p < 0.05). **Metabolite-Exposure Relationships:** Using each metabolite as the dependent variable, we modeled age, sex, Mn_{cumul}, and Fe_{cumul} as predictors. In controls, cerebellar Glu was negatively correlated with age (p < 0.05) and positively correlated with Mn_{cumul} (adj.R² = 0.60, p < 0.01), consistent with preserved glutamatergic regulation at low exposure levels. Fe_{cumul} was positively correlated with tCr (adj.R² = 0.40, p < 0.05) and Cho (adj.R² = 0.31, p < 0.05). In welders and in the combined cohort, no metabolite-exposure correlations were significant. **Metabolite-Motor Relationships:** Using UPDRS-III as the dependent variable, we modeled age, sex, and all cerebellar metabolites as predictors. In welders, this model explained 44% of the variance (adj.R² = 0.44, p < 0.001); older age (p < 0.001) and lower tCr (p < 0.05) predicted worse motor function. In controls, no metabolites significantly predicted UPDRS scores. In the combined cohort, the model remained significant (adj.R² = 0.30, p < 0.001), with age (p < 0.001), sex (p = 0.05), and lower tCr (p < 0.001) predicting worse performance. For rigidity, welders showed moderate negative correlation with NAA and moderate positive correlation with age and mIns.

In the combined cohort, rigidity increased with age, sex, and mIns, and decreased with tCr. For tremor, only age was a significant positive predictor. **Conclusions:** Cumulative Mn/Fe exposure predicted cerebellar metabolites only in controls: Mn_{cumul} predicted Glu and Fe_{cumul} predicted tCr and Cho. The absence of a Glu exposure relationship in welders may reflect disrupted glutamatergic regulation under chronic Mn/Fe exposure; by contrast, controls showed the expected age-related Glu decline, suggesting reduced glutamatergic turnover with aging. No other metabolites showed significant exposure relations. Motor impairment in welders appeared primarily age-related, with lower tCr (reduced energy reserve), lower NAA (neuronal integrity), and higher mIns (gliosis) associated with worse performance. Overall, cerebellar energy and glial alterations, rather than direct glutamatergic changes, may represent a secondary pathway for Mn/Fe-related motor effects.

3099 Comparison of welding fume exposure metrics in relation to motor function

N. Shin, C. G. Lee, C. B. Knight, J. A. George, J. Park, and U. Dydak. Purdue University, West Lafayette, IN.

Background and Purpose: Particles released from the welding process often contain metals such as manganese (Mn) and iron (Fe). Continuous exposure to Mn in welders has been linked to deficits in motor function, and specifically to increased scores in the Unified Parkinson's Disease Rating Scale (UPDRS) - Part III. Yet, literature uses many different forms of exposure metrics, ranging from years of welding to complex cumulative exposure indices (CEIs). For a study on Mn neurotoxicity in welders, we have recently developed refined short-term and long-term CEIs that are based on personal air sampling during a work shift and a work history questionnaire and take into account changes in department, as well as past jobs that included welding. In this study, seven different exposure metrics, years-of-welding (YW), Mn and Fe air levels, CEI for past three months (CEI_{3m}) and cumulative CEI (CEI_{cumul}) for both Mn and Fe were compared 1) to determine group differences between welders (W), non-welding factory controls (FC), and non-exposed university controls (UC) and 2) to explore relations with UPDRS scores for each of these exposure metrics. **Methods:** A total of 78 subjects (37 welders, 28 FCs - age matched to the welders, and 12 UCs) was recruited from a trailer manufacturing company in the USA. Years of welding were based on months of welding, but did not take part-time jobs or the type of welding into account. Personal air sampling was conducted following NIOSH Method 0600 and the metals collected on the filters were analyzed using inductively coupled plasma-optical emission spectroscopy (ICP-OES). Mn_{air} and Fe_{air} were determined and used to calculate CEI_{3m}(Mn), CEI_{3m}(Fe), CEI_{cumul}(Mn), and CEI_{cumul}(Fe). Specifically, CEI calculations incorporated welding hours and days per week, respirator use, as well as prior jobs using weighting factors. The UPDRS-III was assessed by a trained specialist. Independent t-tests were used for group comparisons, and linear regression models including age as covariates were run to predict UPDRS-III as a dependent variable for each of the exposure metrics as predictor. **Results:** The three groups did not differ significantly in age, but had different variances in all variables. UPDRS-III scores were 6.7±4.3 (W), 5.1±3.6 (FC), and 1.9±1.6 (UC) and were only significantly different between W and UC, as well as FC and UC (p<0.0001), but not between W and FC. Mean Mn air levels for the three groups were 220±232 µg/m³ (W), 8.0±10.3 µg/m³ (FC), and 0.07±0.06 µg/m³ (UC). All 7 exposure metrics, YW, air levels, and CEIs, found a significantly higher exposure to both Mn and Fe in welders compared to either control group (all p<0.005). Noteworthy, all exposure metrics but YW also found a significantly increased exposure in FC compared to UC (all p<0.01). In the linear mixed models for UPDRS-III, age was always a significant predictor for all models. In welders, YW was also a significant predictor (p<0.05) of UPDRS. Air levels as well as CEI_{3m} were only significant predictors of the UPDRS across all subjects, not within welders or FC alone, for both Mn and Fe. In contrast, CEI_{cumul} were more significant predictors of UPDRS-III than age both in welders alone (p<0.04 for Mn and <0.02 for Fe) as well as across all subjects (p<0.00005), but not in FC alone. **Conclusions:** These results confirm once again that chronic exposure to welding fumes, particularly Mn and Fe, contributes to measurable motor function impairment, in addition to age. Moreover, these findings demonstrate that the group of "factory controls", mostly assembly workers working in the same large factory hall as the welders, experience a significant co-exposure to welding fumes, which would not be picked up when using only years of welding as an exposure metric. This explains that the difference in motor function, while still worse in welders than FC, does not reach significance. This furthermore suggests that the parent study would benefit from a larger and age-matched "university control group" of truly non-exposed subjects. Finally, UPDRS-III scores are not predicted by short-term exposure metrics, such as air levels or past-3-months CEIs, but only by long-term CEIs, such as CEI_{cumul}. This is true for both Mn and Fe. However, Mn and Fe exposure are highly correlated and thus the role of Fe exposure through welding fumes will need to be further explored.

3100 Role of brain HIF signaling in motor function and manganese neurotoxicity

K. Windsor, and S. Mukhopadhyay. University of Texas at Austin, Austin, TX.

Background and Purpose: Excess Mn accumulates in the basal ganglia of the brain, which leads to neurological disease. Our prior work identified SLC30A10 as a Mn-specific efflux transporter that protects against Mn toxicity. We discovered a fundamental role for the HIF signaling pathway in regulating Mn homeostasis via transcriptional activation of SLC30A10. Recent data from our group further suggests that there are organ-specific effects of Mn-induced HIF activation. However, the definitive role of HIF activation in the brain is unclear. **Methods:** In this study, we sought to determine the role of neuronal HIF signaling in response to elevated Mn. We generated several cell-specific HIF1α and HIF2α knockout mice lines targeting key neuron types in the basal ganglia: dopaminergic, GABAergic, or glutamatergic neurons. Knockout mice and littermate controls were treated with Mn modeling human environmental exposure. Mn-induced neuromotor dysfunction was measured using balance beam and open field behavioral assays at four weeks of age. **Results:** Dopaminergic knockout of HIF1α did not impact Mn-induced sensorimotor dysfunction as measured by the balance beam assay, whereas in the open field assay, Mn-treated knockout mice moved more and rested less than Mn-treated littermate controls. Glutamatergic knockout of HIF1α did not impact Mn-induced motor dysfunction. However, untreated knockout mice moved more slowly to cross the balance beam, and moved less and rested more in the open field assay compared to untreated littermate controls, suggesting a glutamatergic role of HIF1α in basal motor function. Pan neuronal and glial knockout of HIF2α also impacted basal motor function; untreated knockout mice moved less and rested more in the open field assay compared to untreated littermate controls. In addition, whereas Mn treatment caused decreased movement in control mice, Mn treatment did not cause further motor deficits in HIF2α knockout mice. **Conclusions:** Our results suggest that both HIF1α and HIF2α play a role in basal motor function, while their role in Mn-induced motor deficits is uncertain.

3101 Sex-Specific Hippocampal Metabolomic Perturbations Following Chronic Hexavalent Chromium Exposure in Guinea Pigs

Q. Wise¹, S. T. Vilele¹, M. Delnicki¹, G. C. Griffin¹, S. S. Diven¹, J. Easley¹, J. C. Kouokam¹, I. Meaza¹, H. Lu¹, A. Brownell¹, S. F. Gueye¹, N. Butzke-Souza¹, J. T. Wise², A. I. Vitorino Maia³, F. Donnarumma³, J. P. Wise Sr.¹, J. L. Wise¹, and J. P. Wise Jr.⁴. ¹University of Louisville, Louisville, KY; ²University of Hawai'i, Honolulu, HI; ³Louisiana State University, Baton Rouge, LA; and ⁴University of Toledo, Toledo, OH.

Background and Purpose: Hexavalent chromium [Cr(VI)] is a ubiquitous environmental pollutant and potent toxicant, currently ranked as the number one chemical hazard in US public drinking water. To date, most mechanistic data describing Cr(VI) toxicity come from lung, liver, and kidney tissues. While these studies have yielded extensive datasets, there remains comparatively little information on neurotoxicity. Even less is known about how pathways of Cr(VI) neurotoxicity may vary by sex. This study assessed how chronic Cr(VI) exposure induces distinct metabolic signatures in the hippocampus that reflect oxidative stress, altered energy metabolism, and neurotransmitter disruption, and how these signatures differ between male and female guinea pigs. **Methods:** Hartley guinea pigs were given either tap water or 5 mg/L Cr(VI) in drinking water for 90 days. Hippocampal tissues were collected and processed for untargeted metabolomics and metalomics. Inductively coupled plasma-mass spectrometry was conducted to determine hippocampal Cr accumulation. Statistical analyses used the Mann-Whitney test with significance set at p < 0.05. **Results:** Hippocampal metabolomics from Hartley guinea pigs exposed to 5 mg/L Cr(VI) in drinking water for 90 days revealed distinct metabolite profiles that differed markedly between males and females. In males, Cr(VI) exposure was associated with a broad loss of metabolic reserve capacity: creatine levels were lower and glyceric acid levels were also reduced, suggesting a diminished ability to buffer energy demand. There were reductions in several amino acids that support neurotransmitter synthesis, including lower GABA, glutamate, and histidine, suggesting a weakened ability to sustain synaptic signaling. Males displayed decreased membrane-building precursor molecules such as O-phosphorylethanolamine and neuraminic acid, implying stress on membrane synthesis. Levels of antioxidant-linked intermediates such as γ-glutamyl-2-aminobutyric acid and phenyl-lactate were lower, consistent with a reduced redox response. N1-acetylsermidine decreased, indicating reduced polyamine turnover, which is important for stress resilience and synaptic plasticity. Cr(VI) exposure in females was accompanied by increased dipeptides and increased glutamate, lysine, O-phosphorylethanolamine, and neuraminic acid, indicating amino acid and membrane-related support pools are increased in response to Cr(VI) exposure. Females displayed coordinated decreases in major myelin-associated lipid classes, including lower levels of ceramides, sphingomyelin, and galactocerebrosides. This pattern of lipid loss is consistent with vulnerability of white-matter-related lipid structures and may indicate stress to myelin integrity. **Conclusions:** Chronic Cr(VI) exposure induced distinct hippocampal metabolomic fingerprints between sexes. Male guinea pigs exhibited broad depletion of metabolic substrates that normally support energy buffering, neurotransmitter cycling, antioxidant defense, and membrane synthesis. Meanwhile, females exhibited increases in amino acid metabolites but coordinated losses in myelin-associated lipids. Together, these results demonstrate chronic Cr(VI) exposure produced distinct metabolic response patterns in the hippo-

campus between sexes. The hippocampus is a key structure for learning and memory, making these metabolic shifts relevant to functional neurotoxicity. These metabolic shifts align with prior Cr(VI) findings, including disrupted GABA/glutamate pathways and evidence of myelin-related vulnerability. Further, these results underscore the importance of evaluating sex as a biological variable for brain susceptibility to environmental toxicants. Support from R35ES032876 (JPWSr.), "la Caixa" Foundation LCF/BQ/EU22/11930060 (IM), T32ES011564 (STV, MD, GCG), R21ES033327 (JPW), and USDA Multistate Research Project W5045 (JTFW).

PS 3102 From Exposure to Emotion in Welders: Does Metabolism in the Anterior Cingulate Cortex Play a Role?

L. M. Aguiar, J. A. George, K. M. Witkowiak, N. Shin, C. Knight, C. G. Lee, J. Park, D. Foti, and U. Dydak. Purdue University, West Lafayette, IN.

Background and Purpose: Despite the function of manganese (Mn) and iron (Fe) as critical nutrients, chronic exposure to these metals can lead to their accumulation in the brain, disrupting normal metabolite levels and metal metabolism. This has been linked to increased psychological distress, including depression and anxiety, particularly among individuals with higher cumulative manganese exposure. Mood and emotional regulation are closely tied to metabolism, particularly in the Anterior Cingulate Cortex (ACC), the brain region that plays a pivotal role in cognition and mood. This study sought to evaluate how exposure to metals found in welding fumes, particularly Mn and Fe, affect metabolite concentrations in the ACC. The study further investigated how these neurometabolic changes mediate the relationship between metal exposure and psychological domains, examining correlations between exposure and metabolites as well as metabolites and mood. **Methods:** We studied 35 career welders and 29 non-welding factory controls. All participants obtained a single-voxel ¹H Magnetic Resonance Spectroscopy (MRS) exam on a 3T Siemens Prisma scanner of the Anterior Cingulate Cortex (ACC) using short-TE semi-LASER (sLASER) to quantify metabolites: N-acetylaspartate (NAA), total creatine (tCr), choline (Cho), myo-inositol (mlns), and glutamate (Glu). Participants completed the Brief Symptom Inventory (BSI; 9 symptom domains) yielding summary scores for each domain, as well as the Global Severity Index (GSI). Personal air sampling during one work shift and a work history questionnaire were used to calculate cumulative exposure indices (CEIs) for Mn and Fe. Group differences in exposure levels, ACC metabolite concentrations, and BSI outcomes were tested with two-tailed Student's t-tests. Associations were evaluated using Spearman rank correlations. Statistical significance was defined as $\alpha = 0.05$. **Results:** Welders had significantly higher exposure indices for Mn and Fe than controls. However, no significant differences were observed for any of the ACC metabolites between the groups. Both groups reported high levels of mood symptoms, indicating comparable levels of psychological distress on self-reported rating scales. In welders, a moderate negative correlation was identified between NAA and Fe cumulative exposure index (FeCEI) ($R = -0.355$, $p = 0.036$) as well as MnCEI ($R = -0.373$, $p = 0.027$). Cho presented a moderate positive correlation with FeCEI ($R = 0.337$, $p = 0.048$). Correlations between MnCEI and Cho trended in the positive direction, while MnCEI vs. Glu, and FeCEI vs. Glu trended in the negative direction. In FC, no correlation between exposure and metabolites was found. However, moderate positive correlations were observed between NAA and the domains of Obsession-Compulsion ($R = 0.436$, $p = 0.042$), Hostility ($R = 0.467$, $p = 0.029$), and Psychoticism ($R = 0.467$, $p = 0.028$). Similarly, Glu showed moderate positive correlations with Obsession-Compulsion ($R = 0.437$, $p = 0.042$) and Depression ($R = 0.440$, $p = 0.041$). Strong positive correlations were found between Cho and Psychoticism ($R = 0.664$, $p < 0.001$) as well as between Glu and Anxiety ($R = 0.657$, $p < 0.001$). Correlations between metabolites and GSI showed significance only in Glu ($R = 0.464$, $p = 0.03$). **Conclusions:** Cumulative Mn and Fe exposure indices showed a negative correlation to NAA levels in welders, but not factory controls, indicating that higher exposure to these metals is linked to decreased NAA levels in the ACC, possibly due to damage or loss of healthy neurons. In welders, increased Fe levels are linked to elevated Cho. This may reflect increased cell membrane turnover or activation of glial cells in response to metal exposure. Study results suggest that higher metabolite levels in the ACC are linked to greater psychological distress across several symptom domains. However, the strong positive correlation between Glu and anxiety is not consistent with typical findings. Overall, this data does not suggest that any of the metabolites investigated in the ACC in this study play a mediating role between welding fume exposure and mood. Future studies may need to include whole brain MRS approaches to study the role of brain metabolism in mood changes associated with welding fume exposure.

PS 3103 Symmetry of Quantitative MRI Indicators of Brain Manganese and Iron and Relation to Welding Fume Exposure, Mood and Motor Function

A. Mitchell, Q. Wang, K. M. Witkowiak, N. Shin, C. Lee, C. Knight, J. Park, D. Foti, and U. Dydak. Purdue University, West Lafayette, IN.

Background and Purpose: Chronic occupational manganese (Mn) exposure can cause adverse health effects such as deficits in motor and cognitive function, as well as mood disturbances. Welders exposed to Mn through welding fumes, even at low levels, have been shown to accumulate Mn in the brain and perform worse

than controls on tests of motor function. Quantitative Magnetic Resonance Imaging (qMRI) quantifies the relaxation rates R1 and R2*, altered by paramagnetic Mn and iron (Fe), respectively. As part of a larger neuroimaging study in welders, this analysis investigated whether Mn and Fe deposition was symmetric in the human brain, and if qMRI changes in specific brain regions related to exposure metrics of Mn and Fe, mood or motor function. **Methods:** A total of 104 subjects, consisting of 53 career welders and 51 non-exposed, age-matched controls, participated in this imaging study after giving written informed consent. qMRI data was acquired on a Siemens 3T Prisma scanner and reconstructed to R1 and R2* maps, allowing us to explore regions-of-interest (ROIs) from major brain structures, including the caudate nucleus (CN), globus pallidus (GP), and putamen (Put). Each ROI value was compared between left or right brain regions using a two-tailed t-test with two-sample equal variances to test for symmetry. Motor function was assessed through the Unified Parkinson's Disease Rating Scale (UPDRS) Part III. The Brief Symptom Inventory test is a self-administered survey on 9 mood domains, summarized by the Global Severity Index (GSI) score. Cumulative and short-term (past 3 months) exposure indices (CEIs) for Mn and Fe were estimated using personal air sampling and a work history questionnaire. Group differences for mean ROI values, CEIs, GSI data, and UPDRS scores were explored using two-tailed t-tests with unequal variances. Spearman correlations were used to test correlations of qMRI values with exposure, UPDRS and GSI scores. **Results:** All ROIs were found to be symmetric. All exposure metrics showed a significant group difference for welders versus controls. Consistent with higher Mn deposition, welders showed lower T1 ($=1/R1$) than controls across all basal ganglia: CN ($p = 0.007$), GP ($p < 0.0001$), and Put ($p < 0.05$). R2* showed no group differences. When considering all subjects, R1 did not correlate with R2* in any ROI, whereas R2* correlated strongly across regions. In all ROIs, R2* related to age ($p < 0.001$) and to cumulative CEIs (all $p < 0.04$). In the GP, R1 was not correlated to age in the pooled analysis but showed a positive correlation with both short- and long-term exposure metrics ($p > 0.4$, $p < 0.001$ for all). In welders alone, this correlation was only a trend for short-term CEI, but still significant for Mn and Fe air levels and cumulative CEIs. Interestingly, in welders, R1 was also positively correlated with age. Significant symptom associations were found for R1 in the GP with GSI ($p = 0.024$), which vanished in the pooled analysis, and for R1 and R2* in all ROIs with UPDRS ($p < 0.01$) both in all subjects and welders alone. **Conclusions:** Mn and Fe brain deposition across all ROIs were found to be symmetric, allowing us to use bilateral means of each ROI for analysis. In the analysis of welders versus controls, T1 was significantly lower across all basal ganglia ROIs for the welding group, consistent with increased Mn brain deposition in welders. The lack of group differences in R2*, a proxy for brain Fe, indicates that exposure to welding fumes does not alter brain Fe, whereas its relation to cumulative CEI even in non-welders is consistent with age-linked Fe effects. In contrast, R1, a proxy for brain Mn, was not related to age, except in welders alone, likely only due to increased cumulative Mn deposition with age in welders. Instead, R1 is associated with short- and long-term Mn exposure and thus is a better function of exposure. Increased UPDRS scores indicating worsening motor function were positively associated with both Mn and Fe brain concentrations, in line with a well-described decline both with cumulative exposure to Mn as well as the known decline with age, which in turn is linked to increased brain iron. The association with mood scores in welders only is also in line with previous literature on mood - exposure associations in Mn exposed subjects. A whole-brain analysis, exploring many more brain regions for such associations is in progress.

PS 3104 Chromium (VI) and Manganese (III) Exposure Induces Lifespan Reduction and Endothelial Barrier Disruption

D. Kim¹, N. Boonpraman¹, S. T. Vielee², N. Kuhn¹, J. P. Wise Jr.³, and S. Sammi¹.

¹Michigan State University, Grand Rapids, MI; ²University of Louisville, Louisville, KY; and ³University of Toledo, Toledo, OH.

Background and Purpose: Chromium (Cr) and manganese (Mn) are trace metals that pose significant risk at elevated levels. Naturally occurring Cr(III) can be converted to a more toxic form, Cr(VI) in the presence of manganese oxides (MnOx), especially Mn(VI), resulting in soluble Mn(II) or (III) oxides. Co-occurrence of Cr(VI) and MnOx commonly occurs in geogenic sources (e.g. ultramafic bedrock) and cast iron pipes. Both Cr(VI) and Mn(III) are independently associated with oxidative stress, mitochondrial dysfunction, and disruption of neurovascular integrity. While Cr(VI) exposure is linked to motor neuron diseases, the underlying mechanism is unknown. Comparative evaluation of metal toxicity at both the organismal and cellular levels is essential to understand the mechanisms underlying metal-induced neurovascular impairment. In this study, we employed *Caenorhabditis elegans* as an *in vivo* model and human umbilical vein endothelial cells (HUVECs) as an *in vitro* system to assess the biological effects of Cr(VI) and MnOx exposures across different levels of biological organization. **Methods:** Synchronized *C. elegans* at the L1 larval stage were exposed to sodium chromate ($\text{Na}_2\text{Cr}_2\text{O}_7$; 5, 50, and 100 mg/L) and manganese (III) oxide (Mn_2O_3 ; 5, 50, and 100 mg/L), either individually or in combination. Combination treatments included 5 mg/L Cr(VI) + 5 mg/L Mn(III), 5 mg/L Cr(VI) + 50 mg/L Mn(III), 50 mg/L Cr(VI) + 5 mg/L Mn(III), and 50 mg/L Cr(VI) + 50 mg/L Mn(III). Exposures were conducted for 24 h at 22 °C. Lifespan assays were performed, and survival distributions were analyzed using the Kaplan-Meier method to evaluate treatment-related effects on organismal longevity. For the cellular assessment, HUVEC monolayers were exposed to sodium chromate at concentrations of 0.5, 1, and 2 μM . Trans endothelial electrical resistance (TEER) was measured for up to five days to monitor time- and concentration-dependent changes in endothelial barrier integrity.

Results: Lifespan analysis of *C. elegans* revealed a statistically significant reduction in survival following metal exposures. Control worms exhibited a median lifespan of approximately 12 days, whereas exposure to sodium chromate and manganese (III) oxide resulted in median lifespans of 11-13 days and 9-11 days, respectively. Worms co-exposed to both metals exhibited overall shorter lifespans (8-10 days), suggesting potential additive toxicity between chromium and manganese. Kaplan-Meier survival analysis confirmed significant differences among treatment groups (log-rank test, $p < 0.0001$), and an apparent dose-dependent decline in lifespan was observed in single-metal exposure groups. TEER measurements showed minimal changes at 0.5 μM chromium, with resistance remaining close to baseline levels (0.95-1.09 relative to control). In contrast, both 1 μM and 2 μM exposures exhibited a gradual and sustained reduction in resistance through day 5, reaching approximately 0.76-0.82 of baseline levels (18-24 % decrease). This pattern suggests a progressive weakening of endothelial barrier stability and intercellular cohesion over time. **Conclusions:** Chromium (VI) and manganese (III) exposures led to significant reductions in *C. elegans* lifespan, with combined treatments producing additive effects. TEER analysis revealed a gradual decline in endothelial resistance following 1-2 μM chromium exposure, suggesting progressive weakening of barrier stability over time. Collectively, these results demonstrate that heavy metal exposures disrupt physiological homeostasis in a concentration-dependent manner and may contribute to cellular and tissue-level dysfunction. Consistent with previously reported mechanisms involving oxidative stress, mitochondrial dysfunction, and weakening of intercellular junctions, these observations suggest that metal exposure may trigger early alterations that compromise vascular and physiological integrity, warranting further molecular investigation.

PS 3105 Non-monotonic NMDA receptor localization alterations resulting from low-dose, early developmental lead (Pb) exposure in excitatory hiPSC-neurons

J. S. Smith, K. P. Dean, J. Colacino, P. M. Jenkins, and D. C. Dolinoy. University of Michigan, Ann Arbor, MI.

Background and Purpose: Developmental lead (Pb) exposure remains a major public health concern due to its lasting impact on brain function through disrupted excitatory neurotransmission—a feature commonly shared by many neuropsychiatric disorders. The CDC's blood lead reference level is 3.5 $\mu\text{g}/\text{dL}$, a threshold exceeded by 2.5% of U.S. children. Excitatory neurotransmission is heavily regulated by N-methyl-D-aspartate receptor (NMDAR) synaptic localization and composition. In the hippocampus and prefrontal cortex, NMDARs contain two obligatory NR1 subunits and two modulatory NR2A or NR2B subunits. NR2A-containing receptors are predominantly synaptic, whereas NR2B-containing receptors localize to both synaptic and extrasynaptic membranes. Synaptic NMDAR activation promotes synaptic strengthening, while extrasynaptic activation drives synaptic weakening and can induce autophagy. Thus, developmental shifts in NMDAR subunit composition and localization are critical for cortical maturation, and perturbations to this process in early life have been implicated in psychiatric disorders such as ADHD, schizophrenia, and bipolar disorder in adulthood. Previous research has indicated an increase in synaptic NMDARs resulting from early developmental exposure to 1 μM Pb in hippocampal rat cultures (Neal et al., 2010). However, the impact of Pb exposure on NMDAR localization in human-neuronal synapses resulting from low dose Pb exposure is unknown. **Methods:** Neurotypical patient-derived hiPSCs were differentiated into excitatory neurons via NGN2 overexpression and co-cultured with rat astrocytes. Cells were exposed to 0, 0.16, 0.625, or 2.5 μM Pb via culture media between day-in-vitro (DIV) 8-DIV28, corresponding to concentrations of blood Pb of approximately 0, 3.32, 12.95, and 51.80 $\mu\text{g}/\text{dL}$, respectively. Neurons were fixed in paraformaldehyde (PFA) and stained for axon initial segment marker (ankyrin-G), post-synaptic density protein (PSD95), obligatory NMDAR subunit (NR1), and dendritic marker (MAP2), and imaged via confocal microscopy ($n = 3$ per condition). IMARIS was used to quantify NR1 colocalization with PSD95. Synaptic NMDARs were calculated as the proportion of NR1-PSD95 colocalized spots relative to total NR1 puncta, and analyzed using two-way ANOVA with Tukey's multiple comparisons. **Results:** NR1 colocalization with PSD95 was significantly increased following exposure to 0.16 μM Pb relative to control ($p = 0.0084$), but was significantly lower in the 2.5 μM Pb group relative to the 0.16 μM Pb group ($p = 0.0033$). No significant differences were observed between 0.625 μM Pb and control ($p = 0.473$), or in NR1 and PSD95 values relative to MAP2 at 0.16 μM ($p = 0.213$, 0.205) or 0.625 μM ($p = 0.425$, 0.930). **Conclusions:** To our knowledge, this is the first study examining the impact of Pb exposure on NMDAR synaptic localization in human-iPSC neurons. Experimental results show that low-dose Pb exposure increases synaptic NMDAR localization in hiPSC-excitatory neurons relative to control, and decreases synaptic NMDAR localization at intermediate doses. These findings indicate a non-monotonic effect of early neurodevelopmental Pb exposure, and that neurotoxicological effects of Pb exposure may begin occurring at concentrations below both current public health thresholds and those observed in previous non-human animal model research. Further research is in progress to explore how Pb exposure affects NMDAR subunit composition and associated epigenetic mechanisms in both control cell lines and bipolar disorder patient-derived hiPSCs. This work contributes to understanding the relationship between developmental Pb exposure in excitatory synapses and potential compensatory mechanisms.

PS 3106 Lead(Pb)-induced neuroinflammation in the developing zebrafish brain

H. Weinschutz Mendes, W. A. Tamagno, and J. L. Freeman. School of Health Sciences, Purdue University, West Lafayette, IN.

Background and Purpose: Despite global efforts to decrease lead (Pb) exposure and contamination, the challenge remains substantial, and Pb still poses a significant threat to human health globally, being classified by the World Health Organization (WHO) as one of the top 10 chemicals of major public health concerns. Infants and children are particularly vulnerable to the neurotoxic effects of Pb, due to the complexity of the developmental stage of the Central Nervous System (CNS). Pb has been associated with reduced IQ, attention deficits, impaired brain development, and the onset of neurodegenerative conditions later in life. Dysregulation of neuroinflammation, or inflammation within the CNS, is one of the main mechanisms by which contamination with Pb exerts its effects. This study aims to elucidate how Pb exposure dysregulates neuroinflammation during development, which pathways and cell types are involved, and how these disruptions are associated with certain neurological conditions. The central hypothesis is that Pb developmental exposures in zebrafish, exacerbate neuroinflammation through microglial activation and dysregulate anti- and pro-inflammatory and complement cascade genes. **Methods:** Due to its many advantages, such as the high-throughput tractability of various developmental processes, fast and external development and high similarities with the human genome, the zebrafish has become an ideal animal model for toxicological studies and analyses of neurodevelopmental aspects. To study the effects of Pb on dysregulation of neuroinflammation, zebrafish embryos were exposed starting at 1-2 hours post fertilization (hpf) until 72 hpf to different concentrations of Pb [1, 10, or 100 parts per billion (ppb), $\mu\text{g}/\text{L}$], which represent values below (1 ppb) and above (10 and 100 ppb) the limit established as safe by Center for Disease Control and Prevention (CDC). This exposure period encompasses important developmental windows when the zebrafish brain is formed and is comparable to critical windows of exposures in humans. First, microglia dysregulation was assessed through live-imaging surface staining and immunostaining of microglia cells within the brain of zebrafish. Next, through RNA and protein analyses, dysregulated genes and protein expression of markers for neuroinflammation, including complement cascade-related genes, microglia activation, and genes implicated in synapse elimination, were evaluated. **Results:** Following Pb exposure, a concentration-dependent increase was identified in the number of microglia cells throughout the brain in zebrafish through live-imaging with neutral red staining at 96 hpf. This increase was significant in the 10 and 100 ppb Pb exposed groups, with more microglia cells visible in the forebrain region of the zebrafish when compared to the negative control. Analysis of RNA expression through qPCR indicated a possible immediate neuroinflammatory response due to Pb toxicity, with an increase in *mpeg* (macrophage expressed 1 gene) and *c3a.1* (Complement Component 3 gene) expression in some of the Pb-exposed groups at 120 hpf. **Conclusions:** In this study, analyses of neuroinflammatory responses following Pb exposure provides important mechanistic understanding of the neurotoxic effects of Pb and its impacts on neurodevelopment, particularly involving neuroinflammatory processes. This understanding can guide needed identification of biomarkers for early detection of the neurotoxic effects of Pb and of neuroinflammation. Ultimately, these findings can be used to improve interventions to mitigate the effects of Pb exposures, which continue to be devastating not only for development but also having consequences throughout different life stages.

PS 3107 Developmental Methylmercury Exposure Causes Persistent Proteomic Perturbations in Cortically Differentiated Human Induced Pluripotent Stem Cells

R. Mishra, A. M. Tukker, H. Kim, V. P. Thirumalaikumar, and A. B. Bowman. Purdue University, West Lafayette, IN.

Background and Purpose: Developmental exposure to the environmental toxicant Methylmercury (MeHg) is linked to long-lasting neurotoxic outcomes such as cognitive decline, but molecular mechanisms behind these persistent effects remain unclear. Our prior work (published and unpublished) identified persistent transcriptomic alterations following transient developmental MeHg exposure; here, we further assessed whether such persistent changes are also observed/translated at the protein level and across different MeHg concentrations using global proteomics. We hypothesized that developmental exposure of different environmentally relevant MeHg concentrations can induce persistent proteomic changes that manifest across different stages of brain cortical development. **Methods:** Three neurotypical human induced pluripotent stem cell (hiPSC) lines—two female (AD2-2, CC3) and one male (CD10)—were differentiated into cortical lineages via dual SMAD inhibition. Developing cultures were exposed to 1, 10, or 100 nM MeHg from days 7-13, when neuroepithelial and radial glial cells predominate, followed by differentiation and collection in form of cell pellets at days 43 and 120. Cell pellets were processed for LC-MS/MS-based global proteome profiling using data-independent acquisition (DIA). Normalized protein matrices were analyzed using RStudio and Qiagen Ingenuity Pathway Analysis (IPA) to identify significantly altered proteins and pathways. Autophagy, one key perturbed pathway, was validated by immunofluorescence (IF) using p62, LC3, and ubiquitin markers, and autophagic flux was examined after Bafilomycin (10 nM) treatment. **Results:** DIA proteomics quantified over ~8,000 proteins across MeHg concentrations and time-points. Principal component analysis

(PCA) at D43 revealed distinct separation of 100 nM MeHg from vehicle control in all lines, with AD2-2 showing a clear dose-response. Volcano plots indicated lower doses (10, 1 nM) mainly downregulated proteins, while 100 nM induced widespread upregulation. Only one protein/pathway was shared across all doses between all lines (Cell-cycle check points), whereas 100 and 10 nM shared nine. Pathway analysis for top 20 pathways from D43 100 nM overlapped strongly with our prior scRNA-seq data top pathways (e.g. mitochondrial dysfunctions, oxidative phosphorylation, sirtuin signaling etc.). At D120, even 10 nM exposure caused PCA separation from vehicle control indicating persistent proteomic effects. Additionally, 10 and 100 nM MeHg shared 209 altered proteins (compared to 9 for D43) indicating lower dose of MeHg development exposure is causing similar protein changes like higher MeHg dose at later-time points. Comparison between D43 and D120 (100 nM) identified 28 common proteins and 11 pathways across all lines. Common pathways involved proteostasis (autophagy), mitochondrial bioenergetics, and epigenetic regulation. IF confirmed increased p62, LC3, and ubiquitin puncta, indicating lower autophagy flux. Common protein analysis helps in identification of protein biomarkers for early detection of MeHg persistent toxicity. **Conclusions:** Developmental MeHg exposure caused persistent proteomic alterations across all hiPSC lines, with the strongest effects being observed at 100 nM. AD2-2 exhibited concentration-dependent effects, suggesting genetic variation influences MeHg sensitivity. Analysis across both male and female hiPSC lines suggests that the persistent effects of MeHg developmental exposure is sex-independent. High MeHg dose induced protein upregulation, whereas low dose promoted downregulation suggesting different effects of MeHg dose on proteome. Overlap between D43 proteomic and scRNA-seq pathways indicates transcript-to-protein concordance. Shared pathways and proteins between D43 and D120 reveal long-term proteome remodeling after transient developmental MeHg exposure. Protein biomarker was identified to understand the MeHg persistent toxicity and the same is validated using different techniques of IF, and western blotting. Disrupted autophagy suggests loss of proteostasis as a possible mechanism linking developmental MeHg toxicity to later-life neurodegenerative diseases (e.g. Alzheimer's, Parkinson etc.) vulnerability. The work was funded by NIH [R01 ES07331 and AG080917].

PS 3108 Gut Microbe *Akkermansia muciniphila* Mitigates Cadmium-Induced Cognitive and Hippocampal Dysfunction in Mice

H. Wang¹, J. J. Lim², H. Gu³, and J. Y. Cui⁴. ¹Department of Environmental Health Sciences, University of Michigan, Ann Arbor, MI; ²Institute for Systems Biology, Seattle, WA; ³College of Health Solutions, Arizona State University, Phoenix, AZ; and ⁴Department of Environment and Molecular Toxicology, Oregon State University, Corvallis, OR.

Background and Purpose: Cadmium (Cd) is a widespread environmental contaminant and neurotoxicant associated with learning and memory impairments in humans. We and others showed that Cd-induced gut dysbiosis contributes to neurotoxicity through disrupting the gut-brain axis, a bidirectional signaling pathway between the gastrointestinal (GI) tract and the central nervous system (CNS). Given the critical role of the gut microbiome in regulating brain function, modulating the gut microbiome has gained increasing attention as a potential strategy to mitigate cognitive deficits. *Akkermansia (A) muciniphila*, a mucin-degrading bacterium residing in the intestinal mucus layer, has been proposed as a next-generation probiotic with neuroprotective potential. This study investigated whether *A. muciniphila* pretreatment could prevent or mitigate Cd-induced hippocampus-dependent cognitive deficits and explored the underlying mechanisms. **Methods:** Adult male C57BL/6J mice (n = 10/group) were pretreated with live *Akkermansia muciniphila* (1×10⁹ CFU/day, oral gavage, once daily) for 5 days prior to and throughout cadmium (Cd) exposure (3 ppm Cd in drinking water) for nine weeks. Cognitive performance was assessed using a battery of behavioral tests evaluating learning and memory. Molecular changes in hippocampus were analyzed by RNA sequencing to identify differentially expressed genes associated with cognitive function by Cd and *A. muciniphila*. Intestinal tissues were examined by qPCR for genes related to intestinal integrity and inflammation. Short-chain fatty acids (SCFAs), bile acids, and inflammatory cytokines were quantified using targeted biochemical assays. Brain Cd levels were also quantified using ICP-MS. **Results:** Cadmium exposure impaired hippocampus-dependent spatial learning and memory in adult mice. Pretreatment with *A. muciniphila* effectively prevented these behavioral deficits. Short-chain fatty acid or bile acid levels in brain or serum and Cd levels in brain were unchanged by *A. muciniphila*, suggesting other biochemical mechanisms leading to the mitigation of Cd-induced learning and memory deficits. RNA sequencing of the hippocampus revealed two major gene clusters altered by Cd exposure and reversed by *A. muciniphila* treatment. Cd downregulated genes involved in neuronal signaling and synaptic plasticity (e.g., *Otof*, *Lypd1*, *Penk*, and *Trh*) while upregulating stress- and inflammation-related genes (*Hp*, *Alb*, *Serpina1e*, and *Uox*). Consistent with these findings, qPCR and cytokine analyses showed that *A. muciniphila* restored Cd-suppressed tight junction gene expression (*Cldn*, *Tjp*, *Jam*) and reduced circulating inflammatory cytokines (*IL-10*, *IL-1α*). **Conclusions:** *Akkermansia muciniphila* treatment may mitigate Cd-induced cognitive impairments by preserving intestinal barrier integrity and modulating neuroinflammation and synaptic signaling. These results underscore the preventive and therapeutic potential of microbiome-targeted strategies for reducing environmental neurotoxicity.

PS 3109 Quantitative MRI and Light-Sheet Microscopy Reveal Subchronic Manganese-Induced Neuronal Activation in a Neurodevelopmental Mouse Model

K. M. Clark¹, A. A. Tienda¹, L. N. Brigante², D. C. Colvin³, E. S. Calipari¹, A. B. Bowman⁴, and F. E. Harrison¹. ¹Vanderbilt University, Nashville, TN; ²Novartis Biomedical Research, Boston, MA; ³Vanderbilt University Institute of Imaging Science, Nashville, TN; and ⁴Purdue University, West Lafayette, IN.

Background and Purpose: Manganese (Mn) is an essential trace element for dopaminergic function; however, even moderate, sustained Mn exposure through drinking water can disrupt dopamine neurotransmission. Dysregulation of the dopamine transporter (DAT) produces anomalous dopamine efflux and impaired reuptake, resulting in behavioral deficits observed with autism spectrum disorders (ASD) and attention-deficit/hyperactivity disorder (ADHD). To investigate an interplay between gene and environment, we leveraged the DAT^{T356M/+} knock-in mouse model carrying the *de novo* ASD-associated T356M variant originally identified in an individual with restricted and stereotyped behaviors. Although the neurotoxic effects of acute Mn toxicity are well known, the *in vivo* effects of prolonged, lower-level exposure remain unclear. We tested whether subchronic Mn exposure alters DAT-dependent circuit responsiveness to amphetamine (AMP) and methylphenidate (MPH) and used whole-brain neuroimaging modalities to visualize, map, and quantify Mn distribution. We hypothesized that subchronic, low-dose Mn in drinking water would induce region-specific T1/T2 shortening on quantitative magnetic resonance imaging (MRI) without volumetric loss and that these relaxometry changes would align with altered *c-Fos* and tyrosine hydroxylase (TH) activity within the basal ganglia-thalamocortical circuits using light-sheet fluorescence microscopy (LSFM). **Methods:** Male and female DAT^{T356M/+} mice and WT littermates were pseudorandomly assigned at weaning to control water (2.5% stevia) or Mn water (2.5 mg/mL Mn + 2.5% stevia) *ad libitum* for 5 weeks. Locomotor activity was recorded for three 60-minute habituations and a 3-hour drug session on separate days (MPH 5 mg/kg or AMP 3 mg/kg; 1-week washout). *Ex vivo* brains were imaged at 7 Tesla to generate quantitative T1/T2 parametric maps; voxel-wise mono-exponential fits were registered to the Allen Brain Atlas and processed in Slicer 5.4.0 and MATLAB R2024a to quantify means and volumes. Mice received AMP 1 hour pre-euthanasia; brains were fixed in 4% paraformaldehyde, embedded in SHIELD/CLARITY hydrogel, optically cleared, and imaged with a SmartSPIM LSFM at 3.6x/0.2 NA; 488 nm autofluorescence, 561 nm *c-Fos*, 647 nm TH. Stitched volumes were analyzed with SmartAnalytics v2.0 software, a machine-learning pipeline to enable automated, region-wise quantification of TH+ and *c-Fos* + cell counts, volumes, and densities. **Results:** Male DAT^{T356M/+} mice exposed to Mn exhibited increased hyperactivity compared to littermate controls, travelling further than wild-type (WT) littermates during initial habituation sessions. Mn potentiated the effect of both AMP and MPH in males although the effect differed according to genotype. These differences were not observed in females for either drug according to Mn treatment. Mn exposure produced robust T1 shortening across seven brain regions (two-way ANOVA, p<0.0001) in both cohorts, with the largest effects in the globus pallidus, substantia nigra, thalamus, and striatum. This pattern reflects region-selective susceptibility to Mn accumulation and early basal ganglia-thalamocortical disruption before atrophy. Volumetric analyses showed no differences in regional brain volumes across groups, indicating Mn exposure altered relaxation properties in the absence of structural changes. Optically cleared brains showed greater TH+/*c-Fos*+ co-labeling in female DAT^{T356M/+} mice than in WT females and males, indicating enhanced dopaminergic activation. Co-localization was most pronounced in the ventral tegmental area, while the isocortex exhibited the highest overall *c-Fos*+ cell counts. **Conclusions:** By linking drinking-water Mn exposure to alterations in catecholaminergic circuits, these data provide a translational basis for differences in how patients from different environmental contexts respond to AMP, MPH, and associated drugs. This multimodal workflow offers exposure-sensitive, whole-brain biomarkers for preclinical testing and future patient stratification, advancing personalized therapeutics for ADHD, ASD, and related neurological disorders.

PS 3111 Cadmium exposure alters mitochondrial function and promotes *in vitro* aggregation of the tau protein, a neuropathological hallmark of Alzheimer's disease

N. Boonpraman¹, D. Kim¹, F. Shehjar¹, A. Sue², K. McReneris², T. O'Hallaran², B. Combs¹, and S. R. Sammi¹. ¹Michigan State University, Grand Rapids, MI; and ²Michigan State University, East Lansing, MI.

Background and Purpose: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by the pathological accumulation of tau protein and amyloid beta (Aβ). Around 90% of the AD cases are sporadic with no clear genetic cause. Cadmium (Cd) is a heavy metal used in a variety of industrial processes. Typical routes of human exposure include contaminated food, tobacco smoke, and occupational exposures. Cd is known to bioaccumulate, leading to elevated concentrations in humans from chronic exposure, even exceeding safe limits. Up to 20% of Americans have elevated levels beyond what is considered safe. Increased Cd levels are associated with increased risk of AD, lower levels of cognition, and increased levels of AD biomarkers. However, little is known about how Cd might increase risk of AD and what effect it might have on progression of tau pathology. **Methods:** In this study, we use extracted mitochondria, *Caenorhabditis elegans*, and rodent models

of tauopathy to identify how Cd exposure affects disease mechanisms and the characteristic pathological hallmarks of AD. Mitochondria were acutely exposed to CdCl₂ and evaluated for enzyme activity. Mitochondria isolated from sub-chronically exposed mice-brain were tested for enzyme activity (normalized to citrate synthase). *Caenorhabditis elegans* nematodes were exposed to CdCl₂ for two days and stained with reduced Mitotracker red to test for mitochondrial viability. Nematodes expressing anti-aggregation and pro-aggregation tau were tested for Ach-associated paralysis through Aldicarb assay. Using Quantitative Elemental Mapping techniques, we measured Cd accumulation in the nematodes. *In vitro* tau aggregation studies were conducted in Hek 293 cells expressing fluorescently tagged truncated P301S tau (RD cells). The cells were exogenously treated with combinations of 150 nM recombinant tau and CdCl₂, then assessed for tau aggregation compared to controls. **Results:** Exposing nematodes to cadmium induced a dose-dependent decrease in mitochondrial viability and Ach-associated paralysis (Aldicarb assay). Notably, the effect on Ach-associated behavior was higher in anti-aggregation tau strains and highest in pro-aggregation tau strains. Mitochondrial complex II was significantly inhibited in both acute exposure studies and in brain mitochondria isolated from mice exposed to Cd subchronically (21 days). Notably, sex differences were observed as we found that the mitochondria isolated from male mice were more vulnerable. *In vitro* tau aggregation assays in RD cells revealed a significant increase in tau aggregation upon exposure to Cd. **Conclusions:** These results highlight mitochondrial dysfunction as a potential synergistic mechanism of tau- and Cd-induced toxicity. They also indicate that Cd may promote aggregation of tau, a neuropathological hallmark of AD. Together this supports further studies exploring these potentially toxic mechanisms using *in vitro*, transgenic *C. elegans*, and rodent models to understand the interplay between Cd exposure and AD.

PS 3112 The Gut Microbial Metabolite S-equal Partially Protected against Cadmium-induced Neuronal Cell Death Associated with Transcriptomic Signatures involved in Neurogenesis

Y. P. Suh, and J. Y. Cui. Oregon State University, Corvallis, OR.

Background and Purpose: Cadmium (Cd) is an emerging environmental neurotoxicant and blood Cd levels positively associate with increased risk of Alzheimer's disease mortality in older U.S. adults. Neural progenitor cells in the subventricular zone (SVZ), one of only two adult neurogenesis sites, are particularly vulnerable to cadmium exposure due to high metabolic activity and preferential toxicant accumulation. S-equal, a gut microbiome-derived metabolite of the soy isoflavone daidzein and selective estrogen receptor beta (ERβ) agonist, has been suggested to be neuro-protective, yet no studies have tested its effect against Cd neurotoxicity. Importantly, only about 20-30% of individuals in Western populations naturally produce S-equal, compared with 50-70% in Asian populations. This disparity underscores the need to evaluate S-equal supplementation in high-risk groups within the United States. Such efforts could advance precision medicine approaches targeting at-risk populations to Cd exposure. As an initial step towards this goal, the present study tested our hypothesis that S-equal protects against Cd neurotoxicity associated with transcriptomic remodeling. **Methods:** Primary mouse SVZ neural progenitor cells from 8-week-old male C57BL/6 mice were exposed to CdCl₂ and S-equal at various concentrations for 24 hours. Cell viability was assessed using WST-8 colorimetric assay (n=8-20 per group). RNA-sequencing was conducted at selected concentrations and differential expression analysis was performed using DESeq2. Pathway and co-expression network analyses were also performed to identify core genes coordinately responding to Cd toxicity and S-equal intervention. **Results:** Cd induced neuronal cell death in a concentration dependent manner, with the first observed cytotoxicity at 5 μM (17% cell death) and the highest cytotoxicity at 10 μM (32% cell death). S-equal displayed a safe toxicological profile with no observed cytotoxicity at any concentrations tested. S-equal at both 100 and 200 μM partially protected against Cd (5 μM) neurotoxicity. Interestingly, even at lower S-equal concentration (25 μM) and higher Cd concentration (7.5 μM), S-equal still offered partial protection against Cd neurotoxicity. Bulk RNA-Seq was performed to determine the effect of S-equal (25 μM) on Cd (7.5 μM)-induced transcriptomic response. Cd dysregulated 10,320 genes, with the top up-regulated pathways involved in neurodegeneration, amyotrophic lateral sclerosis, and Alzheimer's disease; whereas the top down-regulated pathways were involved in neurogenesis and neuronal differentiation, neuronal survival and synaptic signaling, as well as cell polarity and synaptic architecture. S-equal altered the expression of 1950 Cd-dysregulated genes, among those 655 genes were normalized towards baseline. The top pathways of the S-equal remediated gene battery were synaptic transmission and plasticity, neuronal differentiation, axon guidance and circuit organization, as well as myelination and neuronal membrane integrity. Co-expression network analysis identified 20 core genes coordinately dysregulated across all treatment comparisons (correlation threshold 0.7), revealing key mechanistic pathways including upregulated stress response and neuroprotective genes (Hspa5/GRP78, Sv2c, Elovl4, Nab2). Examples of the S-equal remediated genes include: Vstm2b (neural circuit formation), Necdin/Ndn (Prader-Willi syndrome gene essential for neuronal survival), and Slc22a29 (organic cation transporter). Notably, S-equal also restored the expression of Prox1, a master regulator of hippocampal neurogenesis critical for learning and memory, and Sv2c, a synaptic vesicle protein associated with epilepsy, highlighting preservation of both neurogenic capacity and synaptic function. **Conclusions:** Our study demonstrated for the first time that the gut microbial metabolite S-equal protects neural progenitor cells from Cd-induced neurotoxicity associated with restoring transcriptomic networks involved in synaptic plasticity,

neuronal differentiation, and myelination. Follow up *in vivo* studies are needed to further explore the therapeutic potential of S-equal as a precision neuroprotective intervention for populations at elevated Cd exposure risk.

PS 3113 Evaluation of Neurotoxicity in Guinea Pigs Exposed to Hexavalent Chromium in Drinking Water for 90 Days

J. P. Wise, Jr.¹, J. Vergis¹, S. T. Vilee², M. E. Delnicki², G. C. Griffin², S. S. Diven², J. Easley², J. C. Kouokam², I. Meaza², H. Lu², A. Brownell², S. F. Gueye², N. Butzke-Souza², J. P. Wise, Sr.², R. McCullumsmith¹, and J. L. Wise². ¹University of Toledo, Toledo, OH; and ²University of Louisville, Louisville, KY.

Background and Purpose: Hexavalent chromium [Cr(VI)] is a ubiquitous environmental pollutant and potent toxicant, currently ranked as the #1 chemical hazard in U.S. public drinking water. Cr(VI) toxicity is well-characterized for inhalation exposures with known links to lung cancer; however, there is minimal research available for drinking water exposures. Similarly, the neurotoxic effects of Cr(VI) are poorly characterized in animal models or human studies. There are a few epidemiology studies that established links for motor neuron disease and attention/learning disorders in children, but no clear mechanistic details. These limitations diminish our ability to adequately characterize health risks associated with Cr(VI) exposure from drinking water, presenting a significant knowledge gap given its prevalence. We previously reported Cr(VI) drinking water exposures result in neurotoxicity that appears to target the hippocampus and related behaviors. Here, we present new results from a similar study using Hartley guinea pigs given tap water or 5.0 mg/L Cr(VI) in drinking water for 90 days. We chose guinea pigs, as they are more homologous to humans for vitamin C synthesis and Alzheimer's disease risk, as they require vitamin C supplementation in their diet and their amyloid β sequence is 100% identical to humans. We performed serine/threonine (STK) and phosphotyrosine (PTK) kinase array profiling to determine which protein kinase signaling pathways were impacted by Cr(VI) exposure in the dorsal hippocampus, considering both sexes. The integrated pathway analysis suggested risks for neurodegenerative diseases, with notable signaling effects in neuroinflammation, oxidative stress, myelin damage, synaptic dysfunction, and metabolic stress. **Methods:** Forty Hartley guinea pigs aged 10.5-11.5 months (both sexes) were exposed to Cr(VI) (0 or 5 mg/L) in drinking water for 90 days (N = 10/group). After sacrifice, brains were bisected with one half preserved for histology and the other microdissected into 12 regions for metallomic or proteomic analyses. Metallomic samples from 11 different brain regions were analyzed on an Agilent 8300 (N = 4-5). Kinome array samples were analyzed with STK and PTK chips on the PamStation 12 (PamGene Inc) followed by a bioinformatics workflow including the KRSA (Kinome Random Sampling Analyzer) R package for the dorsal hippocampus (N = 4-5). **Results:** Metallomic analyses revealed significant Cr accumulation in the dorsal hippocampus and pituitary gland of females, but little to no accumulation in males or other brain regions. Kinomic data revealed distinct clustering of results for control vs. Cr(VI) exposed, and between sexes. Dominant effects in males were mitochondrial and genotoxic stress driven by MAPK-GSK3-CHK2 activation and suppression of ATM/ATR and PDGFR/SRC pathways. Dominant effects in females were neuroinflammation and cytoskeletal stress driven by FAK, JAK/STAT, and DAPK/AKT pathways. Effects in both sexes converged on neuroinflammation and cognitive impairment, but by distinct mechanisms. **Conclusions:** We conducted a pilot study with guinea pigs exposed to Cr(VI) through drinking water to better model what may happen in human physiology. Guinea pigs are more similar than traditional rodent to humans for Alzheimer's disease contexts. Our data suggest Cr(VI) may be a risk factor for Alzheimer's disease and other neurodegenerative diseases based on brain regions that are targeted and protein kinase pathways that are activated. Our STK/PTK profiling predicts cognitive impairment, memory loss, neuroinflammation, demyelination, and vulnerability to several neurodegenerative diseases. Funding support from "la Caixa" Foundation LCF/BQ/EU22/11930060 (IM), NIEHS R35ES032876 (JPWSr.), and NIEHS T32ES011564 (MD, STV).

PS 3114 Transcriptional mechanisms of Manganese-induced dysregulation of 14-3-3γ via YY1 in CAD neuronal cells

I. Ajayi¹, K. Ofori¹, E. Pajarillo¹, S. Kim¹, A. Digman¹, M. Aschner², and E. Lee¹. ¹Florida A&M University, Tallahassee, FL; and ²Albert Einstein College of Medicine, New York, NY.

Background and Purpose: Chronic overexposure to manganese (Mn) via occupational and environmental sources causes a neurological condition known as manganism, sharing similar symptoms with Parkinson's Disease (PD). Although several mechanisms of Mn toxicity have been reported, the precise underlying mechanism is yet to be fully delineated. 14-3-3s are a class of regulatory proteins that are abundant in the brain and play a crucial role in various cellular processes by interacting with diverse target proteins. There are seven isoforms of 14-3-3s, regulated by different genes, but dysregulation of the 14-3-3γ isoform has been implicated in neurodegenerative diseases, including Alzheimer's Disease and PD. Moreover, Parkinsonian neurotoxins such as MPTP and rotenone are known to decrease the expression of 14-3-3γ, whereas overexpression of 14-3-3γ protects against neurotoxicity induced by these toxins. However, it is not known if Mn dysregulates the expression of 14-3-3γ, particularly at the transcriptional level. Notably, the promoter sequence of 14-3-

3y contains a putative binding site for transcription factor Yin Yang 1 (YY1), which is well established to be activated by Mn, collaborating with the epigenetic modifier histone deacetylases (HDACs) in other neural cell types, including astrocytes. Therefore, the present study investigated if Mn dysregulates 14-3-3y expression in neuronal cells. **Methods:** Cath-a-differentiated (CAD) neuronal cells were employed in this study. A luciferase assay was performed to measure the promoter activity of 14-3-3y. Quantitative polymerase chain reaction (qPCR) was used to measure mRNA levels/ Western blotting was employed to measure protein levels. Transient transfections were also used to overexpress 14-3-3y, YY1, and HDACs in CAD cells. Co-immunoprecipitation (Co-IP) was performed to determine the interaction between YY1 and HDACs in the nuclear fraction of CAD cells. **Results:** Our results showed that Mn treatment (250 μ M, for up to 12 hours) decreased 14-3-3y promoter activity and mRNA/protein levels in CAD cells. Mn also increased YY1 protein levels and its nuclear translocation at 12h, while overexpression of YY1 decreased 14-3-3y promoter activity, mRNA/protein levels. Moreover, YY1 also recruited several HDAC isoforms, such as HDACs 1, 2, 5, and 6, to repress 14-3-3y transcription. Accordingly, histone deacetylase inhibitors, such as Suberoylanilide hydroxamic acid (SAHA) and Valproic acid (VPA), attenuated Mn-induced decrease in 14-3-3y promoter activity and protein levels. **Conclusions:** Taken together, these results suggest that the Mn-activated YY1-HDAC pathway may mediate Mn-induced decrease in 14-3-3y expression in neuronal cells.

PS 3115 Psychological Symptomatology in Welders and Non-Welders Exposed to Manganese and Iron

K. M. Witkowiak, N. Shin, C. G. Lee, C. Knight, R. Harold, J. Park, D. Foti, and U. Dydak. Purdue University, West Lafayette, IN.

Background and Purpose: Chronic occupational exposure to manganese (Mn) has been shown to lead to psychiatric problems. Mood disorders and changes in mood are among the first symptoms reported in those with chronic Mn exposure. Welding fumes also contain a high percentage of iron (Fe). Disruptions in Fe homeostasis have been linked to the progression of neurodegenerative disorders, which are often accompanied by psychiatric diseases. Furthermore, both Fe deficiency and overload have been shown to relate to psychopathology. Both Mn and Fe exposure are being tested in this study as they are known to share transport and regulatory pathways in the brain. In a past cohort, our lab found that both welders and non-welders at the same factory reported high levels of psychological distress. In a new cohort, we sought to reassess whether reports of psychological distress differed across welders and non-welders and if symptomatology related to Mn and Fe exposure levels. **Methods:** The two groups consisted of 35 welders and 26 non-welding employees at the same factory. Exposure to Mn and Fe was assessed using personal air sampling and a work history interview. The Brief Symptom Inventory (BSI) was administered to evaluate psychological symptoms across nine domains. Domains assessed include somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism. A Global Severity Index (GSI) measuring psychological distress across all domains was also calculated. Furthermore, T-scores that compare the raw scores of participants to a normative non-patient sample were calculated. T-tests were conducted to compare exposure levels and psychological domains across the two groups. Then, Spearman's rho correlations were calculated to assess the relation between exposure levels and psychological distress. **Results:** Welders had significantly higher Mn and Fe exposure than non-welders ($p < 0.001$ for all tests). Welders and non-welders at the same factory displayed similar reports of psychological symptoms across all domains and similar levels of overall psychological distress. 34.3% of welders and 26.9% of non-welders had a clinically significant total level of psychological distress as indexed by the GSI. T-scores above 62 are considered clinically significant for each domain. When plotted against normative data, both groups demonstrated a clinical elevation on the paranoid ideation subscale (W: $T=64$, NW: $T=64$) and the psychoticism dimension subscale (W: $T=63$, NW: $T=64$) compared to a non-patient normative sample. This indicates elevated suspicion of others and increased withdrawal and social isolation. Non-welders at the factory reported a clinical elevation on the obsessive-compulsive subscale ($T=69$) reflecting an increase in subjective cognitive complaints. Notably, Mn and Fe exposure did not significantly correlate with overall psychological distress in both welders and non-welders. **Conclusions:** While welders are exposed to significantly higher levels of Mn and Fe, there is no difference in reports of psychological distress between welder and non-welder factory workers. These findings suggest that elevated psychological distress in factory workers may not be driven only by Mn or Fe exposure and highlight the need to consider workplace, social, and environmental factors when developing interventions to address mental health in occupational settings. Next, it will be important to assess how exposure impacts mood symptoms in individuals over time as well as what other factors may be explaining elevated psychological symptoms in workers at this factory. We plan to collect matched office controls to compare with both welder and non-welder factory workers. This will allow us to assess if other aspects of factory work or socio-cultural factors may better explain this distress.

PS 3116 APOE3/4 Heavy Metal Exposure: Synaptic Dysfunction and Alzheimer's Disease Progression

Y. Wang^{1,2}, and L. Smirnova^{1,2}. ¹Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; and ²Center for Alternatives to Animal Testing, Baltimore, MD.

Background and Purpose: Alzheimer's disease (AD) is a progressive neurodegenerative disorder affecting an estimated 6.9 million Americans aged 65 and older in 2024. Although the exact causes of AD remain unclear, both genetic and environmental factors play crucial roles in its onset and progression. The *APOE4* allele of the apolipoprotein E (*APOE*) gene is widely recognized as the most significant genetic risk factor for AD, and metals such as cadmium (Cd) and chromium (Cr) have been shown to induce neurotoxicity. However, little is known about how these risk factors interact and contribute to AD pathogenesis. This study aims to investigate the interaction between environmental exposure to Cd and Cr and *APOE4* genotype (GxE) in the context of AD, focusing on neuroinflammation-mediated synaptic alterations that may precede the development of the main pathological hallmarks of the disease. **Methods:** In this study, we sought to determine GxE effects on synaptic functions in AD. For this purpose, neural organoid derived from induced pluripotent stem cells (iPSCs) with *APOE3/3* and *APOE4/4* genetic background were used. As additional controls, organoids from age-matched healthy donor and donor with ideopathic AD were processed in parallel. Microglia-like cells (MGLs) were introduced into neural organoids in a stepwise manner through iPSCs differentiation to hematopoietic progenitor cells (HPC) and subsequent integration with NPCs. Neural organoids with and without microglia were exposed to 320 nM Cd, 320 nM Cr, and 320 nM Cd-320 nM Cr mixture for one week at 8 and 12 weeks of differentiation. Immunostaining was used to visualize and quantify synaptic integrity and density, microglia morphology, neurite outgrowth, and astrocyte migration. AD hallmarks such as Amyloid beta plugs and Tau tangles are assessed at 12 week time point with immunostaining and western blot. **Results:** Preliminary results showed distinct effects of Cd, Cr, and their mixture on neurite outgrowth and astrocyte migration in *APOE3/3* and *APOE4/4* neural organoids. Cd exposure consistently inhibited both processes in the *APOE3/3* neural organoid at both time points, whereas its effects were less pronounced in the *APOE4/4* neural organoids. Cr exposure produced variable effects across lines and time points. Mixture exposure did not have a synergistic effect on neurite outgrowth. It significantly increased neurite outgrowth in the *APOE3/3* neural organoid at 8 weeks and in both lines at 12 weeks. At the same time, a significant decrease in astrocyte migration was observed in both lines at both time points. SynapseJ analysis in ImageJ further revealed that metal exposure reduced synapse count in both cell lines at 8 weeks. In contrast, the preliminary 12-week data showed less evidence of perturbed synapsis in both lines. Currently experiments are ongoing to verify the microglia morphology upon exposure in both cell lines as well as spontaneous and evoked electrical activity of these organoids upon exposure to the metals. We are optimizing the experiments to quantify AD hallmark via western blotting and immunostaining. **Conclusions:** These preliminary results indicate that Cd and Cr exposure can differentially affect neuronal and astrocyte development in an *APOE* genotype-dependent manner. While Cd exerted stronger inhibitory effects on neurite and astrocyte migration in *APOE3/3* neural organoids, both *APOE3/3* and *APOE4/4* neural organoids exhibited marked synaptic loss at 8 weeks following metal exposure. This early synaptic vulnerability may reflect disrupted synaptic integrity and neuron-astrocyte interactions. More data is needed to further characterize to synaptic and glial dysfunction, potentially contributing to early neurodegenerative change underlying AD. With the ongoing introduction of MGL-neural organoid, this neural organoid model will provide a baseline system lacking neuroinflammatory components, enabling subsequent studies to investigate how metal-induced early synaptic dysfunctions interacts with inflammation-driven AD mechanisms. These findings may offer critical insights into gene-environment interactions driving AD progression and support the early identification of individuals at risk before the appearance of established pathological biomarkers.

PS 3117 Yin Yang 1 (YY1) Mediates Manganese-Induced Downregulation of REST in CAD Neurons

K. Ofori¹, I. Ajayi¹, E. Pajarillo¹, M. Aschner², and E. Lee¹. ¹Florida A&M University, Tallahassee, FL; and ²Albert Einstein College of Medicine, New York, NY.

Background and Purpose: Prolonged manganese (Mn) exposure leads to a neurological condition known as manganism, which shares similar symptoms with Parkinson's disease (PD). RE1-Silencing Transcription Factor (REST) has been shown to exert neuroprotection in experimental models and is dysregulated in the brains of several neurodegenerative diseases, including Alzheimer's disease and Parkinson's disease. At the transcriptional level, REST increased the expression of antioxidant genes and the dopamine (DA) synthesis gene tyrosine hydroxylase (TH). Notably, our previous studies have shown that Mn decreased REST expression in *in vivo/vitro* experimental models, yet the underlying mechanism of Mn-induced decrease in REST expression is yet to be elucidated. Prior studies have revealed that Mn enhanced a transcription factor Yin Yang 1 (YY1) expression to induce Mn toxicity in neurons and astrocytes, but it is unknown if YY1 is involved in Mn-decreased REST expression. Therefore, the present study investigated whether Mn downregulates REST expression via YY1 in CAD neuronal cells. **Methods:** Cath-a-differentiated (CAD) neuronal cells were used, and REST promoter activity was measured by luciferase assay. Quantitative

PCR (qPCR) and western blot (WB) were employed to assess mRNA and protein levels, respectively. We also overexpressed YY1 and histone deacetylases (HDACs) in CAD cells by transient transfection of YY1 and histone deacetylases (HDACs) plasmid vectors to determine their regulatory effects on REST expression. Chromatin Immunoprecipitation (ChIP) assay was performed to determine the effects of Mn on YY1 binding to the REST promoter. **Results:** Mn decreased REST promoter activity, mRNA, and protein levels in CAD cells. Mn increased YY1 expression, and YY1 overexpression decreased REST and TH transcription. Three YY1 binding sites were identified in the REST promoter, and Mn enhanced YY1 binding to these sites within the REST promoter region. Mn also enhanced YY1's interaction with epigenetic modifiers HDACs. **Conclusions:** Our findings demonstrate that YY1 plays an important role in Mn-induced decrease in REST expression in CAD neurons.

PS 3118 The Behavioral and Neurotoxic Effects of Arsenic and Alcohol Co-Exposure

M. Hernández, G. A. Picha, N. D. Morford-Oberst, S. Medina, and A. M. Barkley-Levenson. University of New Mexico Health Sciences Center, Albuquerque, NM.

Background and Purpose: Arsenic (As) exposure through contaminated drinking water remains a major global health concern. Chronic As exposure has been associated with a range of neurobiological and behavioral abnormalities, including anxiety-like behaviors, impaired learning, and disruptions in dopaminergic (DA) signaling. Similarly, excessive alcohol consumption is a major public health issue that also alters DA transmission, stress pathways, and neurocircuitry related to reward and anxiety. While both As and alcohol independently induce adverse neurobehavioral outcomes, the potential for co-exposure to exacerbate these effects remains poorly understood. Given the overlap in their neural targets, combined exposure to As and ethanol (EtOH) may produce additive or synergistic effects on behavior and neurochemistry. The current study aimed to (1) determine whether chronic low-dose As exposure increases binge-like EtOH intake, (2) assess whether As and EtOH co-exposure exacerbates anxiety-like behaviors, and (3) identify exposure-related changes in behavioral and neural biomarkers associated with DA function and stress regulation. **Methods:** Male and female C57BL/6J mice ($n = 39$) were randomly assigned to one of four exposure conditions in a 2×2 design: arsenic (in the form of arsenite, AsIII) exposure (0 ppm or 1 ppm) $\times$ EtOH exposure (tap water or 20% EtOH). AsIII exposure was delivered continuously in drinking water, while EtOH exposure was administered using a Drinking-in-the-Dark (DID) paradigm to model binge-like self-administration. During daily, 3-week DID procedure, mice had 2-hour access to 20% EtOH or tap water beginning 3 hours into the dark cycle. Behavioral assays were conducted to assess locomotor activity and anxiety-like behavior following exposure. Locomotor activity was quantified by total distance traveled in the open field test (OFT), while anxiety-like behavior was assessed by time spent in the center zone of the OFT. Various tissues, including the brain, were collected for ongoing analyses of As accumulation and neurochemical biomarkers related to DA and stress systems. **Results:** Significant sex-dependent effects of AsIII exposure were observed in locomotor behavior. AsIII exposure decreased locomotor activity in males and increased activity in females ($p < .05$), suggesting a sexually dimorphic response to chronic low-dose arsenic. However, co-exposure to AsIII and EtOH did not produce additional alterations in locomotor behavior. Additionally, there were no significant differences in ethanol or water consumption between groups ($p > .05$), indicating that AsIII exposure did not enhance binge-like drinking behavior under the conditions tested. Anxiety-like behavior was not significantly affected by co-exposure; however, a main effect of sex was detected, with males spending more time in the center zone than females ($p < .05$). This pattern suggests greater anxiety-like behavior in females across exposure conditions. **Conclusions:** Co-exposure to AsIII and EtOH did not exacerbate behavioral phenotypes relative to individual exposures. Nevertheless, the observed sex-specific effects of AsIII on locomotor activity highlight the potential for differential vulnerability to environmental neurotoxins across sexes. Ongoing analyses are quantifying As accumulation in peripheral and neural tissues and assessing alterations in DA and stress-related markers within the striatum and hippocampus. These data will provide critical mechanistic insight into how chronic low-dose arsenic exposure interacts with alcohol to influence brain function and behavior. Collectively, this work advances understanding of combined environmental and substance-based neurotoxicity.

PS 3119 Perinatal Lead Exposure Associated with Increased Diffuse and Vascular β -Amyloid in Aged Murine Brain

R. K. Morgan, E. K. Matei, I. L. Bergin, T. Ishikawa, J. Pan, K. M. Polemi, D. C. Dolinoy, K. M. Bakulski, and J. A. Colacino. University of Michigan School of Public Health, Ann Arbor, MI.

Background and Purpose: Exposure to neurotoxicants during development can have long-lasting implications for cognition. Exposures such as lead (Pb) are suspected contributors to dementia. Several types of dementia, particularly Alzheimer's disease (AD), are associated with abnormal accumulations of β -amyloid (A β). Vascular accumulation of A β can contribute to AD pathology, vascular dementia, or general cognitive decline. A β accumulations contribute to neural toxicity via amyloid angiopathy and neuroinflammation. We explored the impact of developmental Pb exposure on

brain A β accumulation in a mouse model. **Methods:** Female mice (6-8 weeks old) were exposed to 32ppm Pb or control water for two weeks prior to mating through offspring weaning at postnatal day 21. Offspring were aged to 18 months. The final sample size included 11 female and 10 male control and 10 female and 10 male Pb-exposed. The left brain hemisphere was formalin fixed and paraffin embedded. Standard hematoxylin and eosin (H&E) and Luxol Fast blue (LFB) stained slides were used to assess general morphology and myelin, respectively. Immunohistochemical staining with an antibody targeting monomeric, oligomeric, and fibrillar forms of A β 1-42 peptide was performed. Descriptive and quantitative analysis was performed by a board-certified veterinary pathologist blinded to experimental conditions. For immunostaining, slides were digitized and staining intensity/distribution was assessed using pixel classifiers using QuPath (v0.6.0). Controls included an archival mouse AD brain slide (positive), and a non-immune serum in place of primary antibody (negative). The percent of non-staining, lightly staining, and darkly staining area was assessed across the entire tissue. A separate threshold was used to quantify the highest intensity staining, which corresponded to capillaries and foci of mineralization. Differences in all outcomes were compared between sex-stratified exposure groups using two-sided t-tests and significance set to $p \leq 0.05$. **Results:** There was no evidence of neuronal necrosis, endothelial cell/vascular necrosis, decreases in neural number/density, or changes in myelin in any of the samples as assessed. Focal mineralization in the thalamus was noted in 9 of 41 samples but was not specific to exposure group. Distinct A β plaques were absent but there was low to moderate A β immunolabeling diffusely across the grey matter of the cerebrum and thalamus. Mean A β intensity across the entire tissue was higher in exposed female samples relative to controls, with a fold change (FC) of 1.26 ($p = 0.004$). This trend was also present in male tissues (FC = 1.12) but did not reach statistical significance ($p = 0.095$). The highest intensity A β labeling was located in capillary walls throughout the brain and in the mineralized thalamic foci described above. There were significantly more A β positive cells in the exposed samples versus control for both males and females. Exposed males had, on average, 469 A β positive cells per tissue compared to 258 in control (FC = 1.82, $p = 0.032$). Exposed females had, on average, 320 A β positive cells per tissue compared to 166 in control (FC = 1.92, $p = 0.011$). **Conclusions:** Perinatal Pb exposure led to an increase in diffuse A β and A β -positive cells in 18-month murine brain. Although A β plaques were not present, this was not an AD-specific model, and C57BL/6 mice are known to be resistant to AD-like pathology. Diffuse and vascular distribution of A β may be more reflective of the general increase in A β deposition associated with general cognitive impairment or amyloid angiopathies. Ongoing work is quantifying the presence of other dementia hallmarks, including phosphorylated tau and neuroinflammation in the same tissues, as well as perinatal Pb exposure in the 5xFAD mouse model, which robustly presents dementia hallmarks.

PS 3120 RNA-sequencing reveals dose- and sex-specific transcriptomic disruptions in the adolescent rat hippocampus following developmental lead exposure.

S. E. Hardin, A. N. Rodichkin, J. L. McGlothlin, and T. R. Guilarte. Florida International University, Miami, FL.

Background and Purpose: One in three children worldwide are susceptible to the detrimental health effects of lead (Pb²⁺), a toxic heavy metal ubiquitous in the environment. Although the Center for Disease Control (CDC) has set the level of concern to 3.5 $\mu\text{g}/\text{dL}$, they recognize that any amount of Pb²⁺ exposure has detrimental effects to the developing brain. Infants and young children are particularly susceptible to Pb²⁺ neurotoxicity during brain development. Children exposed to Pb²⁺ are at risk of neurodevelopmental delays, cognitive impairment, memory and learning disabilities, and behavioral abnormalities. Epidemiological studies indicate that early life Pb²⁺ exposure is associated with neurodevelopmental disorders (ND) such as Autism Spectrum Disorder (ASD), attention-deficit hyperactivity disorder (ADHD), and Schizophrenia (SZ). A significant number of similarities in the neurobiological pathways affected provoked us to investigate if shared molecular mechanisms are observed across multiple Pb²⁺ exposure levels and how they relate to ND. This study explores the effect of exposure to different levels of Pb²⁺ exposure on gene expression changes in the hippocampus of adolescent animals. **Methods:** We chronically exposed Long-Evans rats to Pb²⁺ acetate (PbAc) using chow containing low (180 ppm PbAc), medium (650 ppm PbAc), and high (1500 ppm PbAc) concentrations, as well as a non-exposed control group. Exposure occurred throughout gestation and after birth, when the pups were chronically exposed to the same diet as the dams until they were used at a specific age. RNA-sequencing (RNAseq) was utilized to explore the differential effects of chronic early life lead exposure (CELLE) at all four doses in the hippocampus of male and female rats. Briefly, RNA was isolated using TRIzol from the hippocampus of male and female postnatal day 28 (PN28) rats at each exposure level ($n=4-5$). RNA pellets were then collected, resuspended in TAE buffer, and read using the BioTek Cytation5 Take3. Purity was assessed and recorded. Finally, isolated RNA was sent to Novogene for sequencing and analysis. **Results:** Blood Pb²⁺ levels of non-exposed controls, low, medium, and high exposure groups were as follows: 1.9 $\mu\text{g}/\text{dL}$ (limit of detection; male $n=12$; female $n=12$), 5.2 $\pm$ 0.5 $\mu\text{g}/\text{dL}$ (male $n=9$; female $n=9$), 15.6 $\pm$ 0.9 $\mu\text{g}/\text{dL}$ (male $n=10$; female $n=10$), and 22.4 $\pm$ 0.8 $\mu\text{g}/\text{dL}$ (male $n=10$; female $n=10$), respectively. RNAseq results indicate that there were significant sex- and dose-dependent differences in male and female PN28 hippocampus-isolated RNA. Males had significantly more differentially expressed genes (DEG) compared to females at low (168:0), medium (13:1), and high Pb²⁺ concentra-

tions (442:4) [significant factors = $-\log_{10}(\text{padj}) > 1.3$; $\log_2\text{FoldChange} < -0.5$ and > 0.5]. Additionally, female DEG follow a dose-dependent increase correlating to blood Pb²⁺ levels. However, DEG in the male cohort were greatest at the high and low concentration, with less DEG in the medium exposure group. Finally, the most enriched GO pathways for both sexes and exposure levels were related to signal transduction, mitochondrial metabolism, and ribosomal structural pathways, while enriched KEGG pathways included signal transduction pathways, mitochondrial metabolism, and neurodegenerative diseases. **Conclusions:** Our hippocampal RNAseq analysis reveals sex- and dose-specific transcriptional responses to Pb²⁺ exposure in adolescent rats, with males exhibiting a markedly higher number of DEG and enriched GO/KEGG pathways. Disruption of signal transduction, mitochondrial metabolism, and ribosomal function in CELLE rats mirror pathophysiological features of ND such as ADHD, ASD, and SZ. Given epidemiological studies indicating that boys are 2-4 times more likely to be diagnosed with ND than girls (Ferri, Abel, & Brodtkin, 2018; Dimitri et al., 2025), our data in CELLE rats suggests environmental exposure to Pb²⁺ may influence ND through convergent neurotoxic mechanisms. To our knowledge, this is the first study to conduct RNA-sequencing of isolated hippocampal RNA in male and female adolescent rats ranging from non-exposed to high-exposure levels with significant implications to children's health.

PS 3121 Akkermansia muciniphila Prevents Cadmium-Induced Alzheimer's Disease-Like Dementia Linked to Epitranscriptomic Modulation in the Mouse Hippocampus

Z. Kowash¹, J. Lim², A. Annalora¹, H. Wang³, and J. Cui¹. ¹Oregon State University, Corvallis, OR; ²University of Washington, Seattle, WA; and ³University of Michigan, Ann Arbor, MI.

Background and Purpose: Cadmium (Cd) is an emerging environmental neurotoxicant associated with Alzheimer's disease (AD) mortality in older adults in the United States. Emerging evidence suggests that the gut-brain axis contributes to neurotoxicity and neuroprotection. Our recent findings unveiled that Cd produced dysbiosis of the gut microbiome associated with memory deficits in mice. For example, *Akkermansia muciniphila*, a mucin-degrading bacterium in the intestine, was decreased by Cd over a time course. Epitranscriptomic N⁶-methyladenosine (m⁶A) modifications in the brain have emerged as novel regulators of AD. Yet, very little is known regarding how Cd or the gut-brain axis contributes to the brain epitranscriptome. This study tested our hypothesis that *A. muciniphila* prevents Cd-induced AD-like dementia associated with epitranscriptomic modulation of the hippocampus. **Methods:** Eight-week-old male C57BL/6J mice (n = 9-10 per group) were orally gavaged *A. muciniphila* (ATCC BAA-835, 10⁹ CFU per mouse/day, 5 days a week) or vehicle for 11 weeks, beginning one week prior to 10-week exposure to CdCl₂ (3 mg/L) via drinking water. Learning and spatial memory was assessed using novel object location (NOL) test at weeks 0, 5, 7, and 9 of Cd exposure. At week 10 of Cd exposure, hippocampal tissue was collected for bulk RNA sequencing and epitranscriptomic analysis. *A. muciniphila* abundance was quantified using qPCR. Cd concentrations in brain tissue were determined using inductively coupled plasma mass spectrometry (ICP-MS). Molecular analyses identified differentially expressed (DESeq2) and methylated hippocampal genes (ArrayStar m⁶A array; FDR < 0.05). **Results:** *A. muciniphila* co-exposure resulted in increased *A. muciniphila* abundance in the gut microbiome, and it protected against Cd-induced memory deficits at all behavioral time points sampled. ICP-MS analysis unexpectedly revealed moderately elevated hippocampal Cd levels in mice co-exposed to Cd and *A. muciniphila* compared with mice exposed to Cd alone, suggesting that neuroprotection occurred despite increased metal burden. *A. muciniphila* supplementation up-regulated hippocampal genes involved in m⁶A modification, whereas Cd downregulated all of them. Interestingly, *A. muciniphila* co-exposure reduced the mRNA levels of most differentially regulated hippocampal genes involved in m⁶A modification, with the exception of *Ythdf1*, a key mediator of methylation-guided translation, whose expression was restored under co-exposure conditions as compared to Cd exposure alone. Minimal hypermethylation patterns were observed in any exposure groups. Interestingly, *A. muciniphila* administration, either alone or in combination with Cd, led to a widespread hypomethylation of hippocampal transcripts, with the top pathway involved in alternative splicing. An overlay between RNA-Seq and epitranscriptomic data unveiled that the majority of the co-regulated genes were co-down-regulated with decreased mRNAs and hypomethylation patterns. This *A. muciniphila*-remediated gene battery against Cd insult was mainly involved in amino acid transport, lipid metabolism, as well as RUNX-mediated inflammatory response. In addition, many of these genes have been recognized to have plausible protective roles in AD-relevant processes, including synaptic signaling, neuroinflammation and innate immune activation, lipid homeostasis, calcium handling, and proteostasis or cellular stress responses. **Conclusions:** These findings support the hypothesis that *A. muciniphila* mitigates Cd-induced AD-like cognitive impairment associated with epitranscriptomic remodeling in the hippocampus rather than through reductions in brain metal burden. Together, these analyses point to m⁶A-dependent regulatory mechanisms as a potential interface through which gut microbial interventions buffer hippocampal function against environmental toxicants.

PS 3122 m6A mRNA Epitranscriptomic Dysregulation Drives Microglia-Induced Neuroinflammation in Models of Environmentally Linked Parkinsonism

D. Miller^{1,2,3}, A. Gregory^{1,3}, A. Ealy^{1,3}, G. Richardson^{1,2}, W. Albers^{1,4}, J. Gardner^{1,3}, A. Sanikapally¹, G. Zenitsky¹, H. Jin^{1,3}, V. Anantharam^{1,3}, A. Kanthasamy^{1,3,2,4}, ¹Isakson Center for Neurological Disease Research, University of Georgia, Athens, GA; ²Department of Biochemistry and Molecular Biology, University of Georgia, Athens, GA; ³Department of Physiology and Pharmacology, University of Georgia, Athens, GA; and ⁴Department of Biology, University of Georgia, Athens, GA.

Background and Purpose: Parkinson's disease (PD) and related disorders, collectively known as Parkinsonisms, can be characterized by the accumulation of pathological α -synuclein (α Syn) in the basal ganglia (BG), including the substantia nigra (SN). The highest non-genetic risk factor for PD is aging, followed by exposure to certain environmental toxins, including the heavy metal manganese (Mn). These factors directly activate glial cell populations, leading to chronic neuroinflammation and progressive neurodegeneration. Emerging evidence suggests that epitranscriptomic mRNA modification represents a top-tier regulatory mechanism governing essential biological processes in both health and disease. Our recent studies suggest the m⁶A epitranscriptomic pathway, specifically the METTL3 writer complex and the downstream reader YTHDF2, is critical in Mn and α Syn-induced glial activation. To this end, we premise that dysregulation in the m⁶A reader YTHDF1 complex is critical in promoting neuroinflammatory processes observed in environmentally induced Parkinsonism. **Methods:** We employed C20 human microglial or U373 human astrocytic cells and exposed them to a non-cytotoxic dose of Mn (100 μ M) conditions for *in vitro* characterization. YTHDF1-2 knockdown (KD) was achieved utilizing siRNA against YTHDF1-2. Overexpression (OE) studies were accomplished via PEI-mediated delivery of YTHDF1/2 or YTHDF1/2-FLAG plasmids. For *in vivo* studies, mice were given saline or Mn (0.4 g/L)-containing drinking water for 30 d or orally gavaged with Mn (30 mg/kg) dissolved in ultrapure water daily for 30 d. **Results:** We observed that Mn significantly increased the expression of the m⁶A readers YTHDF1 and YTHDF3 in microglia as well as astrocytes 24 h post exposure. Mn exposure in astrocytes and microglia significantly increased the levels of proinflammatory chemokines (Cxcl12, Cxcl10, Cxcl8, Ccl2, and Ccl3) and cytokines (IL-1 β , IL-1 α , and IL-6). YTHDF1 KD attenuated Mn-induced proinflammatory factors while YTHDF1 OE exacerbated Mn-neuroinflammation. In contrast, YTHDF2 KD stabilized these transcripts, thus exacerbating Mn-induced neurotoxicity, and YTHDF2 OE attenuated the Mn-induced increase following Mn-induced activation in both immune cells. Together, this work suggests opposing functionality of YTHDF1 and YTHDF2 may modulate neurotoxic signaling processes. Interestingly, we also noted that YTHDF1 KD alleviated and YTHDF2 KD exacerbated activation of Fyn and PKC δ , a tyrosine and serine kinase, respectively, both being strongly implicated in neuroinflammatory processes. This work confirmed our RIP-seq dataset, showing that YTHDF2 regulated the stability of Fyn transcripts. Corroborating *in vitro* results, striatal YTHDF1 and YTHDF3, along with Fyn and PKC δ , significantly increased in IBA1⁺ microglia as well as GFAP⁺ astrocytic cells in Mn-exposed mice compared to controls, with Fyn and PKC δ protein levels being rescued upon YTHDF1 KO and further stabilized with YTHDF2 KO. **Conclusions:** In conclusion, we demonstrate that the YTHDF1 paralogs are dynamically dysregulated in Mn-induced models of glial activation. Our data also reveal that increases in YTHDF1 and YTHDF3 correlate with increased proinflammatory signaling in microglia and astrocytes, while YTHDF2 negatively regulates proinflammatory events. Interestingly, the opposing regulation of the YTHDF1 and YTHDF3 reader translational machinery complex vs the YTHDF2 decay machinery appears to differentially modulate the Fyn-PKC δ axis in neurotoxicant-induced glial activation. Collectively, our study advances our understanding of m⁶A-mediated epitranscriptomic dynamics in models of environmentally induced PD and highlights the YTHDF paralogs as major upstream mRNA regulators of neuroinflammatory processes preceding the onset of neurodegenerative diseases.

PS 3123 Characterizing brain region-specific gene expression changes following perinatal lead (Pb) exposure in the mouse brain

E. K. Matei¹, R. K. Morgan¹, A. Tapaswi¹, H. Wang¹, X. Zhou², D. C. Dolinoy¹, K. M. Bakulski¹, and J. Colacino¹. ¹University of Michigan School of Public Health, Ann Arbor, MI; and ²Yale University Department of Statistics and Data Science, New Haven, CT.

Background and Purpose: Lead (Pb) exposure is associated in epidemiological studies with both childhood neurological disorders and dementias like Alzheimer's disease (AD) later in life. Since AD is characterized, in part, by neuroinflammation and altered gene expression patterns in the brain, it is pertinent to assess whether early-life Pb exposure results in changes consistent with those observed in AD. The purpose of this study is to assess immediate and long-term gene expression changes across brain regions in response to perinatal Pb exposure, to address the question of how Pb exposure contributes to neuroinflammation, neurotoxicity, and AD development later in life. **Methods: Sample Size, Exposure, and Tissue Collection** C57BL/6 females between 6-8 weeks of age were randomly assigned to control or Pb water exposure two weeks prior to mating with C57BL/6 males. Females were exposed to a 32-ppm solution of drinking water mixed with Pb-acetate (pH 4.5). Exposure continued throughout gestation and weaning, until the offspring reached post-natal day 21 (PND21), at which time offspring were either sacrificed (PND21, N = 39) or

switched to control water and housed until 18 months of age (N = 41). At sacrifice, three brain regions - hippocampus, cortex, and cerebellum - were collected from each mouse. Tissues were flash frozen and stored at -80°C prior to use. **RNA Isolation, Sequencing, and Analysis** RNA was isolated from each brain region using the Qiagen Allprep Kit. RNA samples were used for library preparation and sequencing using the plexWell method (SeqWell). Libraries were sequenced on the Illumina NovaSeq X Shared Flow Cell at the UM Advanced Genomics Core, and reads were aligned to the mouse genome via STAR and counted using FeatureCounts. The counts-per-sample matrices generated were filtered to remove genes with low counts using the edgeR filterByExpr() function with default settings. Differential gene expression analysis (adj. P-val < 0.05) of PND21 and 18-month RNA transcript count data, stratified by timepoint, brain region, and sex, was performed using edgeR. Pathway enrichment analysis to identify enriched biological ontologies was performed using the fgsea package, in which a ranked list of genes is used to perform enrichment analysis. **Results:** Analysis of PND21 brain region-specific RNA-sequencing data identified 7 genes (cerebellum), 0 genes (hippocampus), and 6 genes (cortex) that differed in expression between Pb-exposed and control samples. Interestingly, controlling for brain region resulted in 71 differentially expressed genes across all three brain regions in PND21 mice (adj. P-val < 0.05). Example genes of interest found to be differentially expressed include *Rsad2* (adj. P-val = 1.53e-10, log2FC = -0.889), *Mt1* (adj. P-val = 5.26e-06, log2FC = 0.247), and *Ube2l6* (adj. P-val = 2.00e-06, log2FC = -0.386). Genes differentially expressed at PND21 were found to be enriched in hallmark pathways including TNF- α signaling, interferon gamma response, and interferon alpha response (adj. P-val < 0.05). Analysis of 18-month brain region-specific RNA-sequencing data identified 0 genes (cerebellum, cortex, and hippocampus) that differed in expression between Pb-exposed and control samples. Likewise, controlling for brain region resulted in 0 genes differentially expressed across brain regions (adj. P-val < 0.05). Ranked gene expression results from the 18-month-old mice were found to be enriched only in the interferon alpha hallmark pathway, with increased expression of genes enriched in this pathway (adj. P-val < 0.05). **Conclusions:** PND21 mice exposed to Pb during gestation showed differential gene expression changes, while no genes reached genome-wide significance in 18-month-old mice. Pb-exposed mice exhibiting differential expression of genes associated with immune signaling suggests a potential mechanism by which perinatal Pb exposure contributes to AD via neuroinflammation. Future analysis will involve deconvolution of bulk RNA-seq data to determine if cell proportions are affected by Pb-exposure and aging.

PS 3124 Neuroinflammation in Rats after 90 Day Drinking Water Exposure to Low Concentration Hexavalent Chromium

H. Jamal¹, S. H. Roof¹, S. T. Vilee¹, W. J. Buchanan¹, H. Lu¹, S. S. Diven¹, I. Meaza¹, J. L. Wise¹, and J. P. Wise Jr.². ¹University of Louisville School of Medicine, Louisville, KY; and ²University of Toledo, Toledo, OH.

Background and Purpose: We are living in an era of unprecedented aging and extended lifespan. The global geriatric population (65+) is expected to reach 20% by 2050 and at the same time, the centenarian population (100+) will increase 7-fold. These dramatic demographic shifts are set to bring a host of new challenges, in particular the health impacts of environmental pollution on an aging population. Hexavalent chromium [Cr(VI)] is a ubiquitous environmental pollutant and highly potent toxicant - recently identified as the #1 chemical hazard in U.S. public drinking water. However, few studies have considered the interactions between Cr(VI) and brain aging. Reports suggest Cr(VI) induces neuroinflammation, a complex immunological reaction involving activation of microglia and astrocytes. Astrocytes are crucial for brain health as they maintain neurotransmitter homeostasis, provide structural support, help form the blood-brain barrier, among many other roles, while microglia act as resident immune cells. **Methods:** We investigated the intersection of toxicology and aging using the Toxic Aging Coin approach; the heads side considers how different ages are impacted by chemical toxicity, while the tails side focuses on how chemicals accelerate biological aging. We investigated Cr(VI) neurotoxicity by exposing young (3-m.o.), middle-aged (7-m.o.), and geriatric (18-m.o.) male Sprague-Dawley rats to Cr(VI) in drinking water consistent with the World Health Organization (WHO) and United States Environmental Protection Agency (U.S. EPA) maximum contaminant levels (0.05 and 0.1 mg/L, respectively). Effects of Cr(VI) on astrocyte (GFAP) and microglia (IBA-1) activation in the dorsal and ventral hippocampus were assessed as markers of neuroinflammation, using immunohistochemistry and Sholl analysis. Sholl analysis was performed using open source software Fiji and custom python code. We hypothesized that Cr(VI) induces neuroinflammation. **Results:** Initial results from the ventral hippocampus show microglial activation with increasing Cr(VI) concentration seen by decreases in both cell processes length and distance from cell body. Astrocyte activation was also noted with higher average intersection maxima and shifts in intersections further from the nucleus with increasing concentration. **Conclusions:** Our data begins to characterize a mechanism for which Cr(VI) exposure through drinking water induces neurotoxicity. Future work will investigate mechanisms driving microglial and astrocyte activation and better define sex-, age-, and brain region-specific differences. These data will be critical for determining how low concentrations of Cr(VI) in drinking water contribute to neurological diseases. Funding provided by T32-ES011564 (STV) and R21-ES033327 (JPW).

PS 3125 Nickel dysregulates Hox-dependent spinal motor neuron differentiation

V. Goriainova, X. Zhang, J. Zhai, and S. Cuddapah. New York University Grossman School of Medicine, New York, NY.

Background and Purpose: Nickel (Ni) is a naturally occurring ubiquitous heavy metal. However, anthropogenic activities such as industrial processes and widespread use of Ni-containing products have elevated its levels in the atmosphere. Furthermore, fossil fuel combustion, including diesel exhaust, has significantly contributed to its increase in the environment. Humans are exposed to Ni through inhalation, ingestion and dermal contact. Ni is well-known to be toxic to multiple organ systems, including lungs, liver and kidneys. Recently, developmental neurotoxicity has emerged as an important health concern associated with Ni exposure. Studies show that Ni can cross the placental barrier in mice, causing neural tube defects, and early Ni exposure in zebrafish and *C. elegans* leads to impaired neurodevelopment and neuronal damage. In infants, higher Ni levels are linked to lower neurocognitive scores. However, the mechanisms underlying Ni's developmental neurotoxicity remain unclear. In this study, we investigated Ni-induced neurotoxicity during spinal motor neuron development using mouse embryonic stem cells (mESCs) to model early neurodevelopment. **Methods:** Mouse embryonic E14Tg2a stem cells were differentiated into cervical motor neurons using well-established protocols employing retinoic acid and smoothened receptor agonist (SAG). For Ni exposure, the cells were treated with non-cytotoxic doses of 1-150 μ M NiCl₂. Gene expression changes were examined by RT-qPCR. H3K27me3 enrichment was assessed by chromatin immunoprecipitation (ChIP) assay using ChIP-grade antibodies. **Results:** The activity of *Hox* transcription factors patterns every developing organ and tissue along the main body axis. The *Hox* genes are organized into four chromosomal clusters (*HoxA, B, C, D*) each harboring a subset of 13 *Hox* gene paralogs (*Hox1* to *Hox13*). During development, the spinal motor neuron (MN) subtype identity along the spinal cord is controlled by *Hox* activity. While the rostral *Hox1-Hox5* genes are activated in the cervical MNs, the caudal *Hox6-Hox13* are activated at the brachial, thoracic, and lumbar MNs. Our results show that exposure to Ni during cervical MN differentiation resulted in the activation of *Hox10-13*, indicating potential disruption of *Hox* gene regulation and spinal MN subtype switching. Investigation of the underlying mechanisms revealed that Ni exposure caused a loss of the repressive histone modification H3K27me3 at the promoters of *Hox10-13*. Furthermore, we found an upregulation of *Cdx* genes (*Cdx1, Cdx2*, and *Cdx4*), which play a critical role in caudal *Hox* gene activation by binding the regulatory elements within the caudal *Hox* clusters. Moreover, we found upregulation of lncRNA HOTTIP, which also plays an important role in *Hox10-13* activation. **Conclusions:** Ni-induced activation of *Hox10-13*, which are normally not expressed in cervical motor neurons, suggests a loss of motor neuron subtype identity. This disruption may contribute to neural dysfunction and represent a potential mechanism underlying Ni-induced neural toxicity. Furthermore, since *Hox* transcription factors pattern every developing organ and tissue along the main body axis, our findings raise the possibility that Ni exposure may cause broader developmental abnormalities.

PS 3126 Peripheral HIF-2 Deficiency Attenuates Manganese-Induced Motor Deficits Independent of Brain Mn Load

N. Sharma, and S. Mukhopadhyay. University of Texas at Austin, Austin, TX.

Background and Purpose: Manganese (Mn), an essential metal, but induces incurable parkinsonism at elevated levels by unknown mechanisms. Our previous work showed that transcriptional activation of HIF-1/HIF-2 by elevated Mn is required and sufficient for upregulation of SLC30A10 (a critical Mn efflux transporter) within the hepatocyte, thereby contributing considerably to provide protection against Mn induced toxicity. The overall aim of study is to define the role of HIF-1/HIF-2 signaling from liver and intestine in regulating the response of SLC30A10 and motor dysfunction following Mn exposure. As part of this, the current study focused on isolating the role of peripheral HIF-2 in Mn neurotoxicity. **Methods:** We generated endoderm specific HIF2a knockout mice lacking expression of the specific HIF2a isoform in the liver and intestine, exposed mice to a human relevant Mn regimen, and analyzed motor function, metal levels, and gene expression. **Results:** We unexpectedly observed that *HIF2a* knockout mice were protected against Mn-induced motor deficits. But, brain Mn levels of the *HIF2a* knockout mice were comparable to controls. Thus, rescue of the motor phenotype of the *HIF2a* knockouts is independent of a change in brain Mn. Interestingly, blood Fe levels of the knockout mice were significantly lower than controls after Mn exposure, suggesting that HIF2 may impact Mn neurotoxicity via effects on Fe metabolism. **Conclusions:** These findings indicate that peripheral HIF-2 signaling is a critical regulator of Mn induced motor deficits, likely through effects on Fe metabolism.

J. Jacob¹, E. Johnston², and J. Wagner¹. ¹Hawaii Department of Health, Pearl City, HI; and ²University of California, Los Angeles, CA. Sponsor: M. Aung

Background and Purpose: Some methylene tetrahydrofolate reductase (MTHFR) polymorphisms can result in the deficiency of the enzyme MTHFR, which is crucial for the conversion of homocysteine to methionine, an integral precursor for the synthesis of monoamine neurotransmitters. The C677T polymorphism is the most common and clinically relevant genotype, with approximately 30-40% of the global population carrying at least one allele. Individuals with MTHFR enzyme deficiency are prone to hyperhomocysteinemia-induced oxidative stress, which may deplete the body's endogenous glutathione. As a result, toxins like mercury, which depend on glutathione conjugation for excretion, would bioaccumulate, increasing their toxicity. Mercury is considered the most toxic heavy metal that can cause serious neurological and psychiatric health effects. A common source of mercury exposure is through dietary consumption of seafood, which makes mercury poisoning particularly prevalent in populations where fish is a part of the staple diet. Although such correlations have been somewhat identified, the exact toxicological and biochemical processes/pathways involved are still an area of research. Here, we attempt to map such correlations using the existing literature. **Methods:** A structured literature search was conducted using PubMed and Google Scholar. Search terms included 'mercury,' 'Hg,' 'MTHFR,' and 'methylene tetrahydrofolate reductase.' Articles were screened for relevance to biochemical mechanisms, toxicokinetics, or clinical interactions between MTHFR polymorphisms and mercury exposure. **Results:** MTHFR polymorphisms and mercury exposure share several overlapping pathophysiological pathways, particularly those involving oxidative stress and glutathione exhaustion, which may contribute to similar neurological and psychiatric manifestations. **Conclusions:** MTHFR polymorphism may play an important role in some individuals with prolonged and persistently elevated mercury levels, despite taking precautionary measures. Testing for MTHFR polymorphism and/or homocysteine levels may help to identify metabolic factors that could influence the excretion of mercury. Additionally, it has been proposed that supplementation with methylfolate, methylcobalamin, and glutathione may help to overcome some of these issues associated with MTHFR polymorphism.

PS 3130 Developmental lead (Pb) exposure alters noradrenergic regulation of stress behavior in zebrafish (*Danio rerio*)

M. R. Wilson, and A. Abdelmoneim. Louisiana State University, Baton Rouge, LA.

Background and Purpose: Developmental Pb exposure disrupts neurophysiological systems that govern stress and emotional regulation. Prior work from our laboratory demonstrated that Pb impairs behavioral stress responses and alters biomarkers of noradrenergic (NA) signaling. Using *in vivo* fluorescence brain imaging, we observed disruptions in the locus coeruleus (LC) NA neuronal morphology—increasing neuron number, disrupting spatial organization, and suppressing spontaneous neuronal activity—as well as dose-dependent reductions in volume and axonal complexity of NA innervation to the dorsal telencephalon (zebrafish amygdala homolog). These findings drove our hypothesis that developmental Pb exposure perturbs LC NA neurons, thereby altering NA signaling mediated through adrenergic receptors that regulate stress responses. **Methods:** To evaluate this, we combined behavioral pharmacology, calcium imaging, and transcriptomic approaches. Zebrafish larvae were exposed to prazosin (α_1 -antagonist) or yohimbine (α_2 -antagonist) at 0.5, 2.3, 11.0, 56.5, and 280 μ M for 20 min or 12–16 hr. Stress responses were quantified using automated locomotor tracking during acoustic startle response (100 Hz, 100 ms; AMR) and visual motor response (1200 lux, VMR) assays. RNA-seq and calcium imaging were performed on larvae exposed to 75 and 750 μ g/L Pb to assess transcriptomic and LC NA neuronal activity changes. **Results:** Transcriptomic profiling revealed upregulation of oxidative phosphorylation genes alongside downregulation of proteolytic and ion-channel functions, indicating compensatory metabolic activation and impaired calcium signaling. Calcium imaging confirmed reduced spontaneous LC activity despite increased neuron number, suggesting enhanced neuronal survival but diminished functional integration. Acute yohimbine exposure produced significant hyperreactivity during AMR at 56.5 and 280 μ M and during VMR at 11.0 and 56.5 μ M, whereas prolonged exposure (12–16 hr) caused hyporeactivity at 56.5 and 280 μ M. Acute prazosin exposure produced significant increases in AMR endpoints and in VMR maximum distance while VMR total distance was significantly decreased at all but the highest exposure concentration (280 μ M). Similar to the effects of Pb exposure observed in VMR assays, 12–16 hr exposures to Prazosin produced a biphasic response, with significant increases in stress response at moderate concentrations and significant decreases in stress response at higher concentrations. **Conclusions:** Together, these findings indicate that α_1 - and α_2 -adrenergic receptor antagonists differentially modulate stress-response behaviors in zebrafish and that Pb exposure induces a LC phenotype characterized by neuronal hyperplasia coupled with reduced functional output; a phenotype possibly mediated by compensatory metabolic upregulation and disrupted calcium-dependent excitability. Ongoing studies are assessing the role of other adrenergic modulators in stress response and whether they can restore behavioral and neurophysiological changes mediated by Pb exposure. Identifying these mechanisms will advance understanding of NA dysfunction in developmental Pb neurotoxicity and support the development of targeted therapeutic strategies.

PS 3131 The effect of exercise on behavior and motor function following developmental benzo[a]pyrene exposure

D. Fox, C. Gogzheyana, M. Feltner, B. Wetzel, E. Lallai, T. Easybuck, E. Glos, and C. P. Curran. Northern Kentucky University, Highland Heights, KY.

Background and Purpose: Pregnant women and their fetuses can be exposed to neurotoxic polycyclic aromatic hydrocarbons (PAHs) through air pollution and by eating foods cooked at high temperatures. Exercise is known to improve brain function, but little is known about how exercise during pregnancy and early life can affect the developing brain. In this study, we wanted to find out if exercise could protect against exposure to the model PAH, benzo[a]pyrene. **Methods:** To determine if exercise could mitigate the adverse effects, we compared *Cyp1b1* (-/-) knockout and *Cyp1b1* (+/+) wildtype mice. Dams were exercised two weeks prior to mating and until gestational day 10 (G10). From G10 to postnatal day 25 (P25), dams were dosed with either corn oil or 10mg/kg/day of BaP dissolved in corn oil. Offspring ran from P30-P60 when neurobehavioral testing began. Exercise consisted of 1h/day of voluntary running on wheels. We tested anxiety-like behaviors using marble burying and elevated zero maze. We tested mice in open field locomotor activity and used rotarod to assess motor coordination and balance. **Results:** Our results represent the findings from the first seven cohorts of mice tested. There was a significant main effect of genotype for locomotor activity with *Cyp1b1* (+/+) wildtype mice having higher activity levels compared with *Cyp1b1* (-/-) knockout mice. There was a main effect of exercise with offspring that exercised buried significantly fewer marbles ($P < 0.05$). There was a significant gene $\times$ treatment interaction with BaP exposure increasing anxiety-like behavior in wild type mice while decreasing it in the knockouts. There were no significant differences in zero maze. In rotarod, exercise significantly improved rotarod performance on Days 2-5 of testing ($P < 0.01$). **Conclusions:** Our preliminary results suggest that offspring exercise improved both motor function and motor memory in both genotypes of mice, regardless of treatment. We will continue testing until we have n=15-20 litters per group at which point we will also be able to test for sex differences.

PS 3132 Can Exercise Improve Learning and Memory Following Developmental Exposure to Benzo[a]pyrene?

C. Gogzheyana, M. Feltner, D. Fox, S. Lillard, L. Bishop, E. Lallai, T. Easybuck, R. Spigelmyer, and C. P. Curran. Northern Kentucky University, Highland Heights, KY.

Background and Purpose: Normal 0 false false false EN-US ZH-CN X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshadow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin:0in; mso-pagination:widow-orphan; font-size:10.0pt; font-family:"Times New Roman",serif;} Benzo[a]pyrene (BaP) is a neurotoxic polycyclic aromatic hydrocarbon that can be found in grilled foods, air pollution, car exhaust, and more. Pregnant women can be exposed to this carcinogen, which has been shown to cause major health deficits in their offspring. Exercise is known to improve brain function, but little is known about how exercise during pregnancy and early life can affect the developing brain. In this study, we wanted to find out if exercise could protect against exposure to BaP and its potential effect on motor function. **Methods:** Normal 0 false false false EN-US ZH-CN X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshadow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin:0in; mso-pagination:widow-orphan; font-size:10.0pt; font-family:"Times New Roman",serif;} We compared *Cyp1b1* (-/-) knockout and *Cyp1b1* (+/+) wild type mice, because our previous studies showed the knockouts were more susceptible to developmental BaP exposure. We treated the dams with either 10mg/kg/day BaP in corn oil-soaked cereal or corn oil-soaked cereal alone from gestational day 10 (G10) to postnatal day 25 (P25). Dams were exercised for two weeks prior to mating through G10. Offspring exercised from P30-P60 when behavioral testing began. Both groups received 1hr daily of voluntary exercise on running wheels. We used Novel Object Recognition and Morris Water Maze to test hippocampal-dependent learning and memory. **Results:** Normal 0 false false false EN-US ZH-CN X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshadow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin:0in; mso-pagination:widow-orphan; font-size:10.0pt; font-family:"Times New Roman",serif;} Our preliminary findings are based on seven cohorts of mice. *Cyp1b1* (-/-) knockout mice took significantly longer to complete the Novel Object Recognition test compared with *Cyp1b1* (+/+) wild type mice, but there was no significant difference in visual recognition memory. Exercise appeared to benefit BaP-exposed *Cyp1b1* (+/+) wild type mice more than *Cyp1b1* (-/-) knockout mice in the hidden platform phases of Morris water maze. BaP-exposed offspring that exercised had shorter average distances to the platform in the Reverse Phase. However, none of the differences weren't statistically significant. **Conclusions:** Normal 0 false false false EN-US ZH-CN X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshadow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin:0in; mso-pagination:widow-orphan; font-size:10.0pt; font-family:"Times New Roman",serif;} We will continue testing until we have 15-20 litters per group.

C. L. Pham¹, D. Meyer¹, A. Hahn¹, M. Llewellyn¹, C. Wu², G. Gonzalez¹, S. Acra¹, G. Winny¹, E. Kintzele¹, and T. R. Baker¹. ¹University of Florida, Gainesville, FL; and ²National Yang Ming Chiao Tung University, Hsinchu City, Taiwan.

Background and Purpose: Lead (Pb), a World Health Organization-identified toxicant of major public health concern, can cross placental and blood brain barriers during early development, resulting in heritable, life-long neurotoxicity. The aging brain is also uniquely susceptible to neurotoxic insult, triggering more rapid onset of cognitive decline and associated pathology. However, the contributions of lead exposure during these sensitive windows to neuromotor and neurodegenerative disease outcomes are currently not well understood. Thus, our overall goals are to characterize the molecular mechanisms driving Pb-induced persistent neurotoxicity and to identify the roles of individual and "multi-hit" exposures in disease progression using the zebrafish model (*Danio rerio*). **Methods:** We exposed fish cohorts to environmental levels of waterborne lead acetate (1-10,000 µg/L) at two neurosensitive windows: 2-26 hours post fertilization (hpf) in early neurodevelopment, and an acute five-day exposure in aged, 2-year-old fish. Larval fish were evaluated for mortality and neurodevelopmental phenotypes at 5 days post fertilization (dpf), including systemic abnormalities, a light:dark neuromotor assay, and an acoustic stimuli battery measuring habituation and learning. Pooled larvae tissues were collected. Fish were raised and spawned at 9 months post fertilization to produce F1 offspring. Fertility (% egg survival) and fecundity (eggs/female) were assessed. F1 offspring were raised to 5 dpf and evaluated as above. Separately, exposed aged fish were evaluated in a five-minute novel tank test, then euthanized for brain tissue collection. Genomic DNA and RNA were extracted from tissue samples. RNA libraries were generated using the Lexogen QuantSeq 3' mRNA-Seq kit, and DNA was processed for whole-genome bisulfite sequencing using an Illumina NEB Enzymatic-based Methylation library kit; both were sequenced with NovaSeq 6000. Differentially expressed genes (DEGs) were analyzed with DESeq2. DEG cut-offs were set at $|\log_2 FC| \geq 0.75$ and $p < 0.05$. DEGs were entered into IPA software to determine pathway enrichment. Methylation calling was performed using cscall v1.0 and the "mcomp" program. Differentially methylated CpG sites (DMCs) were defined as CpG with p -value < 0.01 . Average genome-wide methylation was compared and differentially methylated genes (DMGs; 1+ DMC) were identified ($p < 0.01$). DMGs were analyzed for gene ontology enrichment using DAVID (FDR < 0.05). **Results:** Early (2-26 hpf) exposure resulted in hyperactivity ($p < 0.001$) and increased rate of yolk sac edema ($p < 0.05$) at low-intermediate lead levels (10 µg/L). This behavioral phenotype persisted into larval offspring, where effects were more pronounced: 1 and 10 µg/L lead exposure induced hyperactivity in F1 larvae ($p < 0.001$), with 100 µg/L F1 displaying novel hypoactivity ($p < 0.05$). Acutely exposed aged fish were less sensitive, demonstrating non-monotonic effects on neuromotor activity at doses ≥ 10 µg/L ($p < 0.01$). Overall, neurotransmission and oxidative stress response transcriptomic pathways were disrupted across doses, with the most DEGs reported at 100 µg/L. We determined that average genome-wide methylation was increased at doses ≥ 100 µg/L, with ion transportation and neuronal signaling pathways most affected. A small subset of cytoskeletal, synaptic, and transcription-regulating genes were both differentially methylated and differentially expressed at the highest doses (100 - 10,000 µg/L). **Conclusions:** Larval lead exposure for 24 hours causes heritable disruptions to zebrafish behavior and development at low-medium doses. Aged fish also demonstrate non-monotonic impacts of lead exposure to behavior, transcriptome, and methylome at higher doses, particularly at 100 and 10,000 µg/L. While specific overlap was minimal, similar neurotransmission pathways were implicated in both the transcriptome and methylome, with a small subset of overlapping potential biomarkers identified. Future work will compare -omics and phenotypic profiles across neurosensitive windows and explore the role of multiple lifespan exposures in contributing to heritable neurobehavioral disease.

PS 3134 Gestational Exposure to Ultrafine Iron-Oxide Particles Produce Sex-Dependent Changes in Behavior and Neurotransmitters in Cortico-Striatal Brain Regions

M. C. Masten, E. Marvin, J. Cubello, J. V. George, E. Murray, T. Covitz, M. Sobolewski, and D. A. Cory-Slechta. University of Rochester, Rochester, NY.

Background and Purpose: Air pollution exposure during gestation has been associated in epidemiological studies with neurodevelopmental disorders (NDDs). Gestational exposures to real-world, complex ultrafine particulate matter (UFP) air pollution have revealed neuropathological changes (neurotransmitter disruption) and behavioral alterations (alterations in sociality and ability to inhibit responding) in mice consistent with symptoms seen in these NDDs. Compositional analyses of ambient UFP mixtures in our experiments have consistently identified iron (Fe) as a major metallic component. In the early postnatal phase, inhalational exposure to Fe nanoparticles alone has reproduced male biased effects seen with ambient postnatal UFP exposure. However, it remains unclear whether gestational exposure to Fe UFP alone contribute to the adverse effects produced by ambient UFP exposures during gestation. Addressing this question is critical as previous UFP exposures result in differential sex-specific susceptibilities between postnatal and gestational exposures. This study hypothesized that exposure to Fe alone during gestation

would produce similar pathology (neurotransmitter disruptions across the lifespan and behavioral changes) as does ambient UFP exposure during gestation. **Methods:** Pregnant C57BL/6J mice were exposed to spark generated ultrafine Fe₂O₃ particles or HEPA-filtered air for 4 hours/day from gestational day 0.5 - 16.5 through whole body inhalation. The average mass concentration of Fe in the exposure group was approximately 4.54 µg/m³ across the exposure dates and average particle diameter was 18.8 nm. Subsets of pups were sacrificed on postnatal day (PND) 14 and PND60. Microdissected striatum and frontal cortex from brains from these mice were analyzed by LC-MS/MS to quantify levels of neurotransmitters, their metabolites, and turnover as well as amino acids. Another subset of mice were assigned to either a behavioral testing group or a non-behavioral group. The behavior group underwent testing on a battery of behaviors including locomotor assessment, novel object recognition, sociability and social novelty preference, social conditioned place preference, and various operant schedules of food reward (fixed interval, fixed ratio - waiting for reward, progressive ratio, and differential reinforcement of low response rates), while the non-behavior group were undisturbed in their home cages. Both groups were sacrificed at PND265. Similar to the other time points, the striatum and frontal cortex from these mice were analyzed by LC-MS/MS for neurotransmitter quantification. **Results:** Male and female mice exposed to Fe (mostly Fe₂O₃) during gestation showed sex-dependent behavior changes on the operant schedules of reward. Male Fe exposed mice had increased response rates on a fixed interval schedule. On a fixed ratio - waiting for reward schedule, male Fe exposed mice displayed increased run rates and decreased long wait times compared to male control mice. Taken together these data indicated a decreased ability to inhibit responding. Conversely, female Fe exposed mice exhibited decreased response rates on both the fixed interval and fixed ratio wait schedules of rewards when compared to the female air exposed control mice. In LC-MS/MS analyses of neurotransmitters, there were significant sex differentiated effects of Fe exposure across the life span, including changes in the dopaminergic system and amino acids in the female striatum, effects recapitulating those previously observed in response to ambient UFP exposures during gestation. **Conclusions:** Gestational exposure to Fe alone reproduces some behavioral and neurotransmitter changes produced by exposures to ambient UFP, indicating that Fe is a contributing factor to UFP-induced toxicity. While exposures during the postnatal phase often shows a stronger male bias, a female specific phenotype of behavioral and neurotransmitter changes emerges after gestational exposure. This indicates that females may be differently sensitive to UFP exposures based on critical window and/or route of exposure. Future research should interrogate these sex-differentiated phenotypes in mice and potential implications to phenotypic differences in humans. PS 3135 Parameterizing a mechanistic model of thyroid hormone kinetics and dynamics for cross species extrapolation using a three dimensional *in vitro* model of the developing brain

A. Charlton¹, J. Leedale², E. de Caro³, I. Scharkin³, L. Merit Stark³, E. Fritsche⁴, and K. Koch³. ¹Syngenta, Greensboro, NC; ²Syngenta, Jealott's Hill International Research Centre, United Kingdom; ³IUF - Leibniz Research Institute for Environmental Medicine, Düsseldorf, Germany; and ⁴Swiss Centre for Applied Human Toxicology (SCAHT), Basel, Switzerland.

Background and Purpose: Thyroid hormones (TH) are critical for neurodevelopment across vertebrates. Multiple OECD test guideline studies require measurement of TH, however the magnitude of disruption in animal studies required to indicate a neurodevelopmental concern in humans is not established. The use of mathematical modelling may facilitate cross-species extrapolation of TH disruption and allow for the establishment of a protective threshold for human risk assessment. Currently insufficient data are available in the published literature to parameterize such a model. This project addresses these data gaps through applying varying, physiologically relevant, concentrations of TH to sophisticated *in vitro* models of the developing rat and human brains. Assessed endpoints include neuronal migration and differentiation, as well as single-cell transcriptional changes. **Methods:** We applied the human Neurosphere Assay, which forms part of the OECD-endorsed developmental neurotoxicity (DNT) *in vitro* battery (IVB) and models seven key neurodevelopmental processes (KNDPs) *in vitro*. Human neural progenitor cell (hNPC) neurospheres were exposed to increasing concentrations of triiodothyronine (T3) and thyroxine (T4), and effects on hNPC proliferation, radial glia migration, neurite outgrowth, neuronal and oligodendrocyte migration and differentiation, as well as oligodendrocyte maturation, were assessed. Time-matched rat NPCs were similarly exposed within the Neurosphere Assay to delineate species-specific differences in TH-regulated brain development. Mathematical modelling was then applied to derive threshold concentrations defining the lower limits of TH required to maintain normal regulation of KNDPs. To elucidate the cell type-specific mechanisms underlying the observed phenotypic effects, single-cell RNA sequencing was performed on proliferating (day 0) and differentiating (days 2, 4, and 8) human and rat NPCs following T3 exposure. **Results:** We observed marked species differences in the regulation of key neurodevelopmental processes by thyroid hormones. NPC proliferation was regulated by physiological concentrations of T4 in both species (0.81 nM in human vs. 1.63 nM in rat), whereas T3 regulated proliferation exclusively in rat NPCs (0.037 nM). In contrast, neuronal migration and differentiation were controlled by low nanomolar concentrations of both T3 and T4 in the human model (0.14-0.18 nM), while developing rat neurons were largely insensitive to TH modulation. Oligodendrocyte maturation

tion was promoted by T3 in both species at comparable physiological concentrations (27 nM in human vs. 3 nM in rat); however, oligodendrocyte differentiation was stimulated by low picomolar concentrations of T3 only in the rat model (16 pM). Moreover, T4 promoted oligodendrocyte differentiation and maturation in rat NPCs (1.2 nM and 30 nM, respectively), but not in their human counterparts, which appeared insensitive to T4. Initial transcriptomic analyses are ongoing to identify molecular signatures underlying these divergent species-specific responses. **Conclusions:** This study indicates that clear species differences exist in neurological development processes *in vitro* in response to altered TH levels. This has implications for the appropriate use of developmental neurotoxicity studies in rodents for human risk assessment of substances which alter the homeostasis of TH. Overall, this study demonstrates the utility of organotypic *in vitro* systems to parameterize mathematical models for human risk assessment.

PS 3136 Emerging Neurotoxicants: PFAS induce Alpha Synuclein Aggregation and Mitochondrial Dysfunction in SH-SY5Y Neuronal Model

D. Wilson, and M. Narayan. University of Texas at El Paso, El Paso, TX. Sponsor: D. Wilson, Society of Environmental Toxicology and Chemistry

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are a class of synthetic organic compounds valued for their chemical stability and widespread use but increasingly recognized as persistent environmental pollutants with developmental neurotoxicity potential. While extensive data describe their systemic toxicity, the molecular effects of PFAS on neuronal proteins and organelles remain poorly understood. This study compares the effects of several PFAS and classical neurotoxins on protein aggregation, mitochondrial function, and stress signaling in dopaminergic SH-SY5Y wild-type and A53T α -synuclein-GFP cell models during neuronal differentiation. **Methods:** To determine whether the mechanism(s) behind PFAS-induced α -synuclein aggregation and mitochondrial dysfunction vary by concentration and chemical class, differentiated WT and A53-T α -synuclein-GFP SH-SY5Y were treated with PFOA, PFOS, PFDA, PFNA, rotenone, or paraquat (0 μ M-30 μ M). Cytotoxicity, neurite outgrowth, and α -synuclein aggregation were measured via fluorescence microscopy and confocal microscopy. Western blot analysis of α -synuclein, phospho-S129, HSP70, and protein disulfide isomerase (PDI) evaluated proteostasis disruption and oxidative stress responses. **Results:** PFAS exposure altered significant changes in neuronal morphology, including increased α -synuclein aggregation and elevated expression of pS129, PDI and HSP70, indicating proteotoxic stress. Each compound produced distinct yet convergent developmental neurotoxic patterns, suggesting multiple mechanistic routes to similar cellular outcomes. **Conclusions:** These findings indicate that structurally distinct PFAS elicit divergent mechanisms of developmental neurotoxicity, highlighting their potential role as environmental triggers of neurodegenerative disease. Ongoing work aims to elucidate upstream signaling networks and identify PFAS and protein interactions driving these effects.

PS 3137 Neurotoxicity of glyphosate and dicamba exposures on zebrafish (*Danio rerio*) embryo-larval model and adult systems.

V. Sridhar, and J. L. Freeman. Purdue University, West Lafayette, IN.

Background and Purpose: Glyphosate is the most widely used agricultural herbicide in the US and over the last 20 years, usage and production tripled. Historic usage has resulted in glyphosate resistant weeds. To combat this issue, alternative formulations such as Roundup Ready Xtend containing a mixture of glyphosate with dicamba is being used with approval in 36 states. Glyphosate can move into drinking water sources and is regulated at 700 parts per billion (μ g/L) by the US EPA. While glyphosate is highly used in the US, it is banned in several countries due to the risk of carcinogenicity (IARC Group 2A, probably carcinogenic to humans) and general toxicity. Dicamba, on the other hand, has not historically been used at a high rate but is changing with the introduction of this new herbicide formulation. Based on historic low use there are no drinking regulatory levels for dicamba currently in the US but with increased use comes additional contamination risks. Currently, there are limited toxicity studies with dicamba but those that exist report genotoxicity and biochemical toxicity. The current study was designed to study the sublethal effects of developmental glyphosate and dicamba exposure alone and in a binary mixture to evaluate developmental neurotoxicity using the zebrafish (*Danio rerio*) to test the hypothesis that binary mixtures of these herbicides are more toxic than singular exposure to either of these herbicides with exposure resulting in developmental and late-life neurotoxicity and genotoxicity and cause neurobehavioral impairments and potential neurodegeneration related outcomes. **Methods:** For the larval phase, zebrafish embryos were collected, and exposed starting 2 hours post fertilization (hpf) to 2 concentrations of glyphosate (700, 7000 ppb), dicamba (100 ppb), 2 binary mixtures (700 or 7000 ppb glyphosate/100 ppb dicamba), or a negative control (0 ppb). Fish were exposed until 72 for qPCR analysis or 120 hpf for neurobehavioral analysis. Behavior was assessed using DanioVision tracking software which altered the light phases into 3 dark and 2 light phases alternatively and tracked the movement of the larvae. For the genotoxicity assay the larvae were rinsed at 72 hpf and qPCR analysis was done for the genes in the BDNF/APP pathway. For the adult phase, zebrafish embryos were exposed to 700 ppb glyphosate, 10, 100 ppb dicamba, or 2

binary mixtures with 700 ppb glyphosate/100 or 10 ppb dicamba, from 2 - 120 hpf after which the larvae were rinsed with filtered water, raised for 8 - 12 months and neurobehavior analysis conducted during the adult phase. Three neurobehavioral tests were completed to assess anxiety (novel tank diving test), sociability (Social Preference Test) and learning and memory (Novel Object Recognition Test). After the neurobehavior was completed, the brains of the adult zebrafish were harvested and qPCR analysis of the genes in the same (BDNF/APP) pathway was assessed to determine adult neurotoxicity. **Results:** Results in the larval behavior assay indicated glyphosate, dicamba and the binary exposures led to a significant reduction in the distance moved, velocity, and time spent moving ($p < 0.05$), indicating hypoactivity amongst the exposed groups with the binary exposures showing a greater significant reduction as compared to the individual exposure treatment groups. From the qPCR analysis, it was found that glyphosate and the binary mixtures downregulated the expressions of *bdnf*, *ntkr2b*, *akt1*, *mapk6*, *appa*, *appb*, *bace1* and *sor11* ($p < 0.05$). In the adult neurobehavior assay, the results of the Novel Tank test and Social Preference Test indicate that the exposed fish are hypoactive and are more anxious, show more social avoidance behavior and impaired learning and memory behavior when compared with the adult control fish. From the qPCR analysis, it was observed that all the genes in the BDNF/APP pathway were upregulated. **Conclusions:** Overall, results show neurobehavioral alterations at environmentally relevant concentrations for single and binary exposures in both larval and early life exposed adult zebrafish. There is also an observed immediate or prolonged dysregulation of the genes in the BDNF/APP pathway indicating that early life exposure to these herbicides do have long life-lasting effects. Also, the binary exposures are more toxic than singular exposures supporting a need for a better understanding of the risks associated with the mixture exposure when considering the composition of the Roundup Ready Xtend.

PS 3138 Enhancing Mechanistic Neurotoxicity Evaluations with *in vitro* LUHMES-based Gene Co-expression Network Analysis

L. Sinke¹, J. Suess², S. Kunnen¹, S. Tangianu², H. van Kessel¹, M. Leist², G. Callegaro¹, and B. van de Water¹. ¹Leiden University, Leiden, Netherlands; and ²University of Konstanz, Konstanz, Germany.

Background and Purpose: Next-generation risk assessment (NGRA) is reshaping chemical safety by integrating efficient, cost-effective, and human-relevant new approach methodologies (NAMs). Toxicogenomics offers potential to extract mechanistic depth from these assays, yet current implementations rarely venture past isolated genes and non-specific gene sets. Since adverse outcomes are frequently preceded by coordinated and tissue-specific transcriptomic perturbations, it is critical that we advance safety assessment with this context in mind. For hepatotoxicity and nephrotoxicity, the TXG-MAPr webtool provides an accessible and interactive platform to explore early events and evaluate novel compounds in liver- and kidney-based test systems. No equivalent resource currently exists for neuronal assays. **Methods:** Here, as part of the EFSA TXG-MAP project, we present the first neuronal TXG-MAPr, built to assess toxicity in developing human dopaminergic neurons. For this purpose, we used LUHMES cells; an immortalised human mesencephalic neuronal cell line that can be reproducibly differentiated into post-mitotic, dopaminergic-like neurons within six days. At the early differentiation stage (days 2 to 3), when neurons are undergoing neurite outgrowth and are highly sensitive to perturbation, LUHMES cultures were exposed to 42 mechanistically informative compounds across multiple concentrations and timepoints, eliciting a range of distinct adaptive and adverse cellular stress responses. **Results:** The resulting network, built using weighted gene co-expression network analysis (WGCNA), comprises functionally-specific gene modules capturing both pathways preserved across tissues, such as oxidative and endoplasmic reticulum (ER) stress, as well as ones specific to the neurodevelopmental setting. We validate and showcase the utility of this TXG-MAPr tool for early-stage compound assessment and predictive toxicology by projecting independent external datasets onto the LUHMES-derived network. Moreover, we link module activity to phenotypic readouts, exploring how transcriptional modules connect to functional perturbations that precede neurotoxic endpoints. **Conclusions:** Taken together, this work expands the TXG-MAPr framework to a neuronal test system, advancing NGRA and promoting scalable, mechanistically-grounded evaluation of developmental neurotoxicity moving forward.

PS 3139 Adolescent Exposure to Ultrafine Particulate Matter Induces Sex-Specific Alterations in Behavior, Myelin and Transcriptome in the Medial Prefrontal Cortex

O. Berghaus¹, C. Leckie¹, H. Park¹, S. Ramjan², D. Marechal¹, T. Wang¹, X. Zhang³, Y. Nomura², and J. Liu¹. ¹City University of New York, Advanced Science Research Center, New York, NY; ²City University of New York, Queens College, New York, NY; and ³Baylor College of Medicine, Houston, TX.

Background and Purpose: Early-life exposure to air pollution is strongly linked to increased risk for cognitive and psychiatric impairments in later life. Adolescence, a developmental period marked by extensive morphological and functional changes of the brain, coincides with the emergence of multiple psychopathologies and may therefore represent a window of heightened vulnerability to environmental insults such as air pollution. Yet, the neurobiological mechanisms mediating these adverse

neurobehavioral effects remain poorly understood. **Methods:** We exposed adolescent mice to ultrafine particles (UFPs) from postnatal day 21 to 49 and examined behavioral consequences and underlying neurobiological alterations in a sex-specific manner. In tandem, a cohort of New York City children aged 8-14 years were recruited to evaluate their executive functioning and overall problems in relationship to their PM_{2.5} exposure level. **Results:** Adolescent UFP exposure induced sex-dependent behavioral alterations in young adult mice. These behavioral differences correspond to sex-specific changes in myelin content and internodal length within the medial prefrontal cortex (mPFC). Transcriptomic profiling of the mPFC revealed a threefold more differentially expressed genes (DEGs) in females than in males, with minimal overlap between sexes. Gene set enrichment analysis identified female-specific enrichment of pathways related to myelination, oligodendrocyte differentiation, and response to oxygen levels, and male-specific enrichment of pathways associated with triglyceride biosynthesis and circadian clock entrainment. *In vitro*, UFP exposure impaired mitochondrial function in oligodendrocyte progenitor cells from both sexes. Finally, in a cohort of New York City children aged 8-14 years, higher PM_{2.5} exposure was associated with greater difficulties in behavioral regulation, executive functioning problems, and overall problem behaviors in boys, but not in girls. **Conclusions:** These findings demonstrate that adolescent exposure to air pollution induces sex-specific neurobehavioral outcomes, accompanied by distinct transcriptional, structural and metabolic alterations, particularly involving myelin, in the mPFC. Together, the results provide a mechanistic framework linking adolescent air pollution exposure to differential susceptibility in males and females.

PS 3140 Disruption of CYP-Mediated Metabolism Modulates Region- and Dose-Dependent Effects of Developmental Exposure to 3,3'-Dichlorobiphenyl (PCB 11) on Neuronal Morphology in Juvenile Mice

R. J. Wilson¹, R. Mendieta¹, D. A. Jazari¹, A. E. Valenzuela¹, X. Ding², H. Lehmler³, and P. J. Lein¹. ¹University of California - Davis, Davis, CA; ²University of Arizona, Tucson, AZ; and ³University of Iowa, Iowa City, IA.

Background and Purpose: Developmental exposure to polychlorinated biphenyls (PCBs) is implicated in the etiology of neurodevelopmental disorders (NDDs), in part through their potential to disrupt normal patterns of neuronal connectivity during critical periods of brain development. While research on PCB developmental neurotoxicity (DNT) has largely focused on higher-chlorinated congeners found in legacy mixtures, lower-chlorinated (LC) PCBs predominate in contemporary environmental samples and human tissues. Of particular concern, PCB 11, an LC congener with documented widespread human exposure, was identified as the second-most abundant PCB congener in the serum of pregnant women at an increased risk of having a child with an NDD. But whether PCB 11 alters neuronal connectivity *in vivo* remains unknown. LC-PCBs are more readily metabolized than HC-PCBs, but the relative contribution of the parent congener vs. their metabolites on neurodevelopment has also not been rigorously addressed. **Methods:** To explore these data gaps, we quantified the dendritic morphology of pyramidal neurons of male and female pups exposed developmentally to PCB 11 in the maternal diet of wildtype (C57BL/6J), cytochrome P450 *Cyp2abfgs* gene cluster knockout (*Cyp2abfgs*-null or CYP-null), and CYP-null mouse that overexpress human CYP2A6 (2A6-Hum) mouse dams. Adult female mice (8-10 weeks old) were exposed to vehicle (peanut oil) or PCB 11 at 0.1, 1.0, or 6.0 mg/kg/d in peanut butter throughout gestation and lactation, and neurodevelopmental outcomes were assessed in their pups. Brains were collected at postnatal day (P) 35 and stained using Golgi-Cox methods. The stained neurons were visualized using a Leica Spinning Disc Confocal Microscope at 40x magnification and traced using Neurolucida software. Pyramidal neurons were analyzed from layer III/IV of the medial prefrontal cortex (mPFC), layers IV/V of the piriform/entorhinal cortex, and the hippocampus, with two to three neurons assessed per animal per region. **Results:** Developmental exposure to PCB 11 produced significant dose-, region-, and genotype-dependent alterations in dendritic arborization. In wild-type mice, exposure to 0.1 and 1.0 mg/kg/d PCB 11 decreased dendritic complexity in mPFC pyramidal neurons, reducing total dendritic length, whereas 6.0 mg/kg/d exposure increased arborization, evident as an increased number of primary dendrites. These effects were absent in CYP-null mice but recapitulated in 2A6-Hum mice, suggesting the dendritic effects of PCB 11 may be mediated by PCB 11 metabolites. Similar genotype-dependent patterns were observed in the piriform cortex, where 6.0 mg/kg/d PCB 11 increased dendritic branching, node number, and total length in wildtype and 2A6-Hum mice, but not in CYP-null mice. These effects on dendritic arborization occurred independent of changes in cell body area. PCB 11 had no effects on dendritic arborization in hippocampal neurons across genotypes. **Conclusions:** These findings extend previous reports that dendritic arborization and neuronal connectivity are vulnerable targets of PCB exposure and identify PCB 11 metabolism as a critical mediator of this developmental neurotoxicity. Given the critical role of dendritic morphogenesis in establishing neural circuitry during brain development, and the evidence from human studies linking disrupted neuronal connectivity to intellectual disabilities and the behavioral and cognitive abnormalities characteristic of NDDs, our findings—together with the strong correspondence between dendritic and previously characterized behavioral effects—suggest that dendritic alterations may underlie the behavioral deficits associated with developmental PCB exposure. This work was supported by NIEHS (R01 ES014901 to XD, HJL

and P.JL), the UC Davis Emmy Werner and Stanley Jacobsen Fellowship (to RJW), the UC Davis Professors for the Future Fellowship Program (to RJW), NIGMS (T32 GM135741 to RM).

PS 3141 The zebrafish microbiome modulates neurobehavioral responses to azoxystrobin

C. Wray^{1,2}, V. Castañeda-Monsalve^{1,3}, B. Engelmänn¹, U. E. Rolle-Kampczyk¹, N. Schweiger¹, D. Ghosh¹, S. Kader¹, C. R. Tyler², N. Jehmlich¹, and T. Ta^{1,4}. ¹Helmholtz-Centre for Environmental Research – UFZ, Leipzig, Germany; ²University of Exeter, Exeter, United Kingdom; ³University of Copenhagen, Copenhagen, Denmark; and ⁴University Leipzig, Leipzig, Germany.

Background and Purpose: The gut microbiome is essential for neurodevelopment via bidirectional gut-brain axis signaling. Environmental chemicals can potentially disrupt this communication by altering community structure and xenobiotic metabolism, yet the functional consequences of such interactions for the host nervous system remain poorly understood. To address this gap, we investigated whether exposure to the broad-spectrum strobilurin fungicide azoxystrobin, a known metabolic disruptor, modulates microbiome composition and function to influence neurobehavioral outcomes. By integrating a controlled microbiota system (simplified human gut microbiota model, SIHUMix) with a vertebrate host model (larval zebrafish), we gain mechanistic insight into microbiota-mediated xenobiotic effects and clarify potential risks posed by azoxystrobin exposure. **Methods:** After stabilization, SIHUMix was exposed to azoxystrobin for 7 days at 10% of the acceptable daily intake (ADI), followed by a 4-day recovery phase. Temporal and functional responses were assessed via integrated metaproteomic and metabolomics profiling. To evaluate host-level consequences of azoxystrobin exposure, microbiome-depleted zebrafish larvae were derived, and a subset was colonized with SIHUMix at 1-day post-fertilization (dpf). Larvae were exposed at 4 dpf and neurobehavioral function was assessed at 5 dpf using the Visual and Acoustic Motor Response (VAMR) new approach method (NAM), complemented by targeted metabolomics. **Results:** Azoxystrobin exposure significantly altered SIHUMix community structure and metabolite production, resulting in a persistently altered microbiota state even after chemical removal. Integrated metaproteomic and metabolomic analyses revealed a functional reprogramming of the microbiota, with upregulation of pathways involved in vitamin and cofactor biosynthesis, nutrient acquisition, and detoxification. Decreased activity in carbohydrate fermentation and amino acid turnover was also observed, consistent with reduced short-chain fatty acid (SCFA) levels. These findings indicate a coordinated microbial stress response and impaired metabolic homeostasis. In zebrafish, azoxystrobin exposure disrupted non-associative habituation learning independent of microbiome status. Notably, azoxystrobin induced dark phase-hyperactivity exclusively in colonized larvae, demonstrating a microbiome-dependent neurobehavioral phenotype. Targeted metabolomics revealed higher baseline levels of serotonin in the colonized control, which decreased following exposure. In microbiome-depleted larvae, serotonin levels were significantly lower than in colonized larvae and remained unchanged after exposure, indicating that microbiota-derived metabolites are required for azoxystrobin-induced serotonergic alterations. This pattern suggests that azoxystrobin and microbiota jointly shape serotonergic signaling, supporting a potential mechanistic pathway by which microbiome metabolic reprogramming contributes to the observed neurobehavioral effects. **Conclusions:** Collectively, these results reveal that chemical-microbiome interactions can manifest at the level of host neurobehavior by linking microbial metabolic reprogramming to disrupted serotonergic signaling. This integrated *ex vivo-in vivo* approach supports the concept that the microbiome is a key determinant of neurotoxic responses and underscores the importance of incorporating microbiome-mediated effects into chemical risk assessment frameworks.

PS 3142 PFAS as myelin-targeting developmental neurotoxicants: cross-model evidence for persistent white-matter and sensory circuit vulnerability

B. Zal^{1,2}, V. Valcarcel-Hernandez^{2,3,4}, L. Butruille⁵, E. Martin¹, B. Stankoff¹, C. Lubetzki¹, P. Passereau⁶, E. Leray⁷, and S. Remaud⁸. ¹Paris Brain Institute (ICM), Paris, France; ²Sorbonne University, INSERM, CNRS, Paris, France; ³Museum National d'Histoire Naturelle (MNHN), Paris, France; ⁴CNRS, Paris, France; ⁵MNHN, Paris, France; ⁶Institut Curie, Université PSL, Sorbonne University, CNRS UMR168, Physics of Cells and Cancer, Paris, France; ⁷InsERM U1309 Health Services and Management, CS 74312, Rennes, France; and ⁸Museum National d'Histoire Naturelle, Paris, France; CNRS, Paris, France.

Background and Purpose: PFAS are bioaccumulative pollutants crossing placental and blood-brain barriers, exposing fetal and neonatal brains. As myelin is lipid-rich and a potential PFAS sink, early exposure may impair white-matter integrity and behaviours relevant to multiple sclerosis (MS). This work analysed whether PFOS and PFOA exposure affect myelin physiology and health consequences. **Methods:** (1) Conditional demyelination was induced in *Xenopus laevis* Tg(*mbp:GFP-NTR*) tadpoles exposed to PFAS during remyelination, assessing visual consequences. (2) Mouse cerebellar slice cultures were demyelinated with lysolecithin and treated with PFAS +/- thyroid hormone (TH). (3) Perinatal mouse PFAS exposure enabled

quantification of neurogenesis in the subventricular zone (SVZ), and consequences on oligodendrocyte maturation, myelin ultrastructure and adult olfactory memory. (4) Giant unilamellar vesicles (myelin-lipid GUVs) assessed PFAS-induced myelin stability. (5) Spatial epidemiology examined links between PFAS exposure and MS prevalence. **Results:** PFOS, but not PFOA, inhibited functional remyelination in *Xenopus*. In mouse cerebellar slices, PFOS reduced remyelination rescued by TH co-treatment, suggesting TH-sensitive pathways. Perinatal PFOS exposure accumulated in myelin and resulted in myelin thinning and axonal damages. SVZ neurogenesis was reduced at P21, but recovered by adulthood, while oligodendrocyte maturation deficits remained. PFOS reduced dopaminergic interneurons in olfactory bulbs, causing lasting olfactory memory deficits. GUV assays demonstrated PFOS-driven alterations in myelin biophysical properties, consistent with myelin destabilization. Lastly, exploratory spatial epidemiology suggested geographic correlation between PFAS contamination and MS prevalence. **Conclusions:** The findings show that PFOS acts as a myelin-targeting developmental neurotoxicant that damages myelin and sensory circuits. This is linked to TH-responsive remyelination and myelin-lipid perturbation. Cross-species and cross-scale data (ultrastructural, biophysical, cellular, behavioural,) highlight the toxicological relevance of this issue and support heightened public-health vigilance on early-life PFAS exposure as a potential modifier of MS risk and sensory health.

PS 3143 Sirtuin pathway under model of persistent methylmercury neurotoxicity in hiPSC-derived cortical neurons

I. Bramatti, A. M. Tukker, R. Mishra, and A. B. Bowman. Purdue University, Lafayette, IN.

Background and Purpose: Methylmercury (MeHg) is a well-known environmental neurotoxicant with human exposure primarily through dietary sources such as fish and rice. MeHg exposure is strongly linked to oxidative stress, disruption of redox homeostasis, and mitochondrial dysfunction. Developmental exposure to MeHg is of particular concern, as it can lead to long-lasting neurotoxic effects that persist in adulthood. Sirtuins (SIRT1-7), are deacetylases or ADP-ribosyltransferases that require NAD⁺ for their enzymatic activity (SIRT1-7) and play a critical role in cellular responses to oxidative stress, cell proliferation and cell death. Given their involvement in neurodevelopment and mitochondrial biogenesis, dysregulation of SIRT1 and SIRT3 signaling has been implicated in various neurodegenerative disorders, including Alzheimer's and Huntington's disease. Studies suggest that the sirtuin pathway may also mediate the toxic effects of environmental pollutants, including mercury. Previous scRNA-seq and proteomics analysis from our lab demonstrated that the sirtuin pathway is significantly altered after developmental exposure to MeHg. Therefore, we hypothesized that developmental exposure to MeHg disrupts SIRT-dependent signaling, leading to persistent neurotoxic effects, and that pharmacological modulation of this pathway could either mitigate or exacerbate MeHg-induced phenotypes. **Methods:** Human induced pluripotent stem cells (hiPSCs) were exposed to non-cytotoxic doses of MeHg (1, 10, and 100 nM) during a developmental window of cortical neuronal differentiation (D7-D13). At D40, the expression and localization of SIRT1 and SIRT3 were assessed by immunofluorescence and quantified using Fiji. SIRT1 activity was evaluated by analyzing its acetylated downstream targets, including NF- κ B and Ac-p53. scRNA-seq and proteomics data were analyzed using R and Ingenuity Pathway Analysis (IPA) to identify the genes and proteins associated with the sirtuin signaling pathway and to explore their connectivity to the different isoforms of SIRT1. Additionally, we modulated SIRT1 and SIRT3 activity using selective inhibitors (i.e. EX-527/Selisistat and 3-TYP, respectively) to evaluate their impact on mitochondrial respiration (SeaHorse XF Mito Stress) and energy production efficiency (SeaHorse XF Real-Time ATP Rate). **Results:** 40 days after cessation of exposure, SIRT1 protein expression was not significantly altered, nor was its nuclear localization. Consistently, there was no impairment of SIRT1 activity as indicated by the absence of increased nuclear translocation of NF- κ B p65, a downstream target of SIRT1 deacetylation. However, scRNA-seq analysis revealed a significant enrichment of the sirtuin signaling pathway, with most of the differentially expressed genes being linked to mitochondrial function. This suggests that while SIRT1 expression and localization may remain unchanged, downstream signaling or potential redistribution between the nucleus and cytoplasm could still be affected. Furthermore, it indicates that SIRT3, localized in the mitochondria, could be further affected by MeHg exposure. To address this, we are investigating SIRT3 activity as well as mitochondrial health after pharmacological modulation of SIRT1 and SIRT3. **Conclusions:** Together, these data help clarify which SIRT1s contribute to the enrichment of the sirtuin signaling pathway and the extent to which each contributes to the long-term effects of MeHg-induced persistent neurotoxicity. This work was supported by NIH [R01 ES07331 (ABB/MA) and R01 AG080917].

PS 3144 Developmental Exposure to PFOA and a Novel Resource Deprivation Stress Enhances Sex-specific Deficits in Motivation and Motor Deficits

E. Murray, T. Covitz, C. Dressel, K. Eggleston, J. George, M. Masten, E. Marvin, D. Cory-Slechta, and M. Sobolewski. University of Rochester School of Medicine and Dentistry, Rochester, NY.

Background and Purpose: Neurobehavioral disorders have complex etiologies with multiple environmental factors (e.g. toxicants, stress, nutritional deficits) potentially conferring risk. However, animal models evaluating combinatorial or complex mixtures effects are limited. Per-fluorinated compounds, such as perfluorooctanoic acid (PFOA), are known to disrupt the formation of cholesterol, dysregulate crucial steroidogenesis, and alter corticotropin-releasing hormone necessary for Hypothalamic-Pituitary-Adrenal (HPA) Axis signaling. This shared biological target provides the foundation for our hypothesis that exposure to PFOA combined with perinatal, maternal stress will result in enhanced, sex-specific neuroendocrine and behavioral dysregulation. **Methods:** To test this hypothesis, pregnant C57BL6/J mouse dams were exposed to either perfluorooctanoic acid (PFOA) - 100 μ g/kg/day, or vehicle (Veh), via oral treat, from gestational day (GD) 0.5 to birth. Mice were housed in modified cages designed for resource deprivation (RD) stress. RD stress is a novel stressor based on unpredictable and uncontrollable access to high-value treats. Animals are paired and separated by a wire mesh. One animal receives the treat while the other is deprived of the treat. The deprived mouse can see, hear, and smell the other mouse and treat. Dams were paired by treatment (PFOA or Veh) on GD7 and randomly assigned to either Enriched or RD group until weaning. Enriched dams received mealworms three times daily. Deprived animals receive three treats, then one treat, then no treats across gestation and lactation. Time to pregnancy, pregnancy duration, number of pups, sex ratio, pup loss, and pup weights were recorded. Behavioral assessments, performed from PND60 onwards, included locomotion, cognitive function, and motivation. Mice were euthanized for blood and tissue collection, where brains were micro-dissected into specific regions and flash frozen. Serum was collected from blood samples to measure peripheral hormones. Neurotransmitters, amino acids precursors, and metabolites were measured via liquid chromatography mass-spectrometry (MS) MS from frontal cortex and striatum. Two-way analysis of variance test, and subsequent post-hoc tests (student's t-test) depending on significant outcomes, were conducted stratified by sex. **Results:** In an open field, RD males had increased vertical and jump time, and there was a marginal interaction where Vehicle-RD exposed males had increased average ambulatory speed. Enhanced effects were observed uniquely in PFOA+RD exposed males. PFOA+RD males have increased stereotypic time and decreased resting time, indicating increases in localized, potentially self-directed, movement. In females, exposure to RD marginally decreased ambulatory time, distance traveled, and number of ambulatory episodes. For the elevated plus maze, male PFOA-RD mice spent an increased amount of time in and number of entries into the center of the maze compared to the PFOA-Enriched mice. Additionally, RD males had significant increase, while females had a marginally significant increase in entries into the open arms. RD stress exposed females had an increased number of total lever presses in a high effort progressive ratio operant paradigm, while no effects were seen in males. RD exposed females also had a uniquely high number of lever presses, higher response rate, and total number of rewards during a 60 second fixed interval task. These data indicate that females exposed to stress had increased motivation for food reward. Neuroendocrine and biochemical shifts were observed in PFOA and RD exposed mice in a sex, region and time point dependent fashion. **Conclusions:** Our results show *in-utero* exposure of RD stress and PFOA alter offspring behavior in a sex-dependent manner. Males exposed to RD present a hyperlocomotive phenotype, while females exposed to RD show evidence of increased motivation for food-mediated reward. Enhanced effects of PFOA and stress were seen in male mice with increased stereotypies and behaviors in the center of the EPM maze. These data indicate that additional stress physiology and CNS systems underlying food reward may have been reprogrammed by these development insults, necessitating more research.

PS 3145 The Effect of Juvenile Polychlorinated Biphenyl Exposure on Autism Spectrum Disorder Related Behaviors and Dendritic Morphology in Mice

L. F. Tanaka, J. Tlapa, E. Reseland, M. Ridlon, T. Jordan, C. Kennedy, A. Lentine, and K. Keil Stietz. University of Wisconsin-Madison, Madison, WI.

Background and Purpose: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder with complex etiology affecting 1:36 children in the United States in 2020, as compared to 1:68 children in 2010. ASD is characterized by alterations in connectivity of key neuronal networks that give rise to phenotypic symptoms like difficulties in socialization and communication, as well as increased repetitive behaviors. Gene by environment risk interactions are posited to contribute to the rise in ASD cases. Mutations in the Shank3, a scaffolding protein in the post synaptic density of dendritic spines, account for 1-2% of ASD cases. Polychlorinated Biphenyls (PCBS) are a group of persistent environmental chemicals identified as risk factors for ASD. The MARBLES PCB mixture represents the 12 most abundant PCB congeners in the serum of pregnant women who already had one child with ASD. *Developmental* exposure to the MARBLES PCB mixture has been shown to reduce social behav-

ior and increase repetitive grooming in wild type mice. However, individuals are exposed to PCBs throughout life, and the juvenile time period (3-6 weeks) is a key period of dendritic pruning and maturation of dendritic spines to form stable connections. Here we test the hypothesis that *juvenile* exposure to MARBLES PCB mixture increases ASD related behavioral phenotype severity in wild type mice and that these PCB effects will be more severe in Shank3 mutants **Methods:** Wild type (WT) and heterozygous Shank3 (B6.129-Shank3tm2Gfng/J) mice of both sexes (n=10-15/group/sex) were orally dosed from weaning (p21) until six weeks of age (p42) with MARBLES PCB mixture at 0, 0.1, or 1mg/kg/d suspended in peanut oil and mixed into peanut butter. ASD related behavioral phenotypes were assessed using social approach, repetitive grooming and social odor discrimination. Mice were euthanized per approved protocol and brains removed. Brains were bisected and stained according to the manufacturers instructions using FD Rapid GolgiStain kit. Neurons from somatosensory cortex, hippocampal CA1, and hippocampal CA3 were visualized using Keyence-BZ X710 in brightfield. Image analysis was conducted using Keyence Analysis software. Sholl analysis was conducted to assess dendritic complexity and the number or primary and secondary dendrites, total dendritic length, and number of dendritic tips were visually assessed by researchers blinded to treatment conditions. **Results:** 3 chamber social approach: Vehicle control WT males spent more time engaged with a novel mouse as compared to a novel object, as expected. PCBs had no effect on this parameter in WT males. Interestingly, vehicle control WT females displayed more variability in social approach, with the amount of time spent with a novel mouse not reaching significance. Female WT mice treated with 0.1mg/kg PCBs did display a significant amount of time in social engagement, but 1.0mg/kg PCB treated females did not. Repetitive grooming: PCBs did not significantly alter time spent self-grooming in WT male mice. However, WT female mice treated with 0.1mg/kg PCBs displayed less time grooming than vehicle control or 1.0mg/kg treated mice. Analysis of PCB effects in Shank mutants is underway. Dendritic morphology: effect of PCB exposure on dendritic complexity using Sholl analysis is underway. **Conclusions:** Juvenile exposure to MARBLES PCB mixture does not reduce time spent engaged in social behavior as measured by social approach in wild type mice, as expected. In some cases, PCB treatment resulted in more time spent engaged in social behavior. Female mice displayed greater variability in behavior and less time spent in social behavior in WT vehicle controls, indicating female ASD related behavior is less consistent than in male mice. Time spent in repetitive grooming behavior in WT mice was similarly not altered by PCB exposure. PCB treated animals trended to have less time spent grooming in both male and female WT mice. Overall, exposure to 0.1mg/kg and 1.0mg/kg MARBLES PCB mixture in a juvenile time of 3-6 weeks does not worsen ASD related behavioral phenotypes. These results highlight the importance of timing of PCB exposure on behavioral consequences and suggest that juvenile exposures may not be as influential as developmental exposures in producing behavioral phenotypes in mice.

PS 3146 Gestational and lactational exposure to the synthetic cannabinoid nabilone at clinically relevant dose levels does not adversely affect offspring development or neurobehavior in rats

C. Klocke, N. Deng, J. Lamca, and W. Jo. Bausch Health, Bridgewater, NJ.

Background and Purpose: Accumulating evidence indicates that the developing brain is vulnerable to the effects of cannabinoids and that gestation may be a critical window of exposure to these compounds. Nabilone is a synthetic cannabinoid that is approved for the oral treatment of nausea and vomiting associated with cancer chemotherapy in patients who have failed to respond adequately to conventional antiemetic treatments. Nabilone is structurally similar to the psychoactive cannabinoid delta-9-tetrahydrocannabinol (delta-9-THC) naturally occurring in *Cannabis sativa L.* (i.e., marijuana) and is thought to act via the cannabinoid receptor 1 (CB1). Despite increasing studies demonstrating adverse effects of gestational cannabinoid exposure on neurodevelopment, it is not fully understood whether these effects extend to synthetic drug cannabinoids such as nabilone. Therefore, a peri- and post-natal developmental toxicity study was conducted in rats to evaluate the effects of gestational nabilone exposure on offspring neurobehavior at clinically relevant dose levels. **Methods:** Experimental work was completed at Charles River Laboratories (Horsham, PA). Pregnant Sprague-Dawley rats (main study, N = 22 dams/group; toxicokinetic [TK] phase, N = 3-6 dams/group) were administered nabilone via oral gavage as a suspension at dose levels of 0 (vehicle), 0.25, 1, or 2 mg/kg/day once daily beginning on gestational day (GD) 7 through postnatal day (PND) 20. Dose levels were selected based on maternal and offspring body weight reductions in a dose range-finding study which resulted in systemic plasma exposures up to 2-fold clinical exposures achieved at the maximum recommended human dose (MRHD). Dams (F₀) were evaluated for viability, clinical signs, bodyweight, food consumption, parturition, litter outcomes, maternal behavior, number of implantation sites, and gross lesions. Nabilone concentrations in maternal plasma and milk were determined by a validated LC-MS method. Offspring (F₁) were evaluated for viability, clinical signs, bodyweight, food consumption, sexual maturation, behavior assessments (functional observational battery [FOB], passive and active avoidance, social interaction, motor activity, acoustic startle habituation, Morris water maze [MWM]), reproductive capacity, and gross lesions. **Results:** In F₀ dams, nabilone reduced gestational and lactational bodyweight gain in a dose-dependent manner with corresponding reductions in food consumption. There were no additional effects of nabilone on the dams at any dose level, including delivery and litter parameters. Offspring bodyweights were reduced in a dose-dependent manner in both sexes throughout the lactation period

and persisted in males out to PND 57 but not in females. Nabilone did not have additional effects on clinical observations, food consumption, sexual maturation, mating/fertility, or necropsy observations in F₁ offspring at any dose level. In social interaction evaluations, high dose males displayed increased number of crossovers away from a social affiliation animal; however, the total number of crossovers (to and from the social affiliation animal) was not affected. Females exhibited increased arousal/alertness in the FOB in a dose-dependent manner without corresponding alterations in open field behaviors, indicating a lack of biological relevance. Nabilone did not significantly affect any other neurobehavioral endpoints at any dose level. **Conclusions:** Overall, this study demonstrates that gestational and lactational exposure to nabilone does not significantly impact offspring neurodevelopment in rats when administered at clinically relevant dose levels. These findings indicate a potential for differential neurodevelopmental toxicity risk based on the type of cannabinoid and underscore the need for continued research into this area.

PS 3147 Expanding the assessment of learning and memory with the Cincinnati water maze

C. A. Loeschel, S. Schneider, R. Buesen, and D. Funk-Weyer. BASF SE, Ludwigshafen am Rhein, Germany. Sponsor: D. Funk-Weyer, EUROTOX

Background and Purpose: With increasing concern around developmental neurotoxicity (DNT), regulatory agencies are encouraging the expansion of learning and memory (L&M) assessment. The Morris water maze (MWM) is widely used and well-established for evaluating spatial/allocentric L&M. The Cincinnati water maze (CWM) under infrared lighting has demonstrated high sensitivity for assessing egocentric L&M. Including the CWM under infrared lighting in regulatory guideline test settings would broaden the evaluation of different parts of the brain and multiple aspects of L&M. Regular conduct in several labs considerably expands the knowledge base of this aspect of neurobehavioral testing, which is currently mainly based on research in a single academic lab. **Methods:** This study aimed to establish and validate the 10T CWM under infrared lighting in an industry setting. Following a successful feasibility study using 10 male and 10 female young adult Wistar Han rats (PND 60), a validation study was conducted with the same number of animals per test group. Scopolamine was administered as a positive control to assess sensitivity. Latency and number of errors were used to assess L&M over 20 days with 2 trials per day. **Results:** Young adult Wistar Han rats can complete the CWM. A sex difference was observed. The validation of CWM was successful; administration of scopolamine demonstrated the ability of the CWM to detect adverse effects on L&M using both latency and number of errors. **Conclusions:** This study demonstrates that the CWM under infrared lighting can be implemented in other laboratories outside of the original Cincinnati site. However, the inclusion into rigid and complex testing setups, like the OECD 443 study requires consideration due to the required time necessary to perform the CWM. This research also expands the knowledge on a different strain of rat, the Wistar Han, which is a common rat strain used in toxicological studies, but had not previously been assessed with the CWM. Ongoing studies are examining the feasibility of testing weanlings (PND 25) in the CWM.

PS 3148 A data-driven approach to identify performance compounds for development of in vitro blood-brain barrier new approach methods

M. Culbreth. Human Foods Program, U.S. Food and Drug Administration, Laurel, MD.

Background and Purpose: The Organisation for Economic Co-operation and Development has recommended an *in vitro* battery (IVB) of new approach methods (NAMs) for evaluation of potential developmental neurotoxicity (DNT). These NAMs capture fundamental cellular processes critical to neurodevelopment; however, none of these approaches incorporate or model the blood-brain barrier (BBB). The BBB is imperative for elimination or minimization of toxic insult to the central nervous system; thus, NAMs which recapitulate chemical-induced effects on barrier formation and/or integrity are essential to the interpretation of potential DNT. As such, NAMs developers will require a set of chemicals expected or not expected to be BBB permeable, with or without anticipated DNT, to demonstrate assay performance. To create a list of performance compounds, the present work utilized a data-driven approach in which publicly available datasets were curated to identify applicable chemicals. **Methods:** To start, a dataset of 1004 chemicals with or without *in vivo* evidence of BBB permeability applied to train two quantitative structure activity relationship (QSAR) models was curated - 944 chemicals were applicable for this analysis. These chemicals were then batch searched by CASRN on the EPA CompTox Chemicals Dashboard - this search identified 629 chemicals. These chemicals were then merged with the 509 chemicals evaluated in at least one DNT IVB assay (ToxCast *invitrodb* v4.2) - this merge identified 47 chemicals. For these 47 chemicals, sensitivity, specificity, and accuracy of the two QSAR models was determined with the *in vivo* evidence applied as the actual value. Moreover, selective activity in the DNT IVB assays for each chemical was calculated. Finally, the chemicals were further curated and ranked - 31 chemicals were identified as potential performance compounds. Those chemicals predicted to cross the BBB that were evaluated in more DNT assays (≥10) and tested across multiple institutions that were selectively active in more assays or not selectively active in any assays, were ranked as high

confidence active or inactive performance compounds, respectively. **Results:** The sensitivity, specificity, and accuracy of QSAR models 1 and 2 were 91%/67%/85% and 97%/46%/83%, respectively. With the assumption that no *in vivo* evidence had been available, QSAR model 1 was applied for the BBB permeability prediction of the 47 chemicals - 35 chemicals were predicted to be BBB permeable, while 12 were not. In addition, 26 chemicals were selectively active in at least one DNT IVB assay, while 21 were not selectively active in any. Furthermore, 16 chemicals were excluded from consideration due to volatility (1), classification as a scheduled drug (8), or evaluation in only one DNT IVB assay (7). Sixteen chemicals were ranked as potential active performance compounds, while 15 were ranked as potential inactives. As an example, bisphenol A was ranked as a high confidence active performance compound because it was predicted to cross the BBB, and it was tested in 14 DNT IVB assays and selectively active in five. Conversely, D-mannitol was ranked as a low confidence inactive performance compound because it was not predicted to cross the BBB, but it was tested in 14 DNT IVB assays and only selectively active in one. **Conclusions:** This data driven approach which relied on *in silico* and *in vitro* datasets, identified 31 chemicals that could be applied as potential performance compounds in the development of *in vitro* BBB NAMs. Moreover, the nuance behind the classification and ranking of these chemicals, highlights the need for BBB NAMs to enhance interpretation of DNT IVB assays.

PS 3149 Disruption of Mesolimbic Dopaminergic Neuron Numbers in the Prairie Vole Brain by Developmental Exposure to a Common Flame-Retardant Mixture

J. Cao¹, S. A. Gillera², and H. B. Patisaul¹. ¹NIEHS, Durham, NC; and ²NCSU, Raleigh, NC.

Background and Purpose: Our laboratory uses the prairie vole (*Microtus ochrogaster*), a socially monogamous, biparental rodent, and model organism for neurodevelopmental disorders (NDDs), to explore how early life chemical exposures impact the development of human-relevant circuits and systems essential to prosocial behaviors such as attachment. Here we focused on two sexually dimorphic subpopulations of mesolimbic dopaminergic (DA) neurons, some of which express ESR1 (estrogen receptor α). Exposure was to vehicle or one of three doses of Firemaster 550 (FM 550), one of the most prevalent commercial flame retardant (FR) mixtures in the US, and containing a near 50:50 ratio of brominated and organophosphate ester components. Here we present the results from the lowest dose from the ongoing study. It has repeatedly been shown in vertebrates that developmental FM 550 exposure sex-specifically alters socioemotional behaviors, including complete loss of pair bonding in male prairie voles. The mechanism remains unknown, hence we examined three highly sexually dimorphic regions underlying attachment behavior: the bed nucleus of the stria terminalis (BNST), the medial preoptic area (MPOA), and the anteroventral periventricular nucleus (AVPV). The mesolimbic dopamine system is essential for attachment behaviors including pair bonding, selective aggression, and paternal behavior. DAergic neurons, identified by tyrosine hydroxylase (TH) immunoreactivity (TH-ir), are more abundant in the male BNST with little to no sex difference in the MPOA or AVPV. Levels of estrogen receptor α (ER α) co-expression in the BNST are strongly related to degree of male prosociality. Additionally, prior work has implicated ER α as a potential hub target of FM 550 exposure. We hypothesized that developmental FM 550 exposure sex and dose-specifically alters TH-ir cell numbers including those co-expressing ER α . **Methods:** Prairie vole dams were injected with 0, 500 (data herein), 1000 or 2000 μ g FM 550/day across gestation and lactation, and the offspring euthanized by transcardial perfusion as adults. Brains were removed, cryoprotected, and frozen flash on postnatal days (PNDs) 77-85, then sectioned at 40 μ m for immunolabeling. TH-ir and ESR1-ir were imaged by confocal microscopy, and analyzed using Image J. Cell numbers of TH-ir with/without ESR1-ir in each section were then confirmed by hand. Data were analyzed by ANOVA with sex and exposure as main effects. **Results:** As anticipated, BNST TH-ir cell numbers were higher in males, especially in the posterior BNST (pBNST). A sex difference was also found in the periventricular (Pe) area of the MPOA, but not in the AVPV. AVPV and MPOA TH-ir numbers were higher in the 500 μ g males while, in females, exposure increased TH-ir numbers in the BNST. In females, the number of TH and ESR-1 co-localized cells were also increased by exposure in all three regions. **Conclusions:** This work will begin to help identify the potential mechanisms by which chemical exposures disrupt the neurodevelopment of circuits and systems underlying socioemotional deficits common to neurodevelopmental disorders. The data also build on our previous work showing that developmental FM 550 exposure disrupts ER α -ir neuron numbers in social brain nuclei and is thus endocrine disrupting.

PS 3150 Leveraging HiBiT cell lines for assessing off-target degradation of developmental and hematopoietic related proteins

A. Rengarajan, K. Pearson, R. Gonzalez, A. Stermer, and A. G. Islamkhan. Merck & Co., Inc., West Point, PA.

Background and Purpose: Targeted protein degraders (TPDs) are a new modality that leverage the ubiquitin-proteasome system to target a protein of interest. Cereblon-based TPDs hijack the cereblon E3 ubiquitin ligase and tag target proteins for proteasomal degradation. However, cereblon-based TPDs can also cause degra-

dation of multiple neosubstrates (e.g., off-target proteins) leading to unwanted toxicities. Herein, we use HiBiT cells to assess degradation of neosubstrate proteins upon treatment with cereblon-based TPDs, focusing on proteins relevant to developmental toxicity (SALL4, GSPT1 and CSNK1A1) and proteins relevant to hematopoietic toxicity (IKZF1, IKZF3 and CSNK1A1). **Methods:** Targeted protein degraders (TPDs) are a new modality that leverage the ubiquitin-proteasome system to target a protein of interest. Cereblon-based TPDs hijack the cereblon E3 ubiquitin ligase and tag target proteins for proteasomal degradation. However, cereblon-based TPDs can also cause degradation of multiple neosubstrates (e.g., off-target proteins) leading to unwanted toxicities. Herein, we use HiBiT cells to assess degradation of neosubstrate proteins upon treatment with cereblon-based TPDs, focusing on proteins relevant to developmental toxicity (SALL4, GSPT1 and CSNK1A1) and proteins relevant to hematopoietic toxicity (IKZF1, IKZF3 and CSNK1A1). **Results:** Each compound had a unique degradation profile. CC-885 degraded all 5 neosubstrates - SALL4, GSPT1, CSNK1A1, IKZF1 and IKZF3. Thalidomide degraded SALL4, and DEG-77 degraded CSNK1A1. Ibrandomide, lenalidomide and pomalidomide degraded SALL4, IKZF1 and IKZF3. N-methylated pomalidomide did not cause degradation of any neosubstrates - SALL4, GSPT1, CSNK1A1, IKZF1 and IKZF3. **Conclusions:** The results demonstrate that cells engineered with HiBiT tag onto cereblon neosubstrates are a useful model for assessing degradation of specific neosubstrates by cereblon-based TPDs and therefore could be used to identify potential developmental or hemopoietic toxicity liabilities of novel TPDs. With further characterization and development, these HiBiT cell lines could also be used to elucidate structure-activity relationships.

PS 3151 Environmentally Relevant Concentrations of Triphenyl Phosphate (TPHP) Impact Development in Zebrafish

L. Williams, B. Schmandt, M. Diduff, and G. Smart. Bates College, Lewiston, ME.

Background and Purpose: Triphenyl phosphate, or TPHP, is a common plasticizer and flame retardant. Studies of tap water as well as lakes and rivers frequently report TPHP in the range of a few to hundreds of ng/L. Zebrafish have emerged as a model to study TPHP toxicity, but most studies have only explored the impact of mg/L exposures which caused pericardial edema and cardiac looping defects. Our question was rooted in the developmental effect of environmentally relevant exposures to TPHP. **Methods:** Developing zebrafish at epiboly were chronically dosed with nM concentrations of TPHP in their media (0.3x Danieau's) and phenotypic and gene expression data was collected for 5 days. **Results:** At the phenotypic level, we found no cardiac looping but chronically exposure 5dpf animals were shorter in length and displayed pericardial edema. Given its impact on the heart, RNA-Seq was conducted at three different time points in heart development—early (18hpf), mid (48hpf) and late (120hpf). 48hpf, where the heart is looped and consists of the atrium and ventricle separated by the atrio-ventricular canal (AVC), had the most differentially expressed transcripts between control and treated samples. TPHP did not alter the RXR pathway as had been shown at the uM level. However, a novel pathway involving the *tbx5a* transcription factor cascade including natriuretic peptides (*nppa* and *nppb*) and bone morphogenetic protein 4 (*bmp4*) were dysregulated. We also demonstrated that TPHP is a weak pro-oxidant, as it increases the oxidative stress response within hours of exposure. **Conclusions:** Our data indicate that TPHP can affect animal development at environmentally relevant concentrations and its mode of action involves multiple pathways that are unique to sub-acute exposures.

PS 3152 Acute and Developmental Toxic Effects of Dichloroacetic Acid in Zebrafish: Role of Oxidative Stress

M. Hariri, C. Whitmer, and K. A. Horzmann. Auburn University, Auburn, AL.

Background and Purpose: Dichloroacetic acid (DCA), a halogenated byproduct of water chlorination and a metabolite of industrial solvents such as trichloroethylene and tetrachloroethylene, has been detected in U.S. groundwater and surface water distribution systems at mean concentrations of 7-20 μ g/L. Although DCA is classified as a likely human carcinogen by the U.S. Environmental Protection Agency (EPA) based on sufficient evidence from animal studies, research on its developmental toxicity at environmentally relevant concentrations and the exact molecular pathways affected by DCA exposure during development remain unclear. In this study, the zebrafish (*Danio rerio*) biomedical model was used to test the hypothesis that DCA induces acute and developmental toxicity in environmentally relevant concentrations through oxidative stress as an underlying mechanism. **Methods:** An LC50 assay was conducted at concentrations up to 100 ppm. To assess toxicity at environmentally relevant levels, wild type zebrafish embryos were exposed to 0, 5, 50, or 500 ppb DCA from 1-120 hours post fertilization (hpf). Embryo survival and hatching were monitored every 24 hours, while larval morphology, heart rate, and visual motor response were assessed at 120 hpf. Embryonic photo motor response was evaluated at 24 hpf. At 120 hpf, activities of key antioxidant enzymes, mitochondrial superoxide dismutase (MnSOD), cytosolic superoxide dismutase (Cu/ZnSOD), catalase (CAT), and glutathione peroxidase (GPX), were measured. Expression of oxidative stress related genes (SOD1, SOD2, CAT, GPX) was also analyzed to identify molecular alterations induced by DCA. **Results:** The 120 hpf LC50 of DCA was greater than 100 ppm. At environmentally relevant concentrations, DCA did not significantly affect survival or hatching rates. At 5 ppb, head and body lengths increased, but the head width to

body length ratio, otolith diameter, and jaw length decreased, with no changes in pericardial area or eye diameter. At 50 and 500 ppb, overall head and body lengths were unaffected, though the head to body length ratio increased. These groups also showed reduced eye diameter, jaw length, otolith diameter, and pericardial area. All exposure groups exhibited elevated heart rates. In behavior assays, the 50 ppb group showed reduced distance moved and velocity in the visual motor response, and both 50 and 500 ppb groups spent less time moving. In the photo motor response, all groups displayed increased burst activity, duration, and count. In antioxidant defenses, cytosolic SOD activity increased at 50 and 500 ppb, while mitochondrial SOD activity decreased at 50 ppb. Glutathione peroxidase activity decreased at 50 ppb but significantly increased at 500 ppb. Catalase activity was unchanged. Gene expression of SOD2, CAT, and GPX was unaffected, but SOD1 expression was significantly reduced in the 500 ppb group. **Conclusions:** The results suggest that DCA disrupts zebrafish development through oxidative stress, resulting in morphological, behavioral, and cardiac impairments.

PS 3153 Developmental Toxicity of Microplastics in Zebrafish (*Danio rerio*): Insights into Larval Behavior

C. E. Bastos Lopes, M. Hariri, A. Nunes, P. Lotsch, and K. Horzmann. Auburn University, Auburn, AL.

Background and Purpose: Microplastics (MPs) are microscopic plastic particles that commonly originate from the breakdown of plastics. Their ability to cross biological barriers, bioaccumulate, and transport harmful agents poses a risk to exposed organisms. However, effects of MPs during developmental stages remain poorly understood. **Methods:** In this study, we aim to describe the effects of two different MPs on zebrafish larval behavior. At twenty-four hours post fertilization (hpf), embryos were mechanically dechorionated, and exposed to 0, 0.1, 1, or 10 µg/ml of MP solutions derived from disposable red plastic drinking cups (solo cups) or plastic forks. Larval behavior was monitored in response to light and tapping stimuli at 120 hpf. For the visual motor response (VMR) test, larvae were exposed to a series of 10-minute periods that alternate between dark and light for a total of 50 min. Data for movement endpoints such as distance moved, velocity, time spent moving, turn-angle, angular velocity, mean meander, and turning direction were collected. For the tapping response test, a solenoid inserted at the bottom of the base of the behavior chamber was used for mechanical stimulation. Each trial consisted of 10 min of acclimation, followed by a single tap (level 8 [most intense]), to elicit startle responses in darkness. For startle responses, the same movement endpoints were analyzed over a period of 3 s after the tap. **Results:** We found no statistically significant differences in behavior after the tapping stimulus for both MP solutions. In the VMR assays, MP exposure induced source- and concentration-dependent behavioral effects in zebrafish larvae. Fork MPs promoted hyperactivity at a low concentration (1 µg/ml) but reduced locomotion and angular activity at a higher concentration (10 µg/ml), whereas cup MPs predominantly impaired locomotion and turning behaviors across concentrations. **Conclusions:** These findings indicate that MP origin influences toxicity profiles, with distinct behavioral phenotypes emerging from different particle sources.

PS 3154 Perfluorohexane sulfonate (PFHxS) induced developmental toxicity is susceptible to photoperiod perturbations

S. Ferdous, C. Frank, H. Sabatini, C. Chouinard, and S. Dasgupta. Clemson University, Clemson, SC.

Background and Purpose: Light is a fundamental environmental cue shaping the biology of nearly all organisms. In vertebrates, rhythmicity is maintained by molecular feedback loops involving circadian clock genes, synchronized to external light through retinal photoreceptors and the suprachiasmatic nucleus (SCN). These 24-hour rhythms regulate key physiological processes including metabolism, hormone secretion, redox balance, DNA repair, and xenobiotic detoxification. Seasonal variations in photoperiods, or artificial light exposure from devices and shift work, can therefore alter the toxicity of chemicals acting through these same pathways. Yet, photoperiod remains an overlooked variable in toxicology—particularly for persistent pollutants such as perfluoroalkyl substances (PFAS). Among them, perfluorohexane sulfonate (PFHxS) has gained concern due to its extreme persistence, strong C-F bonds, and bioaccumulation potential. PFHxS exposure has been associated with metabolic and neurological disturbances regulated by circadian systems. Our prior larval photomotor response (LPR) data showed that PFHxS produces photoperiod-dependent behavioral effects, emphasizing the need to study light as a determinant of developmental toxicity. This study addresses the gap in understanding how photoperiod modulates PFHxS toxicity by integrating transcriptomic and molecular analyses. **Methods:** Embryos were exposed to 0, 0.0025, or 25 µM PFHxS from 2-120 hpf under 14L:10D (14 hr light: 10 hr dark) or 24D (24 hr dark) photoperiod conditions. LC-MS was conducted to analyze PFHxS uptake and mRNA sequencing was conducted on an Illumina platform. Transcription factor-gene interactions were inferred using g:Profiler, TFmiR3, and Cytoscape, with hub networks identified via cytoHubba. To assess reactive oxygen species (ROS), embryos were stained with H₂DCFDA and imaged on fluorescence microscope. DNA damage was assessed by phospho-H2AX whole-mount immunohistochemistry. For assessing cell proliferation, embryos were

pulsed with BrdU and stained with anti-BrdU antibody before imaging and categorical scoring. **Results:** LC-MS data showed equivalent uptake under both photoperiods. At 25 µM, 578 and 2912 genes were differentially expressed under 14L:10D and 24D, respectively—indicating stronger responses in 24D. KEGG analysis showed shared disruption of cell cycle, DNA replication, and xenobiotic metabolism pathways, with upregulation of metabolic and neuroactive ligand-receptor signaling. Unique responses were observed: 14L:10D specifically affected pyrimidine metabolism and PPAR signaling, while 24D uniquely altered MAPK, autophagy, insulin signaling, and base excision repair. TF network analysis further highlighted photoperiod specificity. Under 14L:10D, hubs included MCM2, MYB, UHRF1, E2F8, and IGFBP1, emphasizing developmental and metabolic control. Under 24D, hubs shifted toward stress and repair, including E2F1, JUN, MCM2, MCM5, and PTTG1, reflecting damage-responsive regulation. This network configuration reflects a transcriptional emphasis on DNA damage response, redox imbalance, and cell cycle checkpoint activation, indicating that photoperiod disruption reorients PFHxS responses away from developmental and metabolic programs toward pathways that prioritize cellular defense and repair. Since our transcriptomic data suggested stress and DNA repair signaling, we further conducted assays for ROS, DNA damage, and cell proliferation. Our ROS assay revealed a 26.42% increase under 14L:10D and a 49.91% increase under 24D, indicating that changes in photoperiod impact ROS levels. Likewise, for DNA double-strand breaks, we observed a 32.4% increase in H2AX staining under 14L:10D, but a more pronounced 80.6% increase under 24D, suggesting a photoperiod-specific effect. We also observed an inhibition of cell proliferation, as indicated by BrdU staining, but these effects were not affected by photoperiod changes. **Conclusions:** Our findings showed that photoperiod is a critical factor in shaping the developmental toxicity of PFHxS. Differences in photoperiod altered baseline circadian programs and modulated the severity of PFHxS-induced effects on gene expression, oxidative stress, DNA damage, and cell proliferation. Incorporating photoperiod as an experimental variable is therefore essential for understanding chemical toxicity.

PS 3155 Developmental Exposure to Bisphenols and Maladaptive Behavioral Stress Responses: Causal Links and Mechanistic Insights

A. N. Casillo, and A. Abdelmoneim. Louisiana State University School of Veterinary Medicine, Baton Rouge, LA.

Background and Purpose: Bisphenol A (BPA) is a synthetic monomer used worldwide in products containing plastics and resins. Its extensive use has led to widespread human and environmental exposures linked to adverse health outcomes, largely via its estrogen-mimicking activity. Epidemiological studies also link developmental BPA exposure to stress-related disorders such as ADHD, depression, and anxiety. In response to regulatory and consumer pressure, BPA is increasingly being replaced by alternative bisphenols. However, the safety of these alternatives remains poorly characterized, particularly regarding stress-related neurobehavioral outcomes. To assess the risks associated with exposure to these chemicals, we investigated the effects of developmental exposure to BPA and three common alternatives (BPF, BPAF, and BPS) using the zebrafish (*Danio rerio*) embryo model. **Methods:** Dechorionated 6-hour postfertilization (hpf) embryos were exposed to 008, .04, .2, 1, and 5 µM of each chemical with daily media changes. At 120 hpf, we assessed mortality, morphological deformities, resting activity, behavioral responses to acoustic and visual stimuli as a measure of stress response, and locomotor capacity. Subsequently, at 144 hpf, we measured light-dark preference in larvae exposed to selected concentrations of each bisphenol, as choice-based behavior offers deeper insight into anxiety-related behavior. RNAseq was performed on brains of 120 hpf larvae exposed to 1 µM BPA and exhibiting maladaptive stress behaviors. **Results:** Our target exposures were sublethal; nevertheless, BPA, BPF, and BPAF produced significant developmental defects, and BPS caused a dose-dependent reduction in total larval length. All bisphenols except BPS significantly altered stress behavioral responses, with BPA producing depressant effects across all concentrations tested. BPA increased dark avoidance under control conditions but not under stress; BPF and BPS increased dark avoidance under stress, and BPAF exaggerated differences between control and stress conditions. Transcriptomics suggested perturbation of serotonergic signaling, among other pathways altered. **Conclusions:** These findings support a causal link between developmental bisphenol exposures and maladaptive stress behaviors, highlight risks posed by alternatives to BPA, and offer insights into underlying mechanisms. With stress-related disorders on the rise, it is crucial to assess risks of widely used industrial chemicals and to ensure that alternatives genuinely offer a safer option.

PS 3156 Aryl Hydrocarbon receptor pathway drives TBBPA induced Cartilage development and hemoglobin disruption defects.

K. S. Senarath Pathirajage, T. Johnson, S. Sharma, and S. Dasgupta. Clemson University, Clemson, SC.

Background and Purpose: Tetrabromobisphenol A (TBBPA) is one of the most widely produced brominated flame retardants, incorporated into most consumer products such as textiles, foams, furniture, resins, and electronics, which makes human exposure nearly unavoidable through ingestion, inhalation, and skin contact

Biomonitoring studies have detected TBBPA and its metabolites in urine, placenta, breast milk, and cord blood, with concentrations reaching up to 20 nM in adult plasma and 5.3 nM in cord plasma, underscoring widespread prenatal exposure and potential developmental health risks. Our studies using zebrafish as a model show that, within the tissues most at risk from TBBPA exposure, cartilage is particularly important, as it forms the craniofacial skeleton essential for feeding, respiration, and sensory function. TBBPA also inhibits hemoglobin levels, which play a critical role in establishing hemoglobin production and ensuring adequate oxygen transport. Importantly, these effects were seen in low, environmentally relevant concentrations at nM levels. Disruption of both these tissues can significantly impact embryonic health, physiology and function. Our follow-up transcriptomic analysis revealed that TBBPA exposure significantly dysregulated cartilage-associated genes such as *mmp9* (+3.09) and *sox12* (-0.86), hemoglobin production genes such as *tbx6* (+1.35) and *gata2b* (-0.627). Furthermore, along with robust induction of aryl hydrocarbon receptor (zebrafish *ahr2*) signaling targets, including *cyp1a* (+6.16), *cyp1c1* (+3.74), *ahrra* (+2.32), and *foxq* (+2.59), confirming TBBPA as a potent *Ahr2* agonist. Based on this data, this study aims to leverage zebrafish embryos as a model to study mechanisms of TBBPA impacts on cartilage development and hemoglobin production with the hypothesis that these effects are mediated through the *Ahr2* pathway. **Methods:** Embryos were exposed to 0-0.5 μ M TBBPA from 6 to 120 hpf, with daily solution renewals. To validate transcriptomic results, we first conducted concentration-dependent whole-mount immunohistochemistry (IHC) and examined *Ahr2* and *Cyp1A* protein expression at 24 hpf and 72 hpf (N=10). Subsequently, embryos were co-exposed to 0.5 μ M TBBPA and 1.25 μ M GNF-351- a known *Ahr2* antagonist- to evaluate whether inhibition of *Ahr2* signaling rescues TBBPA-induced phenotypes. Cartilage defects (at 120 hpf) and hemoglobin disruption (at 72 hpf) were assessed using Alcian Blue and o-dianisidine staining, respectively (N=10-15). To further confirm these findings, an *Ahr2* translation-blocking morpholino was injected at the 1-2 cell stage, followed by exposure to 0.5 μ M TBBPA at 6 hpf, and Alcian Blue and o-dianisidine staining as described previously. Statistical analyses were conducted using either one-way or two-way ANOVA, coupled with relevant post hoc tests. **Results:** At 0.005 μ M TBBPA (environmental levels), IHC showed significant upregulation of *Ahr2* and *Cyp1A* proteins, showing 50% and 25% increases at 24 hpf and 150% and 50% increases at 72 hpf, respectively. Co-exposure with the *Ahr2* antagonist GNF-351 partially reversed these effects, reducing *Ahr2* expression by 15% and *Cyp1A* expression by 25% at 24 hpf and 37.5% at 72 hpf. Functional rescue was further evident at the tissue level: o-dianisidine and Alcian Blue staining demonstrated that GNF-351 significantly rescued TBBPA-induced suppression of hemoglobin production and craniofacial cartilage structures respectively. Consistent with these findings, *Ahr2* morphants exhibited a similar pattern of recovery, with partial rescue of TBBPA-induced protein increases by 66.67% for *Ahr2* at 24 hpf and 33.33% for *Cyp1A* at 72 hpf. Correspondingly, o-dianisidine and Alcian Blue staining revealed that *Ahr2* knockdown significantly rescued TBBPA-induced adverse effects on hemoglobin levels and craniofacial cartilage structures. **Conclusions:** TBBPA disrupts craniofacial cartilage formation and hemoglobin production by aberrantly activating *Ahr2* signaling. Acting as an *Ahr2* agonist, TBBPA induces downstream targets such as *Cyp1A* and alters transcriptional programs critical for chondrogenesis and erythropoiesis. Partial rescue by *Ahr2* inhibition or morpholino knockdown confirms the pathway's specificity in mediating these developmental defects, providing mechanistic insight into how early *Ahr2* activation perturbs differentiation processes.

PS 3157 Single-Cell Transcriptomic Profiling of Bisphenol-Induced Disruption in Human Embryonic Stem Cell Osteogenesis

N. Iwobi, and N. R. Sparks. University of California, Irvine, Irvine, CA.

Background and Purpose: Bisphenols (BPs), particularly bisphenol A (BPA), are well-known endocrine disruptors with widespread environmental occurrence. While BPA's toxicological effects are well documented, its analogs bisphenol F (BPF) and bisphenol S (BPS), commonly used as BPA substitutes, remain less understood, particularly regarding their impacts on bone development. BPA has been shown to inhibit osteoblast differentiation and induce osteoblast apoptosis, compromising bone integrity. However, the developmental bone toxicity of BPF and BPS has not been thoroughly characterized. **Methods:** Here, we investigated the effects of BPA, BPF, and BPS on osteoblast differentiation using human embryonic stem cells (hESCs; H9 line) osteogenically induced with 1,25(OH)₂ vitamin D₃ (VD3), β -glycerophosphate (BGP), and ascorbic acid (AA). Human ESCs were exposed to increasing concentrations (0.0001-100 μ M) of each BP during differentiation. **Results:** BPA and BPF caused dose-dependent reductions in osteoblast viability and differentiation, as measured by MTT, alkaline phosphatase (ALP) assay, and bone-specific marker expression. Interestingly, BPS did not induce cytotoxicity even at 100 μ M but inhibited osteoblast differentiation. To elucidate the molecular mechanisms underlying these effects, single-cell RNA sequencing (scRNA-seq) was performed on cells exposed to BPA, BPF, and BPS at IC10, IC25, and IC50 concentrations at three key osteogenic time-points, day 0 (untreated), day 7, and day 20. This comprehensive single-cell analysis enabled high-resolution mapping of transcriptional and pathway alterations during osteogenesis in response to BP exposure. Integration of scRNA-seq data revealed compound- and dose-dependent disruptions in osteogenic lineage specification and cellular heterogeneity. **Conclusions:** Collectively, these findings demonstrate distinct developmental and molecular toxicity profiles of BPA analogs and underscore the need for continued evaluation of bisphenol substitutes in human bone development.

PS 3158 Investigating impact of gene-environment interactions on developmental toxicology of methylmercury; characterizing CRISPR-induced mutations in glutathione pathway genes in zebrafish

D. S. Abarca Palma, E. J. Ferber, C. J. Hoyt, and B. Carter. University of Wisconsin Eau Claire, Eau Claire, WI.

Background and Purpose: The glutathione (GSH) pathway is an antioxidant pathway found in humans and zebrafish. This GSH pathway plays a critical role in detoxifying cells from substances such as methylmercury (MeHg), which is prevalent in the Great Lakes and a concern for public health. There are known genetic variations in GSH genes that affect methylmercury detoxification efficiency in adult tissue; however, less is known about the environment-gene interactions throughout embryonic development. To investigate this context, past lab members created mutations in zebrafish for 2 GSH genes, *gstp2* and *gclm*. Mutations in these genes, however, have yet to be fully and confidently genotyped (*gclm*) or sequenced to confirm mutation sequence (*gstp2*) in the zebrafish. The purpose of this project is to confirm these mutations and generate homozygous mutant zebrafish lines to study how these genes influence methylmercury detoxification in development. **Methods:** Mutations were created by microinjection of CRISPR reagents into 1-cell zebrafish embryos. Zebrafish larvae containing potential mutations were identified using high-resolution melting analysis (HRMA) genotyping, and these fish were raised to maturity. Offspring of mature zebrafish identified with potential mutation were genotyped to characterize the DNA sequence at the CRISPR target area using PCR + restriction enzyme digestion with gel electrophoresis. Gel extraction of the altered PCR amplicon and subsequent DNA sequencing were performed to identify sequence changes. DNA sample concentration was measured by spectrophotometry before being submitted for commercial DNA sequencing. Computational analyses using public tools were used to determine associated DNA sequence changes in protein structure/function. Identified mutant allele carriers were bred to propagate and generate additional mutant zebrafish. **Results:** DNA sequencing revealed a loss-of-function allele was confirmed in the *gclm* zebrafish fish. Computational analyses determined the *gclm* mutation results in a truncated protein 1/6th of the size of the WT protein. Across breeding and genotyping experiments, a limited number of female homozygous *gclm* mutants were identified. These homozygous *gclm* mutant zebrafish were bred with heterozygous *gclm* mutant zebrafish to produce a stock of mutant allele-carrying fish to be genotyped. The *gstp2* project is in earlier stages with a mutation at the CRISPR target site confirmed via gel electrophoresis. Preliminary results indicate germline inheritance of a *gstp2* mutation for one mutant allele, resulting in heterozygote and homozygote *gstp2* mutant zebrafish. **Conclusions:** The *gclm* mutant zebrafish line was successfully confirmed through DNA sequencing and gel electrophoresis, revealing a loss-of-function mutation predicted to produce a truncated protein. A stock of *gclm* mutant allele-carrying fish was produced from the confirmed *gclm* homozygous mutants. They will be genotyped using a Mendelian genetics approach by crossing the mutant allele-carrying fish with a WT and genotyping their offspring. These fish will be maintained for future developmental toxicology studies. In contrast, the *gstp2* line is still in its early stages, with preliminary confirmation of a mutation at the *gstp2* CRISPR target site through restriction digestion and gel electrophoresis. This *gstp2* mutation is yet to be sequenced. Overall, these projects are advancing the goal of producing loss-of-function mutant zebrafish lines for key GSH pathway genes. These lines of fish will enable studying how human genetic variations in GSH genes affect methylmercury detoxification during development.

PS 3159 Assessment of Developmental and Exocrine Pancreatic Toxicity of Aqueous Film Forming Foams (AFFF) in Larval Zebrafish (*Danio rerio*) and its Potential Modulation by the Nrf2 Pathway

S. Emani, K. Satbhai, and A. Timme-Laragy. University of Massachusetts Amherst, Amherst, MA.

Background and Purpose: Per- and poly-fluoroalkyl substances (PFAS) are ubiquitous, anthropogenic chemicals that bioaccumulate and cannot be metabolized or degraded. While studies have elucidated the adverse effects of individual PFAS chemicals on developmental, reproductive, and endocrine functions, less is understood about PFAS mixtures. Aqueous Film-Forming Foams (AFFF), mixtures dominated by PFAS chemicals, have been detected as drinking water contaminants. AFFF consists of six regulated PFAS chemicals: perfluorooctanoic acid (PFOA), perfluorooctane sulfonic acid (PFOS), perfluorohexane sulfonic acid (PFHxS), perfluorononanoic acid (PFNA), perfluorobutane sulfonic acid (PFBS), and GenX chemicals (HFPO-DA), that have been extensively studied in a wide range of animal models. The aim of this study is to comparatively assess the developmental toxicity of mixtures of 27 PFAS in AFFF and 6 regulated PFAS, while investigating the role of Nrf2—a transcription factor known to modulate oxidative stress known to be induced by PFAS chemicals. **Methods:** A mixture of 27 PFAS chemicals and a mixture of 6 regulated PFAS chemicals were synthesized to mimic the composition of a previously identified in a legacy AFFF sample comparable to 3% AFFF. Homozygous Nrf2a wildtype and mutant (*nrf2a*^{th318-/-}) zebrafish with a loss-of-function mutation were crossed with Tg(*ptf1a:GFP*) zebrafish to investigate potential modulatory effects of the Nrf2 pathway through visualization of the exocrine pancreas. Zebrafish embryos were exposed to three different sub-lethal concentrations of 0.00005%, 0.001%, and 0.0025% AFFF, corresponding to total PFAS concentrations of 197

ppb, 4.10 ppm, and 10.07 ppm. 0.1% methanol served as a solvent control made in Danieau's solution. Exposures were static and larvae were imaged using brightfield and fluorescence microscopy at 4 days post fertilization (dpf). Images were blinded and analyzed using ImageJ, and morphological assessments included fish length, pancreas length, pancreas area, yolk sac area, and pericardial area. **Results:** Our results show that the 27 PFAS mixture significantly decreased fish length in wild-type and mutant larvae exposed to 0.001% and 0.0025% AFFF. Yolk sac area was significantly increased in 0.0025% AFFF for both wildtype and mutant, compared to their respective controls. The ratio of exocrine pancreatic length to fish length was significantly lower at 0.0025% AFFF in mutant zebrafish, but not in wildtype fish. In comparison, mutant zebrafish exposed to the 6 PFAS mixture had significantly increased yolk sac area at 0.0025% AFFF, with the other morphological endpoints were not altered significantly. **Conclusions:** The results of this study show that exposure to PFAS mixtures adversely impacts morphology and pancreatic development in larval zebrafish in a dose-dependent manner, modulated by Nrf2a pathway, with implications on metabolic processes. This work is supported by R01ES025748.

PS 3160 Microengineered Palate Systems Reveal How Matrix Mechanics Shape Sonic Hedgehog Signaling

A. Yelleti, and B. Johnson. Michigan State University, East Lansing, MI.

Background and Purpose: Orofacial clefts are among the most common congenital malformations, but the etiology of these conditions is largely unknown due to the complexity of craniofacial development and the current limitations of experimental models. Lip and palate formation is successful when there is proper organized signaling between epithelial and mesenchymal cells that is controlled primarily by the Sonic Hedgehog (SHH) pathway. The SHH protein secreted from epithelial cells diffuses in the extracellular matrix and binds to and activates mesenchymal cell receptors, triggering genetic programs that instruct cells on how to grow, divide, or differentiate. When the face does not develop normally due to a mutation, toxin exposure, or imbalance of signaling, it leads to a cleft lip, cleft palate, or other malformation. To gain further insight into how SHH signaling disruptions result in abnormal morphogenesis, a 3D microphysiological model (MPM) was developed to mimic the epithelial-mesenchymal interface of the developing palate, adapting prior microphysiological approaches for Hedgehog signaling [1, 2]. The system is designed to increase human relevance and to be used as a platform for screening environmental or pharmaceutical agents that alter SHH-dependent developmental processes. This study further evaluates the model's reproducibility and accessibility by testing its performance when implemented by a first-time user with limited prior experience in microphysiological systems, showcasing its potential for broader adoption across research skill levels. **Methods:** MPMs were built with 96-well plates milled using Computer Numerical Control (CNC) and seeded with mesenchymal 3T3 SHH Light II reporter cells suspended in a thiol-modified hyaluronic acid hydrogel (Hystem-C) [2]. Epithelial control and SHH-overexpressing GMSM-K RFP cells were cultivated in side channels and on top of the hydrogel to create an epithelial-mesenchymal signaling axis. Hydrogel crosslinker ratios 1:4 and 1:6 (Extralink:Glycosil) were used to tune matrix stiffness, mimicking differences between mature and embryonic connective tissue. Luciferin-based luminescence imaging quantified SHH pathway activation, and results were assessed using a 0-20 performance rubric evaluating gel integrity, 3T3 distribution, GMSM-K channel alignment, GMSM-K distribution in the well, and luminescence signal. Scores of 0-4 indicated failed wells, 5-10 poor, 11-15 good, and 16-20 excellent performance. This rubric provides an objective, reproducible framework for comparing results across plates and users, allowing for quick assessment of experimental quality. **Results:** During multiple experimental runs (9/10/25 - 10/13/25), SHH signaling was detected in >80% of the wells loaded, with mean luminescence levels of 1.23×10^4 to 2.7×10^4 photons/sec across regions of interest (ROIs). More diffuse, higher-intensity SHH responses were obtained with softer hydrogels (1:6 ratio), whereas stiffer matrices produced sharply peaked but spatially restricted gradients. Highest-scoring wells recorded scores of 15-17 ("Good-Excellent") with aligned epithelium and strong reporter activation. Variability in lower-scoring wells (≤ 10) was often linked to gel polymerization inconsistency, barrier failure, or media leakage. Consistent signal detection across experimental repeats by a first-time operator underscores the MPM's reproducibility and practical usability, even in the hands of a novice user. Low-level SHH activity in overexpressing controls remained after 7 days, suggesting possible endogenous signaling or diffusion artifacts. **Conclusions:** This MPM successfully mimics the epithelial-mesenchymal SHH signaling microenvironment and provides a quantifiable, reproducible system for evaluating developmental processes in orofacial morphogenesis. The standardized scoring rubric improved data consistency and comparability between plates. These results demonstrate that matrix stiffness influences SHH diffusion and activity and highlight the model's value for studying morphogen gradients and chemical perturbation in craniofacial development. Importantly, users with varying experience levels can effectively adopt this system with a high success rate. Future work will aim to use human-derived mesenchymes to improve physiological relevance and will further apply this model to developmental toxicology and risk assessment.

PS 3161 Mitochondrial and neural developmental disruption by ractopamine exposure in zebrafish: Integrated transcriptomic and functional analyses

Y. Huang, H. Chen, S. Wu, and B. Liu. National Taiwan University College of Medicine, Taipei, Taiwan. Sponsor: S. Liu

Background and Purpose: Ractopamine (RAC), a β -adrenergic agonist widely used as a feed additive, has raised global food safety concerns regarding its residues in edible tissues and potential developmental impacts. The present study aimed to evaluate the developmental and physiological effects of RAC exposure using an integrative zebrafish model. **Methods:** Zebrafish embryos were exposed to food-relevant (10-100 $\mu\text{g/L}$) and supraphysiological (500-2000 $\mu\text{g/L}$) concentrations of RAC. Transcriptomic profiling was performed to identify molecular pathways perturbed by RAC exposure, while phenotypic and functional assays were conducted to assess cardiovascular and behavioral responses. Quantitative analysis of RAC uptake in embryonic tissues was determined by competitive ELISA. **Results:** Low-dose RAC (10-100 $\mu\text{g/L}$) exposure perturbed genes involved in mitochondrial ATP synthesis, purine metabolism, and neurogenesis pathways, indicating compromised energy homeostasis and neuronal differentiation. At higher concentrations (1000 $\mu\text{g/L}$), RAC triggered broad transcriptional alterations associated with embryonic patterning, morphogenesis, neural axonogenesis, visual perception, and oxidative phosphorylation. Functional assessments revealed dose-dependent increases in heart rate, blood flow velocity, and locomotor activity in embryos exposed to 500-2000 $\mu\text{g/L}$ RAC, despite only 14-18% uptake of nominal concentrations and the absence of overt structural malformations. **Conclusions:** RAC exposure, even at food-relevant concentrations, disrupted mitochondrial metabolism and neurodevelopmental gene networks in zebrafish embryos, while higher doses further impaired cardiovascular physiology and behavioral performance. These findings provide mechanistic insights into the developmental risks associated with RAC exposure in vertebrates.

PS 3162 Transgenic zebrafish embryo models for AOP-based developmental toxicity evaluation in craniofacial and cardiac anomalies

S. Liu¹, J. Tasaki², T. Takeshita¹, S. Nakagawa², K. Saito², and Y. Ito². ¹Kao Corporation, Kawasaki, Japan; and ²Kao Corporation, Tochigi, Japan. Sponsor: S. Liu, Japanese Society of Toxicology

Background and Purpose: Craniofacial anomalies and heart defects are among the most common congenital malformations worldwide and are most often caused by a combination of genetic and environmental factors, including pharmaceuticals and chemical agents. Understanding conserved developmental mechanisms underlying each defect is essential for evaluating teratogenicity and constructing AOP (Adverse Outcome Pathway)-based evaluation frameworks. Zebrafish embryo have recently emerged as a powerful alternative model for developmental toxicity evaluation owing to their high-throughput capabilities, conserved embryogenesis, and ability to visualize complex developmental processes. In this study, we established transgenic zebrafish reporter lines Tg(sox10:EGFP), Tg(myf7:EGFP), Tg(kdr:mRFP), and Tg(gata1:mKate2) to visualize cranial neural crest cells (CNCCs), cardiomyocytes, vascular endothelial cells, and blood cells, respectively. Using these lines, we investigated chemical-induced craniofacial anomalies and cardiac malformations (Liu et al., *Tox.Sci.*, 2023, 2025). These studies aim to establish a scientifically robust, alternative developmental toxicity evaluation system and challenge its potential application toward OECD test guideline development. **Methods:** Zebrafish (*Danio rerio*) strains RIKEN WT (RW), sox10:EGFP, myf7:EGFP, kdr:mRFP, and gata1:mKate2, all on the RW background, were used. Fertilized eggs were exposed to test compounds from 4 to 96 hours post-fertilization (hpf). Morphological observations were performed using immunofluorescence staining, live and time-lapse imaging via fluorescence, confocal, and light sheet microscopy. Median malformation dose (EC50) and median lethal dose (LC50) were calculated to determine the Teratogenic Index (TI), with TI > 2 defined as positive. In addition to the endpoint reported by similar researchers using wild-type embryos, mechanistic endpoints associated with AOP key events were assessed through gene expression analysis and stage-specific imaging of CNCC migration and cardiac morphogenesis. **Results:** Exposure to known mammalian teratogens impaired CNCC migration, disrupted CNCC-related gene expression, and affected the morphogenesis of the first pharyngeal arch (PA1) at 24 hpf, resulting in craniofacial anomalies. These findings indicate that KEs underlying chemical-induced craniofacial defects include altered cell proliferation and apoptosis in CNCCs and dysregulation of CNCC-related genes, leading to impaired PA1 formation, a process conserved among vertebrates. Similarly, defects in cardiomyocytes, endocardial cells, and cardiac looping resulted in morphological and functional abnormalities. Live imaging revealed that teratogen exposure caused marked malformations in cardiac morphogenesis, such as abnormal heart tube formation, incomplete looping, and reduced chamber size. These teratogens also disrupted the expression of conserved cardiac progenitor markers such as *nkx2.5* and *islet*, suggesting impaired cardiac progenitor development. This sequence of alterations is considered a key event leading to cardiac malformations. Using the KEs as an endpoint, evaluation of more than 40 compounds, including pharmaceuticals and industrial chemicals, showed high concordance with mammalian data (87.0% sensitivity, 88.2% specificity, and 87.5% accuracy). Incorporating mechanistic observations enhanced detection of teratogenic mechanisms in craniofacial and cardiovascular systems compared

with wild-type embryos. These results demonstrate that transgenic zebrafish embryo models can elucidate AOP key events across molecular, cellular, and tissue levels, enabling mechanism-based developmental toxicity evaluation. **Conclusions:** The established transgenic zebrafish embryo models visualize conserved KEs underlying craniofacial and cardiac malformations, supporting predictive evaluation of human developmental toxicity. This AOP-based approach provides a promising platform for developmental toxicity assessment. Our ultimate goal is to conduct integrated validation studies within the NGRA framework, combining AOP and IATA concepts with RAX and *in vitro/in silico* assays, to propose a defined approach toward OECD test guideline development.

PS 3163 Whole-Body Teratogenicity Imaging by Tissue Clearing and Light Sheet Microscopy Combined with AOP-Based Assay in Transgenic Zebrafish Embryo

J. Tasaki¹, S. Liu², M. Aoki¹, and T. Mori¹. ¹Kao Corporation, Haga, Japan; and ²Kao Corporation, Kawasaki, Japan. Sponsor: J. Tasaki, Japanese Society of Toxicology

Background and Purpose: Teratogenicity refers to the induction of structural malformations during embryonic development, often resulting from exposure to pharmaceuticals or environmental chemicals. Accurate detection of affected tissues is essential for assessing developmental toxicity. These structural defects such as craniofacial malformations arise through complex morphogenetic processes involving cranial neural crest cells, and their malformations often present subtle or spatially distributed patterns that require high-resolution, three-dimensional imaging for proper evaluation. Zebrafish (*Danio rerio*) embryos provide a suitable model for teratogenicity assay due to their external development, optical transparency, and genetic homology to humans. Light sheet fluorescence microscopy (LSFM) enables rapid three-dimensional imaging, allowing comprehensive analysis of whole-embryo phenotypes. In this study, a workflow of tissue clearing and LSFM combining transgenic zebrafish embryos was established for whole-body teratogenicity assays. Furthermore, by utilizing a sox10:EGFP line developed for AOP-based assay (Liu et al., Toxicological Sciences 2023), we expanded its applicability to diverse chemical classes including agricultural chemicals, and demonstrated a method for detecting craniofacial and systemic malformations throughout the entire embryo. **Methods:** Zebrafish embryos were used to evaluate the teratogenic effects of model compounds and pesticides. Test concentrations followed Liu et al. (Dev. Dyn., 2020) and Narumi et al. (Front. Cell Dev. Biol., 2020): valproic acid and warfarin were used for imaging studies, and six pesticides were selected for AOP-based assessment. Fertilized embryos were exposed to the test compounds from 4 to 96 hours post-fertilization (hpf) with daily renewal of exposure medium. At 24 and 96 hpf, embryos were fixed and stained with anti-collagen II, lectin PNA, and DAPI for nuclear staining. Samples were cleared using CUBIC or ethyl cinnamate (ECi)-based protocols for three-dimensional visualization. Prior to LSFM, samples were refractive index-matched using a 4:6 mixture of silicone and mineral oils and imaged with the UltraMicroscope Blaze. For AOP-based assays, samples were mounted in low-melting-point agarose and observed using confocal and fluorescence microscopy. Acquired LSFM images were processed and reconstructed with IMARIS software. **Results:** Exposure of zebrafish embryos to valproic acid and warfarin induced craniofacial and systemic malformations, including small jaw and cleft palate, consistent with their known teratogenic profiles. Whole-body imaging following tissue clearing revealed detailed three-dimensional morphological alterations that were challenging to capture using conventional confocal microscopy due to its limited imaging depth and longer acquisition time, despite its higher spatial resolution. Both CUBIC and ECi clearing methods achieved high optical transparency suitable for LSFM observation, enabling visualization of whole-body and skeletal structures at single-cell resolution. In the AOP-based assay, several triazole fungicides induced dose-dependent craniofacial abnormalities and alterations in the first pharyngeal arch (PA1) visualized in sox10:EGFP embryos, suggesting potential mechanistic links to craniofacial malformations. Notably, negative control compounds did not alter PA1 morphology, indicating that, within the AOP framework, this transgenic line can effectively distinguish teratogenic from non-teratogenic chemicals. **Conclusions:** This study demonstrates that combining transgenic zebrafish embryos with tissue clearing and LSFM provides a powerful platform for AOP-based teratogenicity testing within the NAMs framework. The approach enables high-resolution, whole-embryo visualization of developmental abnormalities and facilitates mechanistic interpretation of chemical-induced structural perturbations. The workflow established here expands the applicability of sox10:EGFP zebrafish to diverse chemical categories and supports the reduction and replacement of mammalian teratogenicity assays through advanced imaging-based phenotypic assay.

PS 3164 Application of Chick Embryo-Based Models for Non-Clinical Developmental Toxicity Screening

J. Kim, C. Park, D. Kim, W. Jeong, and J. Lee. Chungnam National University, Daejeon, Korea, Republic of. Sponsor: J. Lee, Society for Birth Defects Research & Prevention

Background and Purpose: Non-clinical developmental toxicity studies are essential to evaluate the potential toxicological effects of drugs and chemicals on embryonic and fetal development. Conventional mammalian models, such as rats and rabbits, have long been the standard for regulatory toxicity studies; however, they involve ethical concerns, high costs, and prolonged study durations. To address these limitations, alternative models have been explored. This study aimed to confirm the applicability of chick embryo-based systems as a complementary approach for developmental toxicity assessment. **Methods:** Studies utilizing chick embryo-based assays in toxicology were examined, focusing on their use in evaluating teratogenic and developmental effects. Comparative analyses were made between chick embryo models and conventional mammalian or *in vitro* systems in terms of biological relevance, experimental feasibility, and ethical considerations. **Results:** Chick embryos have been successfully used in research related to cardiovascular development, oncology, and vaccine studies, demonstrating their developmental relevance and accessibility. The results identified key advantages of chick embryo-based models, including cost-effectiveness, real-time visualization of embryogenesis, and reduced ethical burden. However, limitations were noted, such as interspecies differences and the absence of maternal-fetal interactions. Recent advances in imaging, molecular profiling, and automation have enhanced the applicability of this model for developmental toxicology. **Conclusions:** Chick embryo-based systems provide a promising bridge between *in vitro* assays and mammalian *in vivo* studies. Their integration into non-clinical developmental toxicity studies could improve screening efficiency and reduce animal use, aligning with the 3Rs principles. Further standardization and validation are needed to establish chick embryo-based assays as a practical tool for non-clinical developmental toxicity evaluation.

PS 3165 Developmental and Behavioral Effects of Micro-/Nanoplastics (MNPs) in Zebrafish Embryos and Larvae

K. Yun¹, H. Jin¹, J. Jeon^{2,3}, S. Yang², and K. Kim¹. ¹Department of Environmental Engineering, Seoul National University of Science & Technology, Seoul, Korea, Republic of; ²Department of Applied Chemistry, Kyung Hee University, Yongin-si, Korea, Republic of; and ³Nanobio Measurement Group, Korea Research Institute of Standards and Science (KRISS), Daejeon, Korea, Republic of.

Background and Purpose: Plastic use is pervasive across modern society and the environment, and the continuous accumulation of plastic waste leads to the formation of micro-/nanoplastics (MNPs) through environmental weathering. These particles are now widely detected in aquatic ecosystems, raising concern about their potential impacts on aquatic organisms. Although many studies have examined the toxicity of pristine microplastics, information on the developmental and behavioral effects of environmentally relevant, UV-weathered MNPs remains limited. In this study, we investigated the developmental and neurobehavioral toxicity of microplastics (MPs) in zebrafish embryos, focusing on the comparative effects of plain versus UV-weathered MPs for three years having, various sizes distinct particle shapes. **Methods:** Field-emission scanning electron microscopy (FE-SEM) and field-emission transmission electron microscopy (FE-TEM) were employed to characterize the surface morphology, particle size, and internal structure of the prepared UV-weathered MP. FE-SEM images were obtained using a LEO SUPRA 55 (Carl Zeiss, Germany) operated at an accelerating voltage of 10 kV. For TEM analysis, the samples were dispersed in an ethanol-water mixture, dropped onto a carbon-coated copper grid, and subsequently dried in a vacuum oven. TEM images were acquired using a JEM-2100F (JEOL, Japan) operated at an accelerating voltage of 100 kV. Developmental toxicity testing was conducted according to OECD Test Guideline 236 using zebrafish embryos. From 4 to 120 hours post-fertilization (hpf), embryos were exposed to plain or UV-weathered polystyrene microplastics in two size classes (8 μm and 500 nm), each classified as spherical or fragmented. The four categories were defined as pristine spherical polystyrene (PSPS), UV-weathered spherical polystyrene (USPS), pristine fragmented polystyrene (PFPS), and UV-weathered fragmented polystyrene (UFPS). MNPs were dispersed with 0.01% DMSO and MNP concentrations were 0 (solvent control), 1.25, 2.5, 5, and 10 ppm, with half of the exposure medium renewed every 24 h. Developmental endpoints are hatching rate, survival, malformation incidence, body length, and eye diameter, measured by light microscopy (Nikon, Japan). Larval locomotor behavior was assessed using the light/dark transition test on a ZebraBox system (ViewPoint, France). **Results:** The zeta potential and dispersion stability increased in the order of USPS > UFPS > PFPS > PSPS, with the USPS-treated 500 nm PS showing the most pronounced surface modification and highest colloidal stability. FE-SEM images revealed uniform spherical shapes without significant deformation, while TEM analysis confirmed well-dispersed particles with clearly defined boundaries, indicating that the surface treatments did not alter the particle core structure. Exposure to UV-weathered MPs significantly reduced the hatching rate at 96 hpf. In contrast, the survival, malformation incidence, body length, and eye diameter were not significantly affected. Notably, plain and UV-weathered 500-nm MPs produced significant increased light/dark transition behaviors. Within this size class, the spherical MPs increased and fragmented MPs decreased locomotion.

tor activity. **Conclusions:** Overall, these findings demonstrated that MPs, particularly UV-weathered and nanoscale particles (500-nm particle size), caused morphological defects to zebrafish embryos. Behavioral assays provided a more sensitive measure of MP-induced toxicity. The observed size- and shape-dependent effects emphasize that UV-weathered and nanoscale particles can impact aquatic organisms under environmentally relevant conditions. These results underscore the need for additional research on neurodevelopmental effects of micro-/nanoplastics.

PS 3166 Integrated risk assessment using NAMs and PBK modeling indicates low teratogenic risk from empirical cosmetic-use exposure to Glucosamine

T. Takeshita, S. Liu, J. Tasaki, Y. Nukada, K. Saito, and Y. Ito. Kao Corporation, Tochigi, Japan. Sponsor: T. Takeshita, Japanese Society of Toxicology

Background and Purpose: Glucosamine, an amino sugar widely used in cosmetics for skin conditioning, is considered safe at current use levels by the 2022 Cosmetic Ingredient Review, which reports inclusion as glucosamine hydrochloride up to 0.9% in leave-on products for face/neck and up to 5% in rinse-off products. However, results of OECD TG 414 prenatal developmental toxicity studies for glucosamine are not publicly available. Concurrently, societal expectations and regulatory drivers to minimize animal testing have accelerated adoption of integrated safety assessments that leverage new approach methodologies (NAMs). Although several promising NAMs for developmental toxicity have been developed, few case studies have demonstrated their integrated use in safety evaluation. In the present study, we conducted a case study combining complementary human-relevant NAMs with physiologically based kinetic (PBK) modeling to evaluate whether empirically tolerated human exposure to glucosamine is consistent with a low teratogenic risk under cosmetic use conditions. **Methods:** Two mechanistically distinct NAMs were used. The devTOX quickPredict™ (devTOXqP) assay employing human iPSC-derived cells assessed cytotoxicity and developmental perturbation using the ratio of the metabolite biomarkers ornithine to cystine (o/c ratio) after 48 hours of exposure to glucosamine at 0.0128-1000 µM. A zebrafish embryo assay was conducted using transgenic embryos expressing fluorescent reporters in neural crest cells, cardiomyocytes, and vascular endothelium to increase detection sensitivity and mechanistic insight. Embryos were exposed continuously from 5 hours post fertilization (hpf) to 4 days post fertilization (dpf), and morphological and functional endpoints, including lethality and malformations, were evaluated at 4 dpf. In the zebrafish embryo assay, glucosamine was tested at 62.5-1000 µM. To compare NAMs-derived no-effect concentrations with human internal exposure, a PBK model was built in PK-Sim™. Model performance was evaluated against published human intravenous bolus (IV) clinical data, first post-dose plasma concentration (10 minutes after the IV bolus) and area under the plasma concentration-time curve (AUC). A cosmetic use scenario assumed repeated application of a 0.9% face cream, with daily dose, application area, and dosing interval informed by the SCCS Notes of Guidance 12th revision, and percutaneous absorption flux derived from the literature. A conservative 100% dermal absorption assumption was included to overestimate exposure. **Results:** In the devTOXqP assay, glucosamine showed no cytotoxicity and did not shift the o/c ratio to the developmental toxicity positive threshold up to 1000 µM, indicating a no-effect level at the highest concentration tested. In the zebrafish embryo assay, the positive control (e.g., valproic acid) induced craniofacial defects consistent with neural crest migration defects and also caused significant malformations in cardiac morphogenesis. In contrast, glucosamine produced no statistically significant increase in embryo lethality or malformation incidence compared with controls, at concentrations up to 1000 µM. The PBK model reproduced key features of the human IV clinical data, with initial plasma concentration and AUC predictions within 0.5- to 2-fold of observed values. Under the conservative dermal scenario (0.9% face cream, repeated use, 100% dermal absorption), the predicted steady-state peak plasma concentration was approximately 1 µM. Thus, the modeled human internal exposure is about three orders of magnitude below the no-effect concentrations determined from both NAMs (≥1000 µM). **Conclusions:** Across two distinct NAMs, glucosamine did not elicit developmental toxicity signals up to 1000 µM, which is approximately 1000-fold higher than human internal exposure from representative cosmetic use, even under conservative dermal absorption assumptions. Together, our integrated approach strongly supported a low teratogenic risk for glucosamine under typical cosmetic use conditions.

PS 3167 The Behavioral Toll: PFAS Compromises Anti-Predator Behaviors of Larval Fish

T. King-Heiden¹, E. Adongo¹, G. Versnik², S. Lyons¹, and G. Dehnert³. ¹University of Wisconsin - La Crosse, La Crosse, WI; ²University of Wisconsin - Stevens Point, Stevens Point, WI; and ³University of Wisconsin, Madison, WI.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are ubiquitous environmental contaminants suspected to be neurotoxic, and exposure to high concentrations are associated with altered neurobehavioral development. Their potential to disrupt behavioral endpoints of ecological importance in larval fish following embryonic exposure to environmentally relevant concentrations of PFAS are not understood. **Methods:** This study examines the impacts of early

developmental exposure to 0.8-800 ng/L perfluorohexane sulfonic acid (PFHxS) or perfluorooctane sulfonic acid (PFOS) in two species of fish, zebrafish (0-5 days) and fathead minnow (0-8 days). Embryos were exposed through water with daily 100% renewal (n=12 with 10 embryos per exposure group). In addition to assessing survival, hatching and growth, we compare innate behavioral responses (embryonic motor activity and startle response) in conjunction with functional behavioral tests (predatory escape assay) across PFAS and species. **Results:** Survival, hatching and growth were minimally impacted; however, the startle reflex was impaired following exposure to either PFAS in both species. PFAS-exposed larvae were less able to escape predation, which was most closely correlated with alterations in maneuverability. Interestingly, impacts are independent of the type of PFAS, and fathead minnows appear more sensitive than zebrafish. **Conclusions:** Our data suggests that concentrations of PFOS and PFHxS commonly detected in aquatic ecosystems are sufficient to disrupt survival by making larvae more susceptible to predation. The inter-species differences observed in this study warrant further study to fully understand the underlying mechanisms that account for impaired neurobehaviors and the ecological risks that PFAS pose to aquatic ecosystems.

PS 3168 Tetrabromobisphenol S (TBBPS)-induced developmental toxicity in zebrafish embryos

R. Serradimigni, and S. Dasgupta. Clemson University, Clemson, SC.

Background and Purpose: Tetrabromobisphenol S (TBBPS) is a new brominated flame retardant (BFR) that serves as an alternative to tetrabromobisphenol A. Previous research has revealed that TBBPS can readily accumulate in environmental matrices and potentially pose risk to environmental and human health. However, being an emerging BFR, there is limited knowledge of its toxic effects. The objective of this study is to use zebrafish as a model and determine the effects of TBBPS exposure on early embryogenesis, encompassing gastrulation- a stage of development when cell fate decisions are made. **Methods:** We initiated TBBPS exposures (0 or 40 µM) at 0.75 hours post fertilization (hpf) and phenotyped their progression hourly through cleavage, blastula and gastrula stages (till ~8 hpf). To examine the genetic basis of TBBPS-induced effects, we conducted mRNA sequencing on exposures from 0.75 to 7 hpf. We then immunostained for a series of cytoskeletal and tight junction proteins (α-tubulin, β-tubulin, ZO-1, F-actin) following exposures to a wide range of TBBPS concentrations (0, 0.004, 0.04, 0.4, 4 and 40 µM), including environmentally levels such as 0.004 µM. To determine whether activation of p38, a key regulator of F-actin polymerization, plays a role in TBBPS-induced F-actin disruption, we co-exposed embryos to TBBPS (0 or 40 µM) along with a known p38 inhibitor (5 µM SB 203580) and assessed developmental phenotypes and F-actin levels. **Results:** Our data revealed that TBBPS-treated embryos show delay in development starting at ~4 hpf (dome stage)- a stage constituting early gastrulation, with significant mortality in late-gastrulation. Gene ontology and transcription factor analyses revealed downregulation of cytoskeletal organization and tight junction assembly as potential pathways for TBBPS-induced developmental delays, processes that are crucial for proper gastrulation progression. Cytoskeletal staining showed that F-actin expression was consistently upregulated across all exposed TBBPS concentrations, including at environmentally relevant concentrations (0.004 µM). F-actin polymerization is known to be regulated by the p38 protein, encoded by *mapk14b*, which showed a ~4.7-fold overexpression in our mRNA-seq data. Therefore, we co-exposed embryos with TBBPS and p38 inhibitor SB 203580 and demonstrated a significant recovery in both developmental delay and F-actin levels, with co-exposure groups exhibiting cell-stages and F-actin expression similar to controls. **Conclusions:** Collectively, our genetic and phenotypic data shows that embryonic physiology is vulnerable to early TBBPS exposure, with developmental delays and genetic disruptions during gastrulation stages. We further demonstrate that these effects may be driven by cytoskeletal proteins with MAPK signaling as a mechanistic driver of effects. Therefore, we demonstrate a mechanism for TBBPS developmental toxicity, where TBBPS exposures increase p38 and *mapk14b* levels, disrupting MAPK signaling and resulting in increased F-actin polymerization. This potentially impacts cell migratory movements and gastrulation progression, resulting in developmental delays. Ongoing studies are aimed at detailed assessments of the mechanism underlying TBBPS-p38 interactions.

PS 3169 Butyrate rescues chlorpyrifos-induced social deficits through inhibition of class I histone deacetylases

P. Zhang, and Y. Geng. University of Washington, Seattle, WA.

Background and Purpose: Chlorpyrifos (CPF) is an organophosphate pesticide linked to autism spectrum disorder (ASD) and gut dysbiosis, but the molecular basis of its neurodevelopmental toxicity remains unclear. This study examined whether the gut metabolite butyrate can counteract CPF-induced social deficits in zebrafish and identified the histone deacetylase (HDAC) mechanism underlying this behavioral rescue. **Methods:** Zebrafish embryos were exposed to CPF (15 µM, 0-3 dpf), and juvenile social behavior was quantified at 25 dpf using the Fishbook assay. Seven gut- or liver-derived metabolites (10 µM each) were screened for behavioral recovery, followed by a dose-response test of sodium butyrate (1.25-40 µM). Class-specific HDAC involvement was evaluated by pharmacological inhibition and CRISPR-

Cas9 knockouts of class I and class IIa HDACs, including individual disruption of *hdac1*, *hdac3*, and *hdac8*. Whole-brain RNA-seq assessed transcriptional changes, while untargeted gut metabolomics and metagenomics characterized metabolic and microbial alterations. Nitrite levels were determined by Griess assay. **Results:** Embryonic CPF exposure produced persistent, dose-dependent social deficits that were completely rescued by 10 μ M butyrate ($p < 0.0001$). Valproic acid, a class I/IIa HDAC inhibitor, and CRISPR knockout of class I HDACs mimicked the rescue, whereas class IIa knockout suppressed baseline social behavior. Among single-gene knockouts, *hdac1* loss strongly enhanced social behavior in both control and CPF-treated fish, while *hdac3* or *hdac8* loss provided partial rescue. The HDAC1-selective inhibitor BRD-6929 restored social scores in a dose-dependent manner, confirming HDAC1 as a key mediator. Transcriptomic profiling revealed that CPF downregulated neuronal and synaptic genes, including 14 ASD-associated genes (e.g., *GRIA2*, *GRIA3*, *GRIN1*), whereas butyrate significantly restored their expression. CPF exposure also elevated circadian gene expression and altered nitrogen-metabolism pathways in the gut. Metagenomic data showed increased denitrifying bacteria (*Pseudomonas*, *Microbacterium*) and depletion of nitric-oxide-sensitive *Aeromonas*, accompanied by higher nitrite levels (~2-fold). The nitric-oxide donor SNAP reproduced social impairment, indicating an NO-dependent mechanism. **Conclusions:** Butyrate reverses CPF-induced social and transcriptional abnormalities through inhibition of class I HDACs, primarily HDAC1. CPF disrupts the gut microbiota and nitrogen metabolism, increasing NO production that perturbs HDAC activity and suppresses neuronal-gene expression. These findings define an NO-HDAC regulatory axis linking environmental pesticide exposure to microbiome dysbiosis, epigenetic imbalance, and ASD-related behavioral deficits, highlighting HDAC1 and NO signaling as potential intervention targets in developmental neurotoxicology.

PS 3170 Nanoplastic Exposure Differentially Impacts Placenta Function in a Sex Specific Manner

A. Harbolic¹, H. Alahmadi¹, M. Jojy¹, C. De Oliveira-Cordova¹, R. Reynolds¹, C. Cary², D. McWilliams³, P. A. Stapleton², and G. R. Warner¹. ¹New Jersey Institute of Technology, Newark, NJ; ²Rutgers University, Piscataway, NJ; and ³Villanova University, Villanova, PA.

Background and Purpose: Plastic production has been increasing exponentially. Throughout their lifespan, plastics degrade into smaller particles that accumulate in our bodies and the environment. Recent studies found these plastic particles can cross the placental barrier and reach the fetus. However, the impact of plastic particles on placental function is still unknown. **Methods:** To understand the impact of plastic particles on the placenta, we orally exposed pregnant CD-1 mice to 50 nm or 200 nm polystyrene plastic particles from gestation day 8 to day 15 at a concentration of 5 mg/kg/day. Placentas were collected and sliced in half with one half used for gene expression analysis and the other half for morphological analysis. We determined the sex of each placenta by measuring expression of *Sry* and *Rbm31y*. For morphological analysis, the placentas were embedded in paraffin, sectioned into 8 micron sections and then stained using hematoxylin and eosin. We measured the relative area of the key layers of the placenta (the labyrinth zone, basal zone, and decidua), the maternal and fetal blood spaces, and the intrahemal barrier between them. **Results:** We observed a statistically significant decrease in the area of the decidua in the placentas for the 200 nm treatment group and a borderline significant decrease in decidua area for the 50 nm treatment group compared to control. However, when we separated by sex, only the male deciduals were significantly decreased in the 200 nm group. The labyrinth zone was borderline significantly increased for females in the 50 nm group and the decidua was borderline significantly decreased for the males in the 50 nm group compared to controls. For the blood space measurements, the maternal blood space was significantly decreased in size and the intrahemal barrier was borderline significantly decreased for the 200 nm males compared to controls. **Conclusions:** We observed sex specific changes in placental morphology with different effects at different plastic sizes. The overall effect appears to be driven by males. The decidua is a key site of hormone production, so future studies will evaluate the impact of plastics on hormone production and signaling during development. Additionally, we will look to enhance our understanding of sex specific differences following exposures to different plastic types.

PS 3171 Linking Developmental Toxicity and Oxidative Stress to Alkyl Substituted Naphthalenes in Zebrafish

M. L. Moreshead, A. I. De La Torre, S. J. Carrell, R. Scott, K. A. Anderson, and R. L. Tanguay. Oregon State University, Corvallis, OR.

Background and Purpose: Polycyclic aromatic hydrocarbons (PAHs) form through incomplete combustion of organic materials and anthropogenic sources such as crude oil processing and landfill waste degradation. Increasing fossil fuel use and record-breaking wildfires in recent years have heightened concerns about PAH impacts on human and environmental health. Naphthalene and its alkyl substituted derivatives are the most abundant detected in air and water monitoring samples, posing significant human exposure risk. However, the comparative toxicity of these structurally similar compounds remains poorly characterized. **Methods:** We evaluated 24 alkyl substituted naphthalenes using a high-throughput developmental

zebrafish toxicity assay (6-120 hours post fertilization (hpf)). Based on preliminary results suggesting volatilization issues, modified exposure designs were made using sealed vials with reduced headspace vials and tumbling to ensure uniform uptake. Embryos (n=8/vial) were exposed to five concentrations (3.125-50 μ M) plus a control, normalized to 0.5% DMSO. At 24 hpf, embryos were transferred to 96-well plates for morphological and behavioral assessment at 24 and 120 hpf. Morphological screening revealed that alkyl substituted derivatives were more developmentally toxic than naphthalene, clustering into five distinct clusters based on shared endpoints. We selected one representative compound from each cluster (1, 7-, 1, 5-, 2, 7-dimethylnaphthalene, 2, 4, 5-trimethylnaphthalene, and naphthalene) for body burden quantification at 24 and 48 hpf following 20 μ M exposures. Biospyder Tempo-seq targeted transcriptomics assessed gene expression patterns across all 24 compounds. Finally, reverse molecular docking against ~30,000 predicted human protein-binding pockets identified potential molecular targets, with the top-scoring proteins subsequently validated through follow-up docking. **Results:** Body burden analysis at 24 and 48 hpf revealed that all alkyl-substituted naphthalenes had greater body burden trends compared to the parent compound, with 1, 7-dimethylnaphthalene showing the greatest concentration. Notably, 1, 7-dimethylnaphthalene also formed a distinct morphological cluster and exhibited the highest number of differentially expressed genes (DEGs), suggesting a unique mode of action. Targeted transcriptomics across all 24 alkyl substituted naphthalenes identified 5 frequently dysregulated genes: *ctss2.1*, *fgbp2b*, *kif9*, and *fkbp5*. Of these, *fkbp5*—a glucocorticoid-linked stress modulator in the FK506 binding protein family—was differentially expressed in 18 of the 24 chemicals, implicating oxidative stress pathways in naphthalene-induced developmental toxicity. Reverse docking against ~16,000 human protein structures identified NT5E as a top predicted binding target, ranking first for binding affinity in 17 of the 24 compounds. NT5E encodes proteins essential for immune cellular response that has been linked to oxidative stress regulation. Follow up docking with both human and zebrafish NT5E structures (open and closed conformations), showed comparable binding scores across species with alkyl-substituted naphthalenes displaying higher predicted affinity than the endogenous ligands, adenosine and adenosine monophosphate (AMP). The zebrafish ortholog CD73 is expressed around 24 hpf, coinciding with the exposure window, suggesting disruption of oxidative stress-related immune signaling may contribute to observed developmental effects. **Conclusions:** Alkyl substituted naphthalenes were significantly more toxic than the parent compound, with higher bioaccumulation and distinct developmental effects. The variability in toxicity across chemicals highlights that structure modification dramatically alters naphthalene toxicity. The increased expression of genes related to glucocorticoid signaling (*fkbp5* and *kif9*) could relate to oxidative stress induced toxicity. Predicted binding to NT5E/CD73 suggests the potential for disruption to purinergic signaling which may relate to the observed gene expression changes. Future work will further characterize the interactions between naphthalenes and NT5E *in vivo* and *in vitro* and assess the role of oxidative stress in the observed toxicity.

PS 3172 Optimizing Dosing Initiation in Rabbit Embryo-Fetal Development Toxicity Studies: Avoiding the Pre-implantation Window

Y. Hu, L. Zhang, Y. Zhang, and J. Ma. JOINN Laboratories, Suzhou, China.

Background and Purpose: According to ICH S5(R3), embryo-fetal development (EFD) toxicity studies are required in both rodents and non-rodents (typically rabbits). The assessment stage, covers the period from implantation to closure of the hard palate, and the recommended dosing period for rabbits is specifically suggested as GD (Gestation Day) 6/7 to GD19. However, our facility observed two instances of significantly reduced pregnancy rates in rabbit EFD studies that employed the GD6-GD19 dosing regimen. Therefore, this integrated approach aims to provide a critical analysis and discussion on the time of dosing initiation in rabbit EFD studies. **Methods:** A retrospective analysis was performed on 66 GLP-compliant EFD studies in New Zealand White rabbit from our facility (2020-2025). Data from control groups, including the dosing initiation day (GD6 or GD7) and the corresponding pregnancy rates, were compiled and analyzed. For the two rabbit EFD studies initiating dosing on GD6 that demonstrated apparently reduced pregnancy rates, a detailed analysis of the data and potential underlying causes was performed in combination with rabbit EFD studies of 54 FDA-approved new drugs between 2023 and 2024, and the research data of rabbits in our facility. **Results: 1. Historical Data Analysis Reveals a Generally Stable Test System** A summary of 66 GLP-compliant EFD studies in Rabbits revealed that 62 out of 66 studies initiated dosing on GD6, with control group pregnancy rates (24 animals/group/study) ranging from 61.5% to 100% (Mean $\pm$ SD: 88.8% $\pm$ 10.2%). The remaining 4 out of 66 studies initiated dosing on GD7, and the control group animals exhibited pregnancy rates ranging from 79.2% to 95.8% (Mean $\pm$ SD: 89.6% $\pm$ 7.2%). The overall pregnancy rates demonstrated no marked differences compared to those observed in studies initiating dosing on GD6, and the natural conception rate in Rabbits remains relatively stable. **2. Case Studies Illustrating the Risk Associated with GD6 Dosing Initiation** Despite the overall stability of the test system, two projects exhibited severe pregnancy loss linked to GD6 dosing initiation. For a GnRH receptor antagonists, GD6-GD19 dosing resulted in 0% pregnancy in the high-dose group in the pEFD study; however, in the subsequent GLP study, initiating dosing on GD7 achieved viable litters in all groups (n $\geq$ 16). Similarly, for a non-hormonal compound, the pEFD study (dosing GD6-GD19) showed reduced pregnancy rate (50%) at the high dose without maternal toxicity, which was restored to 91.7%-100% in the GLP study at higher doses by shifting the dosing initiation to GD7. These cases underscore that for compounds with potential or uncharacterized effects on

implantation, initiating dosing on GD7 is a critical strategy to avoid pre-implantation loss and ensure reliable teratogenicity assessment. **3. Industry Trends and Biological Evidence Support GD7 Initiation** A review of new drugs approved by the FDA in 2023–2024 identified 54 compounds for which rabbit EFD studies were conducted. Among these, dosing commenced on gestation day (GD) 6 in 19/54 (35.2%) studies, while 35/54 (64.8%) initiated dosing on GD7. This distribution indicates that, while operating within regulatory guidelines, nearly two-thirds of recent development programs prioritize the post-implantation period for teratogenicity assessment. To investigate this, an internal study in rabbits ($n=6$) found that uteri on GD6 were indistinguishable from non-pregnant animals, with no implantation sites or blastocysts observed on the endometrial surface of the uterine lumen; however, by GD7, implantation sites become macroscopically identifiable as distinct swellings on the uterine wall. Thus, initiating administration on GD6 carries a substantial risk of compromising pregnancy outcome. **Conclusions:** While ICH S5(R3) provides flexibility for initiating dosing in rabbit EFD studies on GD6 or GD7, our integrated analysis demonstrates that GD6 administration coincides with a critical and vulnerable pre-implantation window. This poses a substantial and avoidable risk of compromising pregnancy rates, particularly for compounds with potential effects on implantation, thereby jeopardizing the primary objective of the EFD study—the assessment of teratogenicity. Therefore, we strongly recommend initiating dosing in rabbit EFD studies on GD7 as a standard practice.

PS 3173 Ultrafine particulate inhalation during pregnancy results in placental adaptation and fetal hyperglycemia in rats

T. N. Seymore¹, D. McWilliams², S. Hoffmann³, P. Louro¹, C. Gardner¹, D. Laskin¹, M. Goedken¹, and P. Stapleton¹. ¹Rutgers University, Piscataway, NJ; ²Villanova University, Villanova, PA; and ³Bucknell University, Lewisburg, PA.

Background and Purpose: Inhalation of particulate matter air pollution during pregnancy is associated with fetal growth restriction (FGR). Of particular concern is ultrafine particulate matter (<100 nm in diameter), which can readily cross the alveolar epithelial barrier, enter the circulation and localize in extrapulmonary tissues including the placenta. The placenta plays vital role in the transport of growth-related nutrients such as glucose to the fetus. We hypothesize that transport of nutrients to the fetus will be altered following maternal exposure to ultrafine particulate matter and that this contributes to FGR. **Methods:** Pregnant Sprague Dawley rats were exposed to 9.54 ± 0.28 mg/m³ nano-sized titanium dioxide (nano-TiO₂) (157.30 ± 1.85 nm) as a proxy for ultrafine particulate matter and compared to naïve controls. On GD 20, fasting maternal and fetal blood glucose was measured using a OneTouch Ultra 2 glucometer. Maternal plasma was isolated to evaluate insulin levels using an ELISA kit (Thermo Fisher). Placentas from both male and female fetuses were collected and fixed in formalin for histological evaluation. Paraffin embedded tissue slices were stained with hematoxylin and eosin to evaluate placental zone size and blood space number. Immunohistochemistry and immunofluorescence were used to evaluate the abundance and localization, respectively, of glucose transporter (GLUT) 1, GLUT3 and GLUT4. *Ex vivo* placental perfusion was conducted to assess real-time transport of glucose across the placenta. **Results:** Inhalation of nano-TiO₂ had no effect on maternal glucose or insulin. Conversely, fetal blood glucose was significantly greater in the nano-TiO₂ exposed group when compared to controls (48.2 ± 11.0 vs 32.5 ± 3.0 mg/dL). Histological evaluation revealed a 10% decrease in the labyrinth zone area of exposed dams relative to controls. This morphological change was accompanied by an 11% increase in maternal blood space number and a 35% increase in fetal blood space number. Nano-TiO₂ exposure also resulted in a significant reduction in expression of the primary transporter, GLUT1 (relative DAB intensity of 0.9 vs 1.0) and a significant increase in GLUT4 expression (1.7 vs 1.0); a 15% and 25% increase in membrane localization GLUT1 and GLUT4. In parallel, glucose flux across the placenta was increased in the exposed group as compared to control (AUC: 131.6 ± 14.2 vs 68.8 ± 9.4). **Conclusions:** These data demonstrate that gestational inhalation of ultrafine particulate matter negatively affects the area for nutrient transport in the placenta and reduces expression of the primary glucose transporter. Unexpectedly, fetal blood glucose was greater after maternal exposure, despite the FGR phenotype. These findings suggest dysregulated compensatory changes in the placenta following maternal particulate matter exposure resulting in fetal hyperglycemia, which have implications for adverse metabolic regulation during adulthood. PS 3174 Physiological and Functional Responses in Rat Offspring Exposed to Simultaneous 4G and 5G EMFs from Gestation to Weaning

J. Park^{1,2}, S. Oh², E. Gu², S. Min^{1,2}, M. Jang², Y. Kim², S. Jeon³, J. Moon³, K. Imaida⁴, M. Kawabe⁵, M. Yokohira⁴, and K. Han². ¹University of Science & Technology, Daejeon, Korea, Republic of; ²Korea Institute of Toxicology, Daejeon, Korea, Republic of; ³Electronics and Telecommunications Research Institute, Daejeon, Korea, Republic of; ⁴Kagawa University, Kagawa, Japan; and ⁵Trans Genic Inc., Shizuoka, Japan.

Background and Purpose: The widespread use of mobile phones and wireless communication devices has led to continuous human exposure to complex radiofrequency (RF) electromagnetic fields (EMFs). Although typical exposure levels are

generally not high, experimental and epidemiological findings have raised concerns about the potential effects of early-life RF exposure on offspring growth and development. According to systematic reviews of experimental and human studies, notable alterations were reported in development and reproductive outcomes (Cordelli et al., 2021; Kim et al., 2021; Bodewein et al., 2022). Similarly, a NTP report described changes in pup body weight and neurobehavioral parameters associated with the RF exposure from gestation to lactation period (NTP TR 595, 2018). These previous findings, along with public health concerns, support the need for studies evaluating the effects of repeated and long-term RF exposure on offspring. This study aimed to provide additional data to understand such potential effects by evaluating male rat offspring exposed to simultaneous 4G/5G EMFs under real-life exposure conditions in South Korea from the gestation to lactation period. **Methods:** Pregnant Sprague-Dawley rats were exposed to simultaneous 4G (900 and 2120 MHz) and 5G (3650 MHz) EMFs from gestation day (GD) 5 to postnatal day (PND) 21. Exposure was conducted for 9 hours and 10 minutes per day, with a continuous 10-minute on/off cycle for 18 hours and 20 minutes daily, at a total combined exposure level of 4 W/kg. The offspring was exposed under the same conditions with their dams until PND 21. To ensure experimental validity and consistency, the animals were assigned to three groups: a control group, a sham-exposed group, and an RF-exposed group. During the exposure period, food consumption of dams, body weight of offspring (F₁), and developmental and behavioral parameters were monitored. **Results:** The food consumption showed statistically significant decreases in the RF-exposed group compared with the control group on PND 4 and PND 21. Litter-based body weight of offspring tended to be consistently lower in the RF-exposed group compared with the control and sham-exposed groups throughout the study period. In the physical development, a statistically significant difference was observed in eyelid opening between the control and both the sham- and RF-exposed groups. No notable changes showed in reproductive findings. **Conclusions:** The statistically significant changes in food consumption, litter-based body weight, and physical development were observed at certain time points or were of minimal magnitude. Therefore, these findings are not considered adverse effects related to the RF exposure under the present study conditions. Funding Source: This research was supported by Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (MSIT) (No. RS-2024-00466966).

PS 3175 Human Induced Pluripotent Stem Cell (hiPSCs)-Derived Osteoblasts for *In Vitro* Assessment of Skeletal malformation

P. van Rossum¹, J. Horcas-Nieto¹, G. Hendriks¹, A. Jamalpoor¹, and K. Wolton². ¹Toxys, Leiden, Netherlands; and ²Unilever, Sharnbrook, United Kingdom.

Background and Purpose: Human developmental toxicants can negatively impact embryonic development, causing bone growth retardation and malformations. Assessment of skeletal malformations is a crucial component for regulatory *in vivo* studies addressing prenatal developmental toxicity. Despite the importance of *in vivo* testing, *in vitro* models render themselves highly valuable in the field of developmental and reproductive toxicity (DART) due to the current shift in regulatory requirements and their ability to increase the efficiency of existing DART testing programs. **Methods:** The ReproTracker assay focuses on capturing the teratogenic potential of chemicals by assessing disruptions in the development of human induced pluripotent stem cells (hiPSCs) into neural rosettes, hepatocytes and cardiomyocytes. This study presents the addition of osteoblasts to this platform, expanding the assay's ability to capture the effects of teratogens on bone development. Osteoblast differentiation was determined using the mesodermal biomarker *BRACHYURY*, as well as the bone specific markers *RUNX2*, *SP7*, *COL1A1* and *BGLAP*. In addition, calcium depositions were observed at the later stages of differentiation, further illustrating the functionality of the osteoblasts in culture. **Results:** To validate the capability of these biomarkers for detecting teratogenic potential in the ReproTracker assay, we assessed the effect of well characterized *in vivo* bone developmental toxicants (thalidomide and retinoic acid) and two non-developmental toxicant (saccharin and vildagliptin) at non-cytotoxic concentrations. The tested teratogenic agents decreased the expression of either *BRACHYURY* at day 4, and/or the regulation of the bone biomarkers *RUNX2* and *COL1A1* between days 7 and 14. In contrast, saccharin and vildagliptin did not alter the expression of any of the assessed biomarkers, further illustrating the tight regulation of these biomarkers in osteogenesis and their prospect to identify bone specific teratogens *in vitro*. **Conclusions:** Integration of the osteoblast differentiation in the ReproTracker assay expands the biological coverage of developmental processes recapitulated. Using bone-specific biomarkers as end points to evaluate teratogenic agents, we have developed a tool that not only allows for the detection of skeletal developmental toxicants *in vitro*, but also provides insights into the molecular mode of action of the test article.

N. Aluru¹, R. Lai², and M. E. Hahn¹. ¹Woods Hole Oceanographic Institution, Woods Hole, MA; and ²Faculty of Science and Technology, University of Macau, Macau, China.

Background and Purpose: Cyanobacterial blooms are expanding worldwide and these blooms release potent neurotoxins that threaten aquatic ecosystems, wildlife, and human health. (+)-Anatoxin-a (ATX-a), a secondary metabolite produced by several cyanobacterial genera, is a fast-acting agonist of nicotinic acetylcholine receptors (nAChRs). Upon binding, ATX-a causes sustained receptor activation and persistent muscle contraction, often resulting in respiratory paralysis in exposed animals. While the acute neurotoxicity of ATX-a in adults has been studied in rodent models, developmental effects in vertebrates remain poorly understood. During early embryogenesis, nAChR signaling is essential for establishing neuromuscular junctions (NMJs), promoting muscle fiber patterning, and guiding motor neuron connectivity. Interference with this signaling could have profound effects on motor system maturation. We hypothesized that transient nAChR activation during discrete developmental windows leads to altered neuromuscular activity and gene expression, revealing critical periods of heightened vulnerability. This study aimed to identify such windows of susceptibility and characterize molecular and cellular responses to ATX-a exposure during zebrafish development. **Methods:** Wild-type (TL strain) zebrafish embryos were microinjected with ATX-a (2 ng per embryo or larva) at five developmental stages (0.25, 1, 2, 3, and 4 days post-fertilization, dpf). Embryos were maintained under controlled conditions, and developmental phenotypes, survival, and behavioral responses were monitored up to 7 dpf. ATX-a was quantified in exposed embryos using LC-MS to determine its persistence and estimate internal dose. Gene expression profiling was performed at 6 and 24 hours post-exposure (hpe) to identify transcriptional changes associated with exposure. To visualize structural effects on motor neurons, we employed Tg(*mnx1*:eGFP) transgenic zebrafish expressing GFP in motor neurons. In addition, muscle birefringence assays were performed to assess alterations in muscle structure and organization following exposure. **Results:** ATX-a exposure at 2 and 3 dpf caused rapid-onset muscle contractions within seconds, followed by a transient loss of touch reflex lasting approximately 3-4 hours, consistent with overstimulation of nAChR signaling. No overt morphological abnormalities were observed at any of the developmental stages. Transcriptomic analysis revealed that embryos exposed during early stages (0.25 and 1 dpf) exhibited substantial differential gene expression at 6 hpe, while responses were minimal at later stages (24 hpe), indicating transient but stage-specific transcriptional perturbations. Enrichment analysis revealed overrepresentation of genes associated with muscle contraction, synaptic organization, neuronal differentiation, and cytoskeletal remodeling, suggesting temporary disruption of NMJ formation and function. Visualization using Tg(*mnx1*:eGFP) embryos confirmed transient neuritic and axonal beading consistent with acute neuronal stress, which resolved within 24 hours. Complementary muscle birefringence assays detected subtle but statistically significant changes in muscle fiber patterning in embryos exposed at 1 dpf, supporting the hypothesis that early nAChR activation interferes with muscle development. **Conclusions:** Our findings reveal a narrow developmental window during which ATX-a exposure disrupts neuromuscular signaling, gene expression, and muscle organization, indicating high sensitivity of the developing motor system to transient nAChR activation. Although many effects appear reversible within 24 hours, transient disruptions during these critical periods may have lasting consequences for circuit formation and motor performance. This work underscores the importance of identifying sensitive life stages when assessing the risks posed by cyanobacterial neurotoxins. Given the increasing global prevalence of harmful cyanobacterial blooms, these findings have broad implications for aquatic ecosystem health and potential human exposure scenarios. This research was supported by the Woods Hole Center for Oceans and Human Health (NIEHS P01 ES028938; NSF OCE-2418297).

PS 3177 Ontogeny of placental FcRn protein during human and animal pregnancy to inform developmental toxicity testing

C. J. Bowman¹, W. J. Breslin², C. Chen³, W. Foster⁴, J. Hui⁵, B. Kusmider⁶, S. Laffan⁷, M. Myers⁸, L. Sivaraman⁹, B. Tornesi⁶, S. Westmoreland¹⁰, and J. M. DeSesso¹¹. ¹Pfizer Inc, Groton, CT; ²Breslin Toxicology Consulting, LLC, Indianapolis, IN; ³HESI, Washington, DC; ⁴McMaster University, Hamilton, ON, Canada; ⁵Chara Consulting, LLC, Highland Beach, FL; ⁶Medicines for Malaria Venture (MMV), Geneva, Switzerland; ⁷Amgen, Thousand Oaks, CA; ⁸Gilead Sciences, Inc, Foster City, CA; ⁹Bristol Myers Squibb, New Brunswick, NJ; ¹⁰AbbVie, Worcester, MA; and ¹¹Exponent, Inc, Washington, DC.

Background and Purpose: Species differences exist in Fc domain-containing molecule transfer/biodistribution to the embryo-fetus during pregnancy. Placentation neonatal Fc receptor (FcRn) quantitation in chorioallantoic placenta (CAP) and/or inverted yolk sac placenta (InvYSP) was investigated across species throughout gestation to further understand and inform developmental toxicity testing of Fc domain-containing molecules. **Methods:** Quantitative mass spectrometry was used to quantify FcRn protein in CAP and/or InvYSP throughout gestation in mouse, rat, guinea pig, rabbit, and nonhuman primate (NHP). In human, immunohistochemistry was used to localize and characterize placental FcRn distribution during each trimester. **Results:** FcRn protein was detected and concentration increased throughout

gestation in mouse, rat, guinea pig, and rabbits; with InvYSP concentration markedly higher compared with CAP at all gestational ages. In contrast, NHP FcRn protein concentration in the CAP remained constant throughout gestation. During 1st trimester in human, FcRn occurred in decidua, maternal endothelium, and maternal and fetal macrophages. During 2nd trimester, fetal FcRn increased in syncytiotrophoblasts and fetal chorionic vessels. FcRn expression decreased in maternal endothelium near term. **Conclusions:** FcRn protein was detected throughout gestation (including organogenesis) in placental tissue of all animal species. Regardless of FcRn location, these data support that Fc domain-containing molecules can access the embryo-fetus throughout gestation in all species, with the extent of transfer likely depending on FcRn concentration and size of the placenta. This information on placental FcRn ontogeny will help improve study design and translation of nonclinical developmental toxicity data to safety assessment of human risk of Fc domain-containing molecules.

PS 3178 A Translational *In Vitro* Model of the Human Placental-Embryo Interface for Investigating PFAS Developmental Toxicity

L. Campagnolo, G. Posanzini, C. Bianco, and V. Lacconi. University of Rome Tor Vergata, Rome, Italy.

Background and Purpose: In recent decades, human exposure to PFAS (per- and polyfluoroalkyl substances), particularly perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS), has raised growing concern due to their persistence, bioaccumulation, and adverse effects on reproductive health and embryonic development. Their chemical stability and wide industrial use have contributed to their classification as “forever chemicals.” Studies have shown that PFAS can cross the placental barrier, exposing the embryo during critical stages of growth and potentially leading to long-term consequences. Despite this evidence, the mechanisms underlying their embryotoxicity remain incompletely understood. Therefore, this study aims to contribute to a deeper understanding of PFAS-induced embryotoxicity by developing a reliable experimental model that accurately reproduces the maternal-fetal interface. **Methods:** An *in vitro* placental barrier/simulated embryo model was developed to replicate the maternal-fetal interface in a controlled and reproducible manner. To this end, human placental vascular endothelial (HPVCEs) and human trophoblast stem (hTS) cells were co-cultured on opposite sides of a semipermeable membrane. The hTS cells were induced to differentiate into syncytiotrophoblasts to establish a physiologically relevant model of the placental barrier. Model integrity was validated through transepithelial electrical resistance (TEER) measurements, quantitative Real Time PCR and immunofluorescence analyses. This model was used to study the effects of perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) on placental barrier function. Additionally, to mimic the developing embryo, induced pluripotent stem cells (iPSCs) were differentiated into cardiomyocytes and the potential interference of PFOA and PFOS was assessed. **Results:** Exposure of the placental barrier model to PFOA resulted in a marked, dose- and time-dependent reduction in TEER values, indicating compromised barrier integrity. This effect was accompanied by increased lactate dehydrogenase (LDH) release and a significant increase in cell death (up to 40-42% after 48 h at 50-100 µM) demonstrating the cytotoxicity potential of PFOA. Furthermore, immunofluorescence analysis revealed a concentration-dependent impairment in syncytial structure formation, suggesting that PFOA disrupts both trophoblast differentiation and cell viability. In contrast, exposure to PFOS resulted in only a modest decrease in TEER values, which reached statistical significance at the highest concentration (100 µM). LDH assays confirmed limited cytotoxicity (about 6-9% of cell death after 48 h at 50-100 µM). Immunofluorescence analysis showed reduced syncytiotrophoblast differentiation, suggesting that PFOS primarily affects trophoblast differentiation rather than cell survival. Both PFOA and PFOS impaired iPSC differentiation into contracting cardiomyocytes and triggered pro-inflammatory responses. **Conclusions:** By integrating complementary *in vitro* approaches, we established a functional maternal-fetal model in which the placental barrier protects iPSC-derived cardiomyocytes. This model enables the simultaneous assessment of xenobiotic transfer across the placenta and its downstream effects on embryo-like cells, providing a physiologically relevant simulation of embryonic exposure. Our findings demonstrate the translational value of this model for investigating PFAS-induced developmental toxicity. Beyond validating its applicability to PFAS, the results highlight its potential as a versatile platform for exploring the mechanisms of action and developmental impact of other xenobiotics. These insights reinforce the need for deeper mechanistic studies and stricter regulatory measures to limit human exposure to persistent and bioaccumulative chemicals.

PS 3179 Windows of developmental susceptibility to cannabidiol reveal stage-dependent morphological and behavioral effects

V. Medina¹, C. Callahan¹, T. Shamblin², J. Lott¹, M. Clayton¹, K. Martin¹, C. Roper¹, N. Ashpole², and K. L. Willett¹. ¹The University of Mississippi, Oxford, MS; and ²Mississippi State University, Starkville, MS.

Background and Purpose: Cannabidiol (CBD) is becoming increasingly available and is at times suggested to pregnant women to mitigate pregnancy-related symptoms commonly present during the first trimester, including nausea, insomnia, and pain. The goal of this study is to consider different windows of developmental suscep-

tibility using the zebrafish (*Danio rerio*) model. **Methods:** Wildtype (5D) zebrafish embryos were exposed to control (0.05% DMSO) from 6-102 hours post fertilization (hpf) or 2 μ M CBD from 6-102 hpf, 6-30 hpf, 30-54 hpf, 54-78 hpf, or 78-102 hpf, with mortality and hatching monitored daily. After each exposure window, embryos were collected for gas chromatography-mass spectrometry (GC-MS) to assess CBD bioaccumulation or transferred to clean egg water until 120 hpf. At 120 hpf, behavior (larval photomotor response assay) and morphology, including eye diameter and body length, were evaluated. **Results:** GC-MS quantitation showed that the two later exposure windows (54-78 and 78-102 hpf) exhibited higher larval CBD concentrations than early-stage exposures, but were not significantly different from the full-length exposure (6-102 hpf). Larvae exposed to CBD from 6-102 hpf showed reduced body length, smaller eyes, and decreased locomotor activity, indicating developmental impairment from continuous exposure. Shorter exposure windows caused less pronounced effects, yet incidence of yolk sac edema was increased regardless of exposure window. The embryos in the 30-54 and 54-78 hpf groups had significant growth deficits, while the 78-102 hpf group exhibited dark phase hypoactivity. **Conclusions:** Identifying critical periods of susceptibility will provide insight into how the timing of exposure influences adverse developmental outcomes and can contribute to a better understanding of potential risks associated with CBD use during pregnancy. *This research was supported by grant R01DA057317 from the National Institute of Drug Abuse and National Institute of General Medical Sciences.*

PS 3180 Berberine and Metformin Inhibit Caterpillar Growth and Chrysalis Development

J. E. Schultz^{1,2}, and G. G. Gould². ¹University of California, Davis, Davis, CA; and ²University of Texas Health Science Center at San Antonio, San Antonio, TX.

Background and Purpose: Compounds triggering adenosine monophosphate-activated protein kinase (AMPK) that yield weight loss and anti-diabetic effects are also reported to have geroprotective properties. For example, both the pharmaceutical metformin and herbal supplement berberine aid in managing diabetes and obesity and were found to have lifespan extending effects clinically and in laboratory rodents. Invertebrates such as nematodes, fruit flies, and crickets are emerging as an alternatives to vertebrate animal use to study anti-aging properties of drugs because of their short lifespans. Painted lady butterflies (*Vanessa cardui*) also have short lifespans and are commercially available for controlled studies but are less frequently used in toxicology or aging research. *V. cardui* caterpillars take about two weeks to reach the chrysalis stage, metamorphosis takes about a week, and wild butterflies survive for roughly six weeks to migrate, find mates and start the next generation. The hypothesis for this study was that dietary administration of metformin or berberine to caterpillars would dose-dependently extend the lifespan of *V. cardui* butterflies. **Methods:** To test the research hypothesis *V. cardui* caterpillars were obtained in their second instar, weighed and placed either one or five per cup in clear plastic cups holding caterpillar diets spiked with 0, 0.1, 1 or 10 mg/g metformin or berberine. Caterpillars were monitored for weight on day 5, the date of chrysalis formation, date of butterfly eclosure, butterfly wing size and individual survival (lifespan). After emerging from chrysalises, butterflies were fed watermelon twice per week, so adults were not treated with berberine or metformin. Most data collected were analyzed using one way analysis of variance with Tukey's post-hoc tests to compare dose effects. Survival plots and analyses were used to compare dose effects on the probability of survival. An enzyme linked immunoassay kit was used to measure 20-hydroxyecdysone (20E) in naive chrysalises to assess feasibility. **Results:** Over the course of the study some of the 10 mg/g metformin and all 10 mg/g berberine-exposed caterpillars either failed to form chrysalises or never eclosed from their chrysalises. Most of the 1 mg/g berberine-fed caterpillars failed to molt and died, while 0.1 mg/g berberine had no effect on chrysalis formation or butterfly eclosure. Caterpillars treated with 1 mg/kg berberine or 10 mg/g metformin emerged as butterflies with much smaller wings than control treated butterflies. Treatments of 0.1 mg/g metformin or berberine had no impact on caterpillar development or butterfly size. The lifespan of butterflies did not increase with either metformin or berberine treatments, so the hypothesis that early life AMPK activator exposure would extend the butterfly life span was not supported. Molting hormone (20E) levels in naive chrysalises were 3 ng/ml on average. **Conclusions:** These findings reveal that metformin and berberine fed to *V. cardui* caterpillars dose-dependently inhibited their growth, development, or disrupted their metamorphosis. Metformin in this study had less adverse effects on *V. cardui* development than berberine at matched doses. Both AMPK activators are derived from plant secondary compounds, metformin from French lilac and berberine from goldenseal (among other plants), which may have served to defend these plants from herbivorous insects, especially in immature stages at concentrations in the range of 10 mg/g. Based on these outcomes the hypothesis that metformin or berberine treatments can extend *V. cardui* lifespans should instead be tested by dissolving these compounds at the same dose range in sucrose solutions to administer them to butterflies. Overall *V. cardui* could be a promising alternative to vertebrate animal models for tests of potentially toxic developmental effects of compounds in pre-clinical studies.

PS 3181 From High Dose to High Concern: Are Current Developmental Toxicity Findings for Essential oil- and Fragrance Ingredients Human-Relevant?

V. Rocha¹, G. Adamson¹, L. Maliqi², and A. Natsch². ¹Givaudan Fragrances Corp, East Hanover, NJ; and ²Givaudan Fragrances Corp, Kempthal, Switzerland.

Background and Purpose: European hazard classifications increasingly label fragrance ingredients as reproductive toxicants based on high-dose studies mandated by the European REACH legislation. Many of the molecules which have hence become under regulatory scrutiny in Europe are natural ingredients of plants, spices and essential oils and are part of our natural, daily food. These substances and their close analogues are very efficiently metabolized by liver enzymes, and hence only become toxic at high doses, where the capacity of the liver to detoxify them is saturated, a condition far from realistic human exposure. Developmental effects observed may thus often be under conditions of non-linear kinetics and metabolic saturation, and the effect thus could be specific to the test condition, and not inform about a human-relevant hazard at exposure conditions of workers or consumers, and not even for conditions of accidental spills. **Methods:** A case study is presented for Heliotropine, a natural ingredient of pepper and vanilla. Based on post-implantation loss and skeletal malformations, observed at a dose of 1000 mg/kg bw/d only, a CMR1B label and hence a ban in consumer products was decided in Europe. Metabolism at doses mimicking the doses tested *in vivo* was investigated in plated rat hepatocytes. Internal dose of the key metabolite under the situation of the toxicological tests is estimated based on these *in vitro* data and limited available *in vivo* information. This internal dose is compared to estimates of consumer exposure and the resulting internal dose. **Results:** Heliotropine is detoxified by oxidation and glycine conjugation, with glucuronidation as secondary pathway. This glycine-conjugation pathway is known to be saturable, and this is confirmed by the *in vitro* data for piperonal: Complete elimination of piperonylic acid by this pathway occurs when testing at 50 μ M, while glycine conjugation is saturated above 200 μ M. Comparing these data to the situation in the toxicological test indicates that the effects observed occur at a condition where a large amount of free piperonylic acid is in the circulation and hence the developmental effects observed in the study may reflect metabolic saturation rather than intrinsic developmental toxicity. Based on estimates of consumer exposure from use surveys, this internal dose is several orders of magnitude higher as compared to realistic human exposure. **Conclusions:** Developmental studies are designed in a way that maternal effects must be triggered to validate dose-level selection. However, when developmental effects occur only under maternal stress or metabolic overload, their relevance to human hazard becomes questionable. Authorities often deny a link between nonspecific mild maternal toxic effects and the developmental effects, as this link is difficult to prove at the level of the individual chemical. When high dose studies on natural compounds consistently trigger developmental effects under maternal stress, a sound toxicological discussion is needed whether such effects at conditions affecting the maternal homeostasis are informative for human-relevant hazard assessment. A critical gap are *in vivo* data on toxicokinetics and internal human exposure for workers and consumers to judge human relevance, and this should be considered a critical research need. A regulatory system labeling many ingredients of our natural diet as substances of high concern will not increase public trust in toxicological evaluations.

PS 3182 Photoperiod Dependent Impacts on Toxicity of Nuclear Receptor Ligands

A. A. Rojas, S. Sharma, and S. Dasgupta. Clemson University, Clemson, SC.

Background and Purpose: Artificial light has extended human activity beyond natural daylight but has also introduced unnatural photoperiods, distinct periods of light and no light, that can disrupt circadian rhythms. The circadian rhythms synchronize behavioral and physiological processes to environmental cycles of light and dark, which regulate essential functions like metabolism, cell proliferation, and immune response. Nuclear receptors are transcription factors that regulate a battery of metabolic processes and are suspected to be regulated by the circadian clock. Leveraging zebrafish as a model, we sought to investigate the impacts of photoperiod changes on nuclear receptor signaling. **Methods:** To determine the effect of different periods of light and dark (photoperiods) on behavior, we set up 5 plates with zebrafish embryos (N=32 per treatment) at 0.75 hours post fertilization (hpf), one subject to a photoperiod of 24 hours of light/0 hours of no light (24L), a photoperiod of 18 hours of light/6 hours of no light (18L), a photoperiod of 14 hours of light/10 hours of no light (14L), a photoperiod of 6 hours of light/18 hours of no light (6L), and a photoperiod of 0 hours of light/24 hours of no light (0L). Embryos remained in those conditions until 5 days post fertilization (dpf), when a larval photomotor response (LPR) was conducted to assess the effects of photoperiod exposure. Following this, we selected 2 photoperiods, 14L and 0L, and conducted mRNA sequencing. At 5dpf, samples were pooled, RNA was extracted, and sequencing was conducted on an Illumina platform, with bioinformatics analyses being conducted using DeSeq2. Finally, to understand the interaction between photoperiods and nuclear receptors, we screened a nuclear receptor ligand comprised of 74 diHerent nuclear receptor (NR) ligands (Enzo Screenwell Library), including agonists and antagonists of 14 diHerent nuclear receptors. Embryos were plated in embryo media at 0.75 hpf (N=16 per treatment) and subjected to photoperiods of 14L and 0L. At 4 dpf, embryo media were removed, and 100 μ L of chemical ligand solution was added. Following chemi-

cal exposure, embryos were returned to their respective photoperiods for a 10-hour exposure. At 5dpf, larval photomotor response, an assay commonly used as a behavioral readout of physiological health, was conducted to assess LPR following chemical and photoperiod exposure. **Results:** When zebrafish embryos were grown up under the 5 diHerent photoperiods, we saw a significant diHerence in LPR responses, depending on the photoperiod, with embryos showing hypoactivity under 0L photoperiods compared to other periods. Our transcriptomic data revealed disruption of several core clock and clock-controlled genes, including reduced expression of several nuclear receptor target genes. Across the screening of nuclear receptors via the LPR assays, we observed three response patterns: no eHect, a photoperiod independent chemical driven eHect (where we saw eHects irrespective of photoperiods), or a photoperiod dependent eHect, where there was a significant interaction between the chemical and photoperiod based on a 2-way ANOVA. Several nuclear receptor ligands, including PXR, PPAR α , RXR, and RAR showed photoperiod-dependent eHects, signifying photoperiod-driver nuclear receptor activity. **Conclusions:** Our findings demonstrate that nuclear receptor activity is sensitive to photoperiod variation. These interactions have potential implication in drug toxicity, becoming relevant for individuals who are exposed to rapid photoperiod changes and disrupted photoperiods.

PS 3183 Fit-for-purpose refinement and application of a risk of bias assessment on literature reporting prenatal acetaminophen exposure and neurodevelopmental effects

S. Fitch¹, M. Vincent¹, L. C. Bylsma¹, J. Rhoden², and D. Wikoff¹. ¹ToxStrategies, Asheville, TX; and ²Kenvue, Summit, NJ.

Background and Purpose: Observational studies are subject to systemic bias and confounding due to the nature of the study design. Risk of Bias (RoB) tools provide a structured and objective way to assess for the presence and seriousness of bias inherent to the study design. These tools are a critical component of the systematic review process and are most informative and transparently applied when refined to the research question, such that bias and confounding are assessed in a manner specific to the exposure and outcome of interest. Herein, the objective is to refine a RoB tool to be topic-specific and subsequently apply the tool to studies investigating prenatal acetaminophen use and potential associations with neurodevelopmental effects, including Attention-Deficit/Hyperactivity Disorder (ADHD) and autism spectrum disorders (ASD). **Methods:** The U.S. National Toxicology Program's (NTP) RoB Rating Tool was selected and refined a priori to the research question. To guide refinements for evaluations of confounding, factors commonly associated with ADHD and ASD were identified from previous literature reviews of risk factors. From such, a directed acyclic graph was developed to facilitate identification a minimal adjustment set of confounders or effect modifiers. Exposure ascertainment methods were refined to support evaluation of the reliability of the exposure measurement (e.g., direct measurement vs. self-reported recall) and the temporal relevance of the exposure, including consideration of the timing of biomarker collection to account for rapid metabolism. The refined tool was applied to studies reporting clinician-diagnosed ADHD and/or ASD. **Results:** Topic-specific refinements included definition of key confounders of interest (including indication of use, familial or genetic factors, maternal comorbidities, and maternal mental health) and explicit definition of exposure characterization related to timing and quantification of APAP exposures. Additionally, clarifying modifications were made to the guidance to assist reviewers with selection of bias determinations. Based on the RoB assessments of eligible studies, bias due to uncontrolled and residual confounding was likely to be present in all studies. Few studies adequately accounted for familial or genetic predisposition ADHD or ASD or maternal comorbidities; no studies comprehensively addressed all critical modifying factors. Exposure misclassification was identified as a major source of systemic bias; all studies relied on retrospective maternal recall, often temporally distant from use without information on timing, duration, or frequency, or on unvalidated biomarkers collected at or near the time of birth. Because criteria for review inclusion involved clinician-diagnosed ADHD or ASD, lower RoB was generally observed for the outcome ascertainment domain. Across the evidence base reviewed, a consistent overall RoB pattern was observed with all studies exhibiting at least one key domain rated as probably or definitely high. **Conclusions:** The assessment demonstrated that available epidemiological data has limitations attributable to systemic bias; these limitations preclude confidence in utilizing available epidemiological evidence to assess causality. This research exemplifies the importance of formal critical appraisal via RoB evaluation when conducting systematic review, particularly when assessing the strength of a body of evidence for causal relationships.

PS 3184 Uncovering lineage-specific molecular mechanisms and gene signatures of developmentally osteotoxic chemicals using human embryonic stem cells

P. Babakhanian, T. Spaeter, C. Gatdula, R. Cheema, and N. zur Nieden. University of California Riverside, Riverside, CA.

Background and Purpose: Congenital skeletal malformations represent a significant number of birth defects affecting the population and thus pose a huge public health concern. Among potential environmental contributors to their incidence are commonly used medications, supplements, pesticides, preservatives, and plasticizers. While effective in their respective uses, previous studies suggest they may interfere with developmental processes and increase risk and incidence of skeletal birth defects. Such defects can be found in various skeletal sites in the craniofacial, axial, and appendicular skeleton, which embryologically derive from different progenitor cells. However, it is unclear whether all skeletal teratogens act through common molecular mechanisms independently of the osteogenic progenitors they harm. If identified, such mechanisms could be targeted to intervene in the etiology of adverse effects associated with exposure. **Methods:** We have recently been able to model skeletal embryotoxicity of forty such chemicals *in vitro* using human embryonic stem cells and investigating their cytotoxic and developmental effects. The embryonic stem cell test (EST), through three endpoint analyses, determines concentrations at which a 50% decline is seen in cell viability and differentiation capacity. Based on prior screening data we selected chemicals with previously documented defects specific to any of the three skeletal lineages and three additional chemicals with multi-site effects, culminating in a final list of twelve chemicals that were subjected to RNA sequencing at the half-maximal inhibitory concentration of differentiation inhibition. **Results:** Bioinformatic analysis was performed to shed light on common differentially expressed transcripts and signaling pathways affected in consequence of exposure amongst chemicals in each category. Specifically, we present here data identifying overlapping differentially regulated transcripts amongst neural crest-specific chemicals and associated gene ontology analysis. Indeed, overlapping transcripts categorized as neural crest specific demonstrating the general possibility of identifying common exposure gene signatures specific to a developmental lineage. **Conclusions:** Future studies validating the identified gene and pathway candidates in additional chemicals will confirm these 'toxicity' gene signatures and signaling molecules, paving the way for their manipulation to prevent adverse outcomes. In its totality, this project demonstrates the utility of stem cell-based models in developmental toxicology as a humane and mechanistically relevant alternative to animal testing.

PS 3185 Developmental light conditions modulate basal mRNA profiles in zebrafish

A. M. Gehl, L. Truong, and R. L. Tanguay. Oregon State University, Corvallis, OR.

Background and Purpose: Embryonic zebrafish are widely used to assess chemical toxicity; however, laboratories employ inconsistent lighting protocols during exposure studies. While adult zebrafish are maintained under a standard 14:10 hour white light:dark photoperiod, embryo exposure protocols vary considerably ranging from continuous darkness (to prevent chemical photodegradation) to various light conditions. Beyond standardization concerns, lighting conditions may influence developmental susceptibility to chemical toxicants by modulating biological process during critical developmental windows. Despite this potential, the influence on light exposure on chemically-induced toxicity in developing zebrafish remains poorly characterized. We hypothesize that differential light exposure would alter zebrafish susceptibility to certain chemicals toxicants. **Methods:** Dechorionated zebrafish embryos were exposed to three lighting conditions from 6 to 120 hours post fertilization (hpf): blue light, darkness, or a 14:10 hour white light:dark photoperiod (control). Endpoints included morphological screening, the larval photomotor response (LPR) behavioral assay, and transcriptomics analysis at 24, 48, 72, 96, and 120 hpf (n=96 for morphology and behavior; n=4 biological replicates for transcriptomics). Based on transcriptomic findings and reported light-sensitivity, we then co-exposed embryos to four chemicals individually (diclofenac, bisphenol A, bisphenol F, and diphenhydramine) under different lighting conditions (n=36 per concentration, 7 concentrations plus an on-plate chemical control and light-only control plate). Dose-response curves were analyzed for shifts in EC50, LC50, or lowest effect level (LEL) using F-test (p<0.05). **Results:** Lighting conditions alone did not produce morphological abnormalities at 120 hpf. Transcriptomic analysis revealed light-dependent changes in gene expression, with differentially expressed genes (DEGs) increasing from 247 DEGs at 24 hpf to 983 DEGs at 120 hpf. Pathway enrichment analyses were completed using DEGs shared by the blue light and darkness treatment groups and DEGs unique to each group at each timepoint. The analysis using the shared DEGs by the dark and blue light treatments identified circadian rhythm-related terms across all timepoints, suggesting ongoing light-responsive biological processes were altered throughout development. Additionally, terms unique to blue light and darkness treatments were identified. For example, "lipid metabolic process" was significant at 96 and 120 hpf for the dark treatment group but not the blue light group, indicating unique responses to differential light treatment. Chemical co-exposure demonstrated that lighting conditions altered toxicological susceptibility. Diclofenac exposure under blue light or photoperiod conditions produced behavioral effects (LEL= 0.00195 μ M in the excitatory phase of LPR), while dark-exposed embryos showed no effects at concentrations up to 80 μ M. **Conclusions:** Different lighting conditions during embryonic

development significantly alter the basal transcriptome over developmental time. As embryos mature, the number of transcriptomic changes increases, suggesting that a broader range of biological processes is affected by this non-chemical stressor at later stages. Moreover, lighting conditions influence sensitivity to developmental toxicity from certain chemical exposures, indicating that light exposure is an often-overlooked factor modifying toxicological responses. The observed variation in diclofenac sensitivity across lighting conditions further suggests that inconsistencies among zebrafish toxicity studies may, in part, result from differences in experimental lighting conditions.

PS 3187 Toxicological Evaluation of Age-Dependent Responses to a SARS-CoV-2 mRNA Vaccine Candidate in Juvenile and Adult Sprague-Dawley Rats

H. Bae^{1,2}, H. Jo³, I. Park³, N. Kim³, E. Kwon², J. Ahn², N. Lee^{2,4}, J. Nam⁵, J. Yun³, and B. Kang^{6,2}. ¹Seoul National University College of Medicine, Seoul, Korea, Republic of; ²Department of Experiment Animal Research, Biomedical Research Institute, Seoul National University Hospital, Seoul, Korea, Republic of; ³Laboratory of Veterinary Toxicology, College of Veterinary Medicine and Research Institute for Veterinary Science, Seoul National University, Seoul, Korea, Republic of; ⁴Department of Veterinary Pathology and Research Institute of Veterinary Science, College of Veterinary Medicine, Seoul National University, Seoul, Korea, Republic of; ⁵Department of Biotechnology, The Catholic University of Korea, Bucheon, Korea, Republic of; and ⁶Graduate School of Translational Medicine, Seoul National University College of Medicine, Seoul, Korea, Republic of.

Background and Purpose: mRNA COVID-19 vaccines have received emergency authorization for adolescents (12-17 years) in several countries, and some regulatory authorities have extended approval to children aged 5-11 years. However, age-dependent safety data for mRNA vaccination remain limited. Therefore, this study aimed to evaluate acute systemic responses to mRNA vaccination in juvenile and adult rats. **Methods:** The mRNA vaccine candidate (CUK3/LNP128) was injected intramuscularly into both thigh muscles of male and female SD rats at 100 µg/100 µL per head, twice at 2-week intervals. Adult rats received the first dose at 10 weeks of age and juveniles at 3 weeks, and the necropsy was performed 2 days post-secondary injection (2dpi) for the evaluation of acute systemic responses. **Results:** No notable differences in clinical signs, body weights and blood chemistry were showed similar responses in juvenile and adult rats. In hematological and coagulation changes showed similar responses including increases in WBC, neutrophils, and eosinophils, decreased platelets, and prolonged activated partial thromboplastin time (aPTT) in both groups. However, juvenile group showed more pronounced reduction in reticulocytes and increase in nucleated red blood cells. Both groups showed increases in spleen, liver, and kidney weights, while the decrease in thymus was more marked in juvenile group compared with adult group. **Conclusions:** These findings indicate that the hematological and immune systems during juvenile development may be more sensitive to mRNA vaccination. We consider that these findings will contribute to the development of regulatory guidelines for the safety assessment of mRNA vaccines considering age-related differences.

PS 3188 BTEX constituent effects resultant of low-level exposure during critical windows of early development in zebrafish

M. L. Connell¹, D. Meyer¹, G. Gonzalez¹, C. Wu², E. Kintzele¹, E. Cavaneau¹, A. Hahn¹, E. Vandermeulen¹, and T. R. Baker¹. ¹University of Florida, Gainesville, FL; and ²National Yang Ming Chiao Tung University, Hsinchu City, Taiwan.

Background and Purpose: Volatile organic compounds (VOCs), such as mixtures of benzene, toluene, ethylbenzene, and xylene (BTEX) are ambient anthropogenic pollutants. Especially prevalent in urban environments, BTEX's are a public health concern because high levels may be found in residential drinking water wells near landfills, waste sites, or leaking underground fuel storage tanks which can enter indoor air through vapor intrusion. The constituents of the BTEX mixture are understudied for many potential adverse health outcomes. Benzene, the most volatile compound of the BTEX mixture, is one of few VOCs with enough human and animal data to constitute carcinogenicity whereas ethylbenzene is labeled as a probable carcinogen. BTEX exposure has also been linked to many non-cancer adverse health outcomes, yet few studies have focused on early developmental windows in which hematological, immune, metabolic, reproductive, and endocrine systems are immature. **Methods:** In this study, the zebrafish model was utilized to carry out controlled VOC exposures during a critical window of development. Sealed glass vials with septum tops, a previously validated method for volatile exposure, were employed with gastight syringes for optimized chemical delivery. Phenotypic data collection was conducted following low-level exposure (0.001-10 ppm) exposure to benzene, toluene, ethylbenzene, or xylene at 5 days post fertilization (dpf) and tissue samples were collected immediately (5 dpf) for transcriptomic endpoints. Behavioral assays were carried out at 24 hours post fertilization (hpf) and 5 dpf to characterize early and very early signs of neurotoxicity. Statistical significance was established at $p < 0.05$, $\log_2\text{fc} > 0.5$. RNA samples were only included for sequencing with RNA integrity numbers (RIN) above 7. **Results:** At 5 dpf, exposure to ethylbenzene and toluene were significantly associated with altered locomotive behavior during the light and

dark periods at levels as low as 0.001 ppm. For toluene, the 0.1 ppm group displayed widespread hyperactivity compared to the control group. Toluene exposure was also shown to affect hyperactivity for the 10 ppm dose in the light and the ultra low (0.001 ppm) dose in the dark. At 24 hpf, spontaneous tail coiling (STC) was significantly increased (1 ppm) by toluene exposure. Skeletal deformities and swim bladder abnormalities were increased in the benzene exposed and ethylbenzene exposed groups respectively. Significant decrease in survival ($p < 0.05$) was observed for the 0.01 ppm, 1 ppm, and 10 ppm doses after a 5-day exposure to ethylbenzene. Many genes and pathways were perturbed in exposure groups and comparative pathways of interest are associated with carcinogenesis, endocrine systems disorders, neurological system disorders, and reproductive system disorders. Key pathways, including insulin secretion signaling and inflammation pathways, were altered ($p < 0.05$) as a result of BTEX constituent exposure. **Conclusions:** The strongest evidence of toxicity in our study was among the F0 group apical endpoints. Behavioral outcomes were significantly altered in the light by multiple doses of ethylbenzene but the 10 ppm exposure group was hypoactive in both the light and dark periods. Similarly, impaired behavior was an important finding for toluene and xylene exposure which can be indicative of early developmental delays. We also establish mortality data that will inform future toxicological study of VOCs and complex VOC mixtures. While there wasn't any one gene or gene family impacted in all BTEX chemicals, we observed a number of genes linked to neurological development and endocrine functioning in the BTEX exposed zebrafish. Due to the high conservation of molecular pathways between zebrafish and mammals, our data are compared to results in other exposure models and cohorts providing further insight into potential mechanisms that could be implicated in the developmental effects of VOCs on public and human health.

PS 3189 ASD-relevant neurodevelopmental toxicities of the monoterpenes Thymol and p-Cymene

B. He, P. Zhang, A. Chen, C. Hong, E. Kong, and Y. Geng. University of Washington, Seattle, WA.

Background and Purpose: The increasing prevalence of autism spectrum disorder (ASD) has drawn significant attention to its environmental origin. Environmental factors are estimated to contribute to 40% of ASD risk. However, the identities of these factors and their mechanisms of action remain poorly understood due to limitations of current research approaches. **Methods:** To bridge this gap, we screened the ToxCast library using a high-throughput social behavioral assay platform, Fishbook, to discover emerging ASD-relevant toxicants. **Results:** From the 140 toxicants screened, we identified Thymol and p-Cymene, both belonging to the chemical class monoterpenes, as potent inhibitors of social behavioral development through embryonic exposure. Monoterpenes are natural compounds commonly found in food flavorings, essential oils, and personal care products. Through a proteome-wide reverse molecular docking screen, we discovered lysine demethylase 5 (KDM5) family proteins, in particular KDM5C and KDM5D, as predicted binding targets of Thymol and p-Cymene. The KDM5 family proteins are histone demethylases that selectively remove methyl groups from histone H3 lysine 4 (H3K4me-2/3), which are epigenetic marks typically associated with active gene transcription. Embryonic exposures to thymol and p-cymene increased the global level of H3K4me3, indicating that these toxicants likely inhibited KDM5 activity. RNA-sequencing detected profound up-regulation of genes associated with genetic risk factors of autism following Thymol and p-Cymene exposure. **Conclusions:** In summary, this work discovered Thymol and p-Cymene as risk factors for social behavioral development and revealed KDM5 as a potential mediator of their neurodevelopmental toxicity.

PS 3190 Early Developmental Neurotoxicity of Quaternary Ammonium Compounds

J. A. Gomes, J. Chen, L. Li, A. M. Gutierrez, Y. Fernandez, and J. F. Robinson. UCSF, San Francisco, CA.

Background and Purpose: Quaternary ammonium compounds (QAC) are widely used as disinfectants, antiseptics, and preservatives across medical, household, and industrial applications, with global use surging since the COVID-19 pandemic. As a result, humans are routinely exposed through dermal, oral, and inhalation routes. Biomonitoring and experimental studies confirm widespread exposures (10-150nM in >50% of US subjects) and transfer to the embryo/fetus. Prenatal exposure during neurulation and early organogenesis are of particular concern, as this developmental window is highly vulnerable to structural defects and functional disorders of the central nervous system (CNS). While the mechanisms driving QAC developmental toxicity remain poorly defined, animal models demonstrate that two major QAC subclasses - benzalkonium chloride (BAC) and dialkyldimethyl ammonium chloride (DDAC) - are associated with increased embryo mortality, CNS malformations, and neurobehavioral abnormalities. Additional research is needed to resolve differences in toxicity and potency across QAC subclasses. Here, we profiled BAC and DDAC exposures in rat whole embryo culture (WEC) and human embryonic stem cell (hESC) and their neural progenitor derivatives (NPCs) to elucidate morphological, cellular and molecular mechanisms underlying QAC developmental neurotoxicity (DNT). **Methods:** Rat embryos were cultured ex vivo with BAC-C12 or DDAC-10 (1.5 or 3.0 µM) or vehicle controls (media or 0.1% DMSO) for 48 hours, followed by evalua-

tion of morphological and functional parameters. hESCs and NPCs were exposed to BAC-C12, BAC-C16, DDAC-10, or ODDAC (30µM and 100µM) for 24h, followed by cell viability/proliferation and cell death assessment using neutral red cellular uptake and lactate dehydrogenase (LDH) activity assays, respectively. Benchmark concentration modeling was performed with BMDExpress 2.3. The effects of BAC-C12 and DDAC-10 (0.01-3µM) on neural migration was assessed following 72h of chronic exposure. To identify early molecular targets underlying QAC-induced DNT, we profiled transcriptomic responses to BAC-C12 or DDAC-10 (0.01-3µM) in NPCs at 3h and 6h. Data processing and analyses were performed using R. **Results:** Rat embryos exposed *ex vivo* to BAC-C12 or DDAC-10 exhibited concentration-dependent teratogenicity, with ~30% of embryos malformed at 3.0µM. Both compounds induced axial and midline defects, anterior and caudal neural tube anomalies, and impaired development of forebrain, midbrain, hindbrain, caudal neural tube and heart. Somite number and total morphological score (TMS) were significantly reduced ($p < 0.05$). In hESCs and NPCs, BAC-C12, BAC-C16, DDAC-10, and ODDAC decreased viability (<10%) and increased LDH activity (10%) at concentrations lower than <7µM (24h). At subcytotoxic-concentrations, BAC-C12 and DDAC-10 significantly reduced neural migration (72h). We identified 357 (BAC-C12) and 1,501 (DDAC-10) genes to be differentially expressed (DE) ($p < 0.001$; absolute log2FC > 1.2) in exposed NPCs. In general, changes in expression followed a monotonic pattern with increasing concentrations, and responses were concordant between the 3h and 6h timepoints as well as between the two compounds. Common DE genes ($n=205$) were enriched for cholesterol biosynthesis, one-carbon metabolism, DNA damage response, and cell cycle arrest - pathways previously associated with QAC activity in neurocellular models and/or implicated in NTDs and other neurodevelopmental disorders. These findings suggest that both BAC and DDAC exposures are of concern for the developing CNS and highlight common pathways that could contribute to teratogenicity and neurodevelopmental disorders in humans. **Conclusions:** Overall, our findings from rat embryo culture and human embryonic stem cell models demonstrate that two major QAC subclasses - BAC and DDAC - induces disruption of early neurodevelopment at low concentrations. Ongoing experiments are assessing additional subclasses of QACs and characterizing the molecular alterations following chronic exposure of NPCs derivatives, and the rat whole embryo culture (WEC) model.

PS 3191 Machine-Learning Assisted Predictive Developmental and Reproductive Toxicity Assessment Using *C. elegans* as a New Approach Methodology

S. Mondal¹, A. Medewar¹, A. Laing¹, A. Shen¹, J. Brown¹, G. Carrion¹, and A. Ben-Yakar^{1,2}. ¹vivoVerse, Inc., Austin, TX; and ²The University of Texas at Austin, Austin, TX.

Background and Purpose: Developmental and Reproductive Toxicity (DART) assessment is an essential component of product safety evaluation and is traditionally performed using vertebrate models. The nematode *Caenorhabditis elegans* (*C. elegans*) has emerged as a promising *in vivo* alternative due to its short lifecycle, conserved toxicological pathways, genetic homology with humans, and diverse genetic backgrounds. However, broader adoption of *C. elegans* in DART testing has been constrained by low-throughput methods and a limited range of measurable endpoints. **Methods:** To overcome these limitations, we developed a microfluidic-based imaging platform combined with machine learning (ML) analysis pipelines that enable high-throughput, multiparametric assessment of sublethal phenotypes relevant to DART endpoints. Using a 2.5D U-Net architecture, we achieved precise segmentation of *C. elegans* bodies (average Dice score: 97.80) and accurate quantification of body length, area, and volume. To further assess reproductive toxicity, we developed an *in-utero* embryo detection and classification model based on Masked Autoencoder (MAE) backbone followed by an anchor-free, center-based object detection head. In the first stage, a self-supervised MAE learns robust feature representations from large volumes of unlabeled *C. elegans* data. In the second stage, these pretrained representations are fine-tuned through supervised learning for embryo localization and developmental-stage classification (early stage and late stage). The multiparametric endpoints were integrated to enhance assay sensitivity and reproducibility. **Results:** The *in-utero* embryo imaging approach demonstrated high sensitivity for detecting reproductive toxicity by quantifying embryo numbers under different stage of development. At an intersection of union threshold (IOU) of 0.70 and non-maximum suppression (NMS) of 0.85, the model achieved an F1 score of 95.3% for early-stage embryos and 90.7% for late-stage embryos. Compared to manual scoring, the automated pipeline is 360x faster while maintaining consistent embryo detection and classification accuracy and minimizing observer bias. Our automated DART platform shows highly reproducible data (4-16% coefficient of variance) and validated using concentration-dependent response with two well characterized reference chemicals (methylmercury and propiconazole) and strong concordance with rat data. Additionally, assays measuring systemic toxicity (motility and food consumption) were developed to complement DART testing and serve as internal control benchmarks. **Conclusions:** Our microfluidic and ML-enabled *C. elegans* DART platform provides a rapid, reproducible, and predictive alternative to vertebrate-based toxicity testing. The approach significantly expands the measurable endpoints for *C. elegans* and establishes it as a New Approach Methodology (NAM) for DART. This system enables ethical, high-throughput *in vivo* toxicology testing at a fraction of the cost and time required for mammalian studies.

PS 3192 Multi-Omics Profiling of Zebrafish Embryos Exposed to 3,4-Dichloroaniline: Insights from a Pilot Workflow Study.

A. Muriana¹, A. Weiner¹, M. Viant², E. Sostare², M. Gallego¹, I. Ibarburu¹, L. Cruchley-Fuge³, O. Edbali³, A. Southam³, R. Weber³, and J. Colbourne². ¹BBD BioPhenix S.L.-Biobide, San Sebastian, Spain; ²Michabo Health Science Limited, Coventry, United Kingdom; and ³University of Birmingham, Birmingham, United Kingdom.

Background and Purpose: Zebrafish embryos are increasingly used in toxicological screening as a New Approach Methodology (NAM) due to their genetic homology to humans, rapid organogenesis, and ethically refined alternative to mammalian systems for developmental toxicity screening. Besides, this NAM aligns with OECD Test Guideline 236 and also offers a promising platform for early-stage chemical safety assessment in drug development. This pilot study aimed to implement a multi-omics workflow for assessing molecular responses to chemical exposure in zebrafish embryos, using 3,4-dichloroaniline (DCA) as a reference compound. **Methods:** Embryos were exposed in 96-well plates to DCA at two concentrations (0.6 and 2 mg/L) from 2-4 hpf and again at 2 dpf. Samples were collected at 4 dpf, pooled in groups of either 4 or 8 embryos, and flash-frozen for omics analysis. Metabolites, lipids, and RNA were extracted at the University of Birmingham, and metabolomics and lipidomics were conducted using four LC-MS assays C18 and HILIC chromatography in both ionization modes. RNA quality and quantity were assessed to confirm suitability for transcriptomics. **Results:** Pooling 8 embryos yielded ~50% more LC-MS features than 4 embryos, though both pool sizes provided sufficient biomass for information-rich metabolic and lipid datasets. Metabolic variability was low across QC samples and acceptable across biological replicates. DCA revealed clustering by dose, though some unexpected sample splitting was observed, likely due to differences in timing during embryo collection, as indicated by internal lab records. RNA yields were consistently high across all samples, confirming the suitability of the workflow for transcriptomic analysis. In addition, DCA was detected in HILIC positive ionization mode, but with low and variable intensity. **Conclusions:** This study successfully implemented a zebrafish embryo multi-omics exposure and extraction workflow, demonstrating its feasibility for future toxicological investigations and regulatory applications. The ability to measure metabolomics and transcriptomics data from the same embryo pool should maximize our ability to integrate these mechanistic responses to chemical exposure. Furthermore, deriving 24 pooled samples for multi-omics per 96-well exposure plate ensures this workflow can be used for high throughput screening. While DCA was useful for workflow testing, its limitations as a metabolomics-positive control highlight the need for more suitable reference compounds. Given these limitations, alternative omics-compatible positive controls are currently under evaluation for future studies. Consequently, next we will focus on refining SOPs to reduce sample variability—particularly by optimizing embryo collection timing and improving washing procedures to prevent cross-contamination between treatment groups—and on selecting omics-compatible positive controls to strengthen the regulatory relevance of this zebrafish-based multi-omics workflow.

PS 3193 Uncovering the Role of Glucocorticoid Signaling in Arsenic-mediated Stress Behavioral Alterations

D. McAtee, and A. Abdelmoneim. Louisiana State University - School of Veterinary Medicine, Baton Rouge, LA.

Background and Purpose: Arsenic (As) is a widespread environmental contaminant linked to numerous adverse health outcomes. Growing epidemiological and experimental evidence suggest its role as a risk factor for stress-related disorders such as anxiety and depression. However, the neuroendocrine mechanisms driving these stress behavioral alterations remain poorly understood. Our previous work demonstrated As-induced hyperactive stress behavioral phenotypes in larval zebrafish. Glucocorticoid (GC) signaling plays a key role in regulating behavioral stress responses and As has been shown to dysregulate it. **Methods:** In this study, we investigated the role of GC signaling in mediating physiological and As-induced stress behavioral phenotypes in larval zebrafish. To study this link, we used wild-type and transgenic zebrafish lines along with a combination of approaches, including pharmacologic GC modulations, co-exposures with As, high-throughput stress behavioral assessments, and *in vivo* imaging of corticotropin-releasing hormone (CRH) neuronal structure and activity—key regulator of GC signaling. **Results:** Pharmacological modulation of GC signaling (dexamethasone, mifepristone, and metyrapone) produced behavioral phenotypes that mirrored As exposure; while co-exposure studies supported a mechanistic link. Structural imaging of CRH neurons revealed As-dependent changes in the neuronal count. *In vivo* calcium imaging of CRH neurons demonstrated changes in neuronal activity in response to GC pharmacological modulations and As-induced alterations that can be closely linked to previously observed stress behavioral phenotypes. **Conclusions:** Our findings provide deeper insights into the neuroendocrine mechanisms underlying As-mediated stress behavioral disorders and identify GC signaling as a possible driver of effects, highlighting GC-targeting strategies as potential avenues for mitigation and therapeutic interventions.

PS 3193a To Evaluate the Effect of Patch Application in the Reproduction/ Developmental Toxicity Screening Test using Wistar Rats

R. R. Verma, S. Sau, S. G. Soni, S. Maurya, P. B. Kapuriya, K. Hadiya, V. Bhimani, and M. V. Patel. Jai Research Foundation, Vapi, India.

Background and Purpose: The study was conducted to evaluate the potential systemic, reproductive, and developmental effects of a dermal patch (applied with 0.2 mL of reverse osmosis (RO) water) in Wistar rats. **Methods:** Adult males and females (n=10/sex/group) were assigned to either a control group (without any treatment) or a dermal patch application group. Males were treated for a duration of 29 days, while female rats were treated from 15 days prior to mating, through gestation phase and lactation phase until postnatal day (PND) 14. Parameters assessed included clinical signs, body weight, food consumption, oestrous cyclicity, mating and fertility indices, gestation outcomes, litter size, pup viability, and developmental milestones. **Results:** No treatment-related effects were observed in mortality, clinical signs, body weight, food intake, or macroscopic findings in adults or pups. Reproductive and developmental endpoints—including mating success, fertility, gestation length, litter size, pup survival, and growth—remained unaffected. While some statistically significant changes were noted in maternal and pup body weights and food consumption, these were deemed incidental and not toxicologically relevant. **Conclusions:** The findings indicate that dermal application of the patch was well tolerated and did not elicit adverse systemic or reproductive effects.

PS 3194 Exploring the Effects of Chronic Exposure to DEHP and DiNP on Uterine Endometrial Glycogen in Mice

I. R. Raneri¹, P. Zarei², S. Ibrahim², M. J. Laws², and M. Dean². ¹CUNY John Jay College of Criminal Justice, New York, NY; and ²University of Illinois Urbana-Champaign, Champaign, IL.

Background and Purpose: Glycogen, a branched glucose reservoir, maintains optimal uterine glucose levels crucial for uterine functions and embryo development. Insufficient glycogen has been linked to infertility and early pregnancy loss, acting as a buffer to store or release glucose when levels are too low or high. Due to the hormonal regulation of glycogen in the endometrium, endocrine-disrupting chemicals, including Di(2-ethylhexyl) phthalate (DEHP) and Diisononyl phthalate (DiNP), may pose risks to endometrial glycogen metabolism. Previous studies have shown that phthalates dysregulate hepatic glycogen by disrupting enzymes involved in both glycogen synthesis and breakdown. As phthalates are known to threaten reproductive health, this study aimed to analyze glycogen in murine uterine tissue chronically exposed to 0.15, 1.5, or 1500 ppm of DiNP. **Methods:** Diastase-labile periodic acid-Schiff staining (PAS/PASD) was used to localize glycogen and reveal its presence in all tissue sections. Immunohistochemistry (IHC) was used to visualize glycogen synthase I, hexokinase I, glycogen phosphorylase, and glucose-6-phosphatase catalytic subunit 3. **Results:** PAS/PASD staining for phthalate-exposed tissues was modestly higher than that of controls. IHC for hexokinase I revealed higher levels in the stroma at 0.15, 1.5, and 1500 ppm compared to the control, suggesting increased glucose uptake in the stroma. Moreover, glycogen phosphorylase immunostaining was higher at 1500 ppm, suggesting increased glycogenolysis. Glycogen synthase I and glucose-6-phosphatase had no differences in staining compared to the control. **Conclusions:** Results indicate that phthalate exposure may impact glucose-relevant enzymes, but future studies are needed to assess additional pathways, including glycolysis and the pentose phosphate pathway. These findings reveal an understudied mechanism of phthalate toxicity, providing a basis for future toxicology studies that assess the impact of endocrine-disrupting chemicals on metabolic pathways crucial for reproductive health.

PS 3195 AhR-Mediated Blood-Testis Barrier Regulation Links PCB Exposure to Sperm DNA Methylation Variability

J. Zhu¹, O. Sergeyev², O. Arowolo¹, and A. S. Suvorov¹. ¹University of Massachusetts Amherst, Amherst, MA; and ²Skolkovo Institute of Science and Technology, Moscow, Russian Federation.

Background and Purpose: According to the evolutionary stochastic epigenetic variation hypothesis, stress may increase variation in naturally methylation regions (VMRs) associated with development and morphogenesis to ensure increased phenotypic variability in offspring and improve chances of survival of the corresponding genetic lineage in conditions of a changing environment. The blood-testis barrier (BTB) plays a central role in regulating the microenvironment for spermatogenesis, and recent experimental evidence has demonstrated that tightening of the BTB results in less methylation in VMRs, while the BTB disruption by various stressors results in increased methylation variation in VMRs. Additionally, it was shown that activation of the aryl hydrocarbon receptor (AhR) pathway directly promotes BTB tightening. Persistent environmental toxicants, such as polychlorinated biphenyls (PCBs), can differentially activate AhR signaling depending on their congener structure, potentially influencing BTB integrity and downstream sperm DNA methylation dynamics. This study investigated whether early-life exposure to coplanar and non-coplanar PCBs alters sperm methylation variance in opposite directions.

Methods: Sperm DNA methylation was profiled in 36 young men (age 8-18) participating in a longitudinal birth cohort study. Concentrations of mono-ortho (coplanar) and tri/tetra-ortho (non-coplanar) PCBs were measured in blood collected at ages 8-9. Reduced Representation Bisulfite Sequencing (RRBS) was performed on sperm collected at age 18, covering over 400,000 CpG sites. Variable Methylation CpGs (VMCs) were identified in sperm DNA. Differentially methylated CpGs (DMCs) associated with blood PCBs were identified using linear regression models. Gene Set Enrichment Analysis (GSEA) and functional enrichment were conducted to compare CpGs affected by PCBs and highly variable CpGs. **Results:** GSEA indicated that childhood exposure to mono-ortho PCBs was associated with differential methylation in CpG sites located predominantly within low-variance regions, whereas tri/tetra-ortho PCBs exposure corresponded to changes concentrated in VMCs (FDR<0.05). Functional pathway enrichment showed distinct biological responses between PCB groups. Mono-ortho PCB-associated genes were enriched in nervous system development and Wnt signaling, whereas tri/tetra-ortho PCB-associated genes were enriched in PI3K-Akt-mTOR signaling and extracellular matrix organization. **Conclusions:** Differential activation of AhR signaling by distinct PCB congeners appears to regulate BTB permeability, creating a selective microenvironment against external stressors and thereby shaping sperm DNA methylation variability. Coplanar mono-ortho PCBs activate AhR, tighten the BTB, and constrain epigenetic variance. In contrast, non-coplanar tri/tetra-ortho PCBs fail to engage this pathway, leading to a more permeable BTB and increased methylation variability. BTB-associated epigenetic signatures represent a mechanistic link between toxicant exposure and sperm epigenetic variability, offering a new insight into reproductive toxicology.

PS 3196 Chronic Exposure to an Environmentally Relevant Phthalate Mixture Induces an Immune Response in Young Adulthood that Might Contribute to Oxidative Stress and Aberrant Extracellular Matrix Remodeling in the Ovary Later in Life

A. M. Safar, R. Santacruz-Márquez, M. J. Laws, N. M. Harrington, and J. A. Flaws. University of Illinois Urbana-Champaign, Champaign, IL.

Background and Purpose: Phthalates, endocrine disrupting chemicals that target the ovary, are used as plasticizers and solvents in products such as food packaging, medical tubing, and personal care products. Humans are ubiquitously exposed to a mixture of phthalates daily, primarily through ingestion. Recent research suggests that phthalates might accelerate ovarian aging. Specifically, chronic di(2-ethylhexyl) phthalate (DEHP) exposure can alter markers of ovarian aging, including altering the ovarian and systemic immune response, increasing ovarian fibrosis, and increasing ovarian expression of antioxidant enzymes in mice. Exposure to an environmentally relevant phthalate mixture containing DEHP (Mix) can impair the main functions of the ovary; however, little is known about the effects of Mix exposure on immune response, oxidative stress, or extracellular matrix (ECM) remodeling in the ovary. Thus, we tested the hypothesis that Mix exposure alters the ovarian and systemic immune state contributing to oxidative stress and ECM remodeling. **Methods:** Female CD-1 mice were exposed to Mix (0.15, 1.5, or 1500 ppm) through the chow for 6 or 12 months. After 6 months, ovaries and sera were collected for use in cytokine arrays to examine the immune state. After 12 months, ovaries were collected for qPCR analyses of antioxidant enzymes (*Cat*, *Gpx*, *Gpx7*, *Gsr*, *Prdx1*, *Prdx2*, *Prdx4* and *Sod1*), ECM components (*Emilin1*, *Emilin2*, *Emilin3*, *Hyal1*, and *Hyal3*), and ECM modulators (*Mmp2*, *Mmp9*, *Timp1*, *Timp2*, *Timp3*, and *Timp4*). **Results:** Mix exposure for 6 months significantly altered the ovarian and systemic immune states. In the ovary, Mix exposure increased 14 (0.15ppm), 10 (1.5ppm), and 8 (1500ppm) and decreased 6 (0.15ppm), 4 (1.5ppm), and 6 (1500ppm) cytokines compared to control. In the sera, Mix exposure increased 6 (0.15ppm), 13 (1.5ppm), and 8 (1500ppm) and decreased 1 (0.15ppm), 3 (1.5ppm), and 4 (1500ppm) cytokines compared to control. In both the ovaries and sera, Mix exposure increased IL17A and altered MMP9 (0.15ppm), increased RBP4, CRP, CCL5, and PDGF-BB and altered adiponectin (1.5ppm), and increased PDGF-BB, decreased CCL20, and altered adiponectin and CCL5 (1500ppm) compared to control. Interestingly, at all doses tested, Mix increased CCL5 in the ovaries and increased PDGF-BB in the sera compared to controls. Mix exposure for 12 months significantly increased *Cat* (0.15 and 1.5ppm), *Sod1* (0.15, 1.5, and 1500ppm), and *Mmp9* (1.5ppm), borderline increased *Cat* (1500ppm), *Prdx1* (1.5ppm), *Prdx2* (0.15 and 1.5ppm), and *Prdx4* (1.5ppm), significantly decreased *Hyal1* (0.15ppm) and *Hyal3* (0.15 and 1.5ppm), and borderline decreased *Hyal3* (1500ppm), *Emilin1* (0.15 and 1.5ppm), and *Timp3* (1500ppm) expression compared to control. Mix exposure did not significantly alter expression of any other selected genes. **Conclusions:** Mix exposure for 6 months induced unique systemic and ovarian immune responses in mice, and Mix exposure for 12 months increased expression of antioxidant enzymes and dysregulated expression of ECM components and modulators in mice. Together, these findings suggest that chronic Mix exposure can induce an immune response in young adulthood that might contribute to oxidative stress and aberrant ECM remodeling later in life, potentially accelerating ovarian aging.

PS 3197 **Orphan Nuclear Receptor 4A1 (NR4A1) and NR4A2 Dual Ligands Inhibit Endometriosis Progression via Gas6-TAM and Epithelial-Mesenchymal Transition Pathways**

W. T. Tsui¹, S. Upadhyay¹, L. Zhang¹, D. Kim¹, G. Wright¹, S. Han², and S. Safe¹. ¹Texas A&M University, College Station, TX; and ²Baylor College of Medicine, Houston, TX.

Background and Purpose: Endometriosis is a chronic inflammatory disease affecting over 5.5 million women in the United States and approximately 176 million worldwide. It is characterized by the ectopic implantation of endometrial tissue, resulting in pelvic pain, infertility, and progressive fibrosis. Current treatment options are primarily hormonal and often unsuitable for long-term use, particularly in women desiring fertility. Our previous work identified the orphan nuclear receptor NR4A1 as a pro-endometriotic factor and a viable target for inverse agonists. Recently, we developed a series of 1,1-bis(3'-indolyl)-1-(3,5-disubstitutedphenyl)methane (DIM-3,5) analogs that exhibit high-affinity binding to both NR4A1 and NR4A2. This research aims to investigate the therapeutic efficacy of DIM-3,5 analogs in modulating NR4A1/NR4A2 activity and their roles in suppressing endometriotic cell proliferation, epithelial-mesenchymal transition (EMT), and fibrosis. Additionally, we examine the involvement of the upstream Gas6-TAM receptor axis as a regulatory component in endometriotic signaling. **Methods:** Several DIM-3,5 analogs were synthesized and evaluated in immortalized human endometriotic epithelial (IHEEC) and stromal (IHESC) cell lines. Cell viability was assessed using the XTT assay. Both cell types were transfected with siRNAs targeting NR4A1 or NR4A2 to assess functional roles. Apoptosis and necrosis were quantified post-knockdown via Annexin V/PI flow cytometry. Protein expression changes associated with the Gas6-TAM receptor pathway, cell growth, EMT and fibrosis were analyzed by Western blotting. Additionally, quantitative RT-PCR was performed to assess mRNA expression of genes involved in the Gas6-TAM axis following compound treatment. Chromatin immunoprecipitation (ChIP) and luciferase reporter assays will be performed to confirm the effect of DIM-3,5 ligands on NR4A1/2 and promoter regions of human TAM kinase genes. **Results:** DIM-3,5 analogs significantly inhibited cell viability at low micromolar concentrations in both IHEEC and IHESC cell lines. Independent knockdown of NR4A1 and NR4A2 similarly reduced cell viability and induced both apoptosis and necrosis, as evidenced by Annexin V assays. Treatment with DIM-3,5 compounds led to marked downregulation of genes involved in cell proliferation, survival, fibrosis, and EMT. Comparable effects were observed following NR4A1/NR4A2 knockdown, reinforcing the functional roles of these receptors in maintaining endometriotic cell survival and fibrotic signaling. In addition, DIM-3,5 analogs and NR4A1/2 silencing significantly suppressed Gas6 expression at both mRNA and protein levels. Activity of the associated TAM receptors (Tyro3, AXL, MerTK) was also decreased. Since the Gas6-AXL axis is implicated in downstream pathways promoting cell proliferation and migration, these results support a mechanistic link between NR4A1/2 modulation and Gas6-TAM signaling in endometriotic cells. Together, these findings highlight DIM-3,5 analogs as promising non-hormonal therapeutic agents for endometriosis. **Conclusions:** Dual targeting of NR4A1 and NR4A2 by DIM-3,5 analogs effectively suppresses pro-endometriotic pathways, including those regulating cell survival, EMT, and fibrosis. These findings support the development of a non-hormonal, mechanism-based strategy for endometriosis treatment.

PS 3198 **Gestational Inhalation of Micro-nanoparticles During Pregnancy Alters the Profile of Metabolites in the Mammary Gland of Sprague Dawley Rats**

T. L. Moore, E. C. Francis, and P. A. Stapleton. Rutgers University, Piscataway, NJ.

Background and Purpose: Fine particulate matter (particles in the air <2.5µm in diameter) is heterogeneous in particle size and chemical composition. Higher concentrations of fine particulate matter have been associated with adverse health outcomes, including pregnancy complications and fetal growth restriction. Both micro-nanoplastics and nano-titanium dioxide (nano-TiO₂) have been found in air samples, indicating the likelihood of inhalation exposure. Presence of micro-nanoplastics (ie: micro-nanoplastics and nano-TiO₂) in human and animal breast milk indicates micro-nanoplastics also cross the blood-milk-barrier. This suggests infants can be exposed to environmental toxins while breastfeeding. Recognizing micro-nanoplastics exhibit distinct behaviors, we investigated their individual impacts on the rat mammary glands during pregnancy. We hypothesized maternal inhalation exposure to inhaled pollutants (micro-nanoplastics or nano-TiO₂) would differentially alter the presence of metabolites within the mammary glands, the initial site of breast milk formation. **Methods:** Pregnant Sprague Dawley rats were randomly separated into naïve or exposed (nano-TiO₂ or polyamide-12 [PPA]) as representative environmental particulates; (n=5-6/treatment group). Whole-body inhalation exposures occurred from gestational day (GD) 5 - GD 19 at aerosol concentrations of ~10 mg/m³ for 4hr per day for both particles. On GD 20, mammary gland tissues were collected for processing. Polar and non-polar metabolomics were acquired using Liquid Chromatography-Mass Spectrometry (LC-MS). Mean differences in mammary metabolites from naïve animals were compared to TiO₂ and PPA groups, respectively via t-test. **Results:** Broad capture targeted LC-MS resulted in acquisition of 76 identified metabolites within the rat mammary glands. Within the nano-TiO₂ exposed mammary glands, 17 (22.4%) metabolites were significantly lower among nano-TiO₂ exposed dams compared to naïve dams (p<0.05). The majority of compounds (58.8%) were amino acids (AA) and AA-metabolites (2 essential AAs, 4 non-essen-

tial AAs, and 4 AA derivatives/intermediates). Remaining compounds were from classes of carbohydrates (17.6%), nucleic acids (11.8%), lipids (5.9%), and vitamins (5.9%). Within PPA exposed mammary glands, 6 (7.89%) were significantly altered by exposure compared to naïve controls (p<0.05). Most (83.3%) metabolites were significantly reduced (xanthine, hypoxanthine, inosine, 4-pyridoxic-acid, ribose) with urocanate being the only metabolite significantly increased by PPA exposure. Both nano-TiO₂ and PPA exposure resulted in a significant reduction in Vitamin B6 (VB6) metabolites. **Conclusions:** Overall, these data suggest micro-nanoplastics have unique impacts on metabolites within the rat mammary glands during pregnancy. Exposure to nano-TiO₂ changed metabolites predominantly related to amino acid metabolism, while exposure to PPA altered metabolites related to purine and histidine metabolism. These outcomes indicate differential physiological impacts within the mammary glands between the particle exposures. Future studies should examine changes in the milk metabolome, lipidome, and proteome near birth to determine whether milk composition differs by exposure to specific micro-nanoparticles.

PS 3199 **A new approached method for long-term evaluation of reproductive toxicity and its recovery using a mouse testis organ culture system**

S. Yokota¹, T. Sato², K. Hashimoto², T. Nishimura¹, T. Yamada¹, H. Arakawa³, and T. Ogawa². ¹Division of Cellular and Molecular Toxicology, Center for Biological Safety and Research, National Institute of Health Sciences, Kawasaki, Japan; ²Department of Regenerative Medicine, Graduate School of Medicine, Yokohama City University, Yokohama, Japan; and ³Department of Regulatory Science, Graduate School of Pharmaceutical Sciences, Nagoya City University, Nagoya, Japan.

Background and Purpose: A rapid *in vitro* evaluation method that shows a high correlation with animal-based toxicity studies would be extremely valuable for the early screening of candidate pharmaceuticals and for designing nonclinical development strategies. Currently, there are no existing alternative *in vitro* methods to animal testing that can evaluate male reproductive toxicity and recovery, comparable to conventional rodent studies. We then developed a new organ culture method using a chip made of polydimethylsiloxane (PDMS) to cover the tissue and press it thin and flat on the agarose gel. This PDMS-ceiling (PC) method, in which the oxygen concentration is lowered from ambient 20 to 15% in an incubator, has been proven to increase spermatogenic efficiency. Cisplatin is a chemotherapeutic agent frequently used to treat numerous solid tumors in pediatric oncology (World Health Organization, 2021). In the present study, we investigated the ability of the PC testis organ culture system to evaluate the effect of clinically relevant cisplatin treatment on male reproductive toxicity and the time necessary for recovery. **Methods:** Acrosin (Acr)-green fluorescent protein (GFP) transgenic mice were used in this study. Seven-day-old mice were used as the source of the testis tissue. The agarose gel was used as platforms for testis tissue placement. A single testis tissue was placed on a gel and a PC chip with a dent depth of 160 µm was placed over the tissue. The culture plates were placed in an incubator at 34 °C with 15% oxygen and 5% carbon dioxide. dMEM was changed once a week and was poured up to half the height of the agarose gel. For cisplatin treatment, a series of culture media were prepared with specified concentrations of cisplatin: 0, 0.4, 1, 4, 12, and 40 µg/mL, designated as cis-0, cis-0.4, cis-1, cis-4, cis-12, and cis-40, respectively. The original medium was replaced with the new media with cisplatin, and testis tissues were exposed to the cisplatin for 24 h. The media containing cisplatin were then replaced with dMEM containing AlbuMAX medium, followed by a series of three washes at two-hour intervals, using fresh culture medium each time to remove any residual cisplatin. The germ cells of Acr-GFP mice expressed GFP in the cytoplasm as they progressed to the pachytene stage (stage IV), allowing the evaluation of the progression of spermatogenesis over time without interrupting cultivation. For semi-quantitative evaluation of Acr-GFP expression, cultured testis tissues were classified into six grades according to the percentage of GFP-positive areas: 0, 0%; 1, 1-20%; 2, 21-40%; 3, 41-60%; 4, 61-80%; and 5, 81-100%. **Results:** At the time of cisplatin treatment (ED0), GFP expression was not observed in any of the tissues as they had only been cultivated for a period equivalent to the maturation stage of eight-day-old tissues. At ED7, GFP expression was almost equal among the control, cis-0.4, cis-1, and cis-4 groups, however, the cis-12 and cis-40 groups showed very little GFP expression. At ED14, the GFP grade in the cis-0.4 and cis-1 groups remained almost equivalent to that of the control. Interestingly, cis-4 showed a significant decrease in GFP expression levels at ED14, followed by a rapid recovery to a level comparable to that of the control at ED35. In cis-12, a partial recovery of GFP expression was observed around ED35, after which GFP expression gradually improved until ED70. However, no GFP expression was detected in cis-40 until ED70. These results were supported by histopathological examination. **Conclusions:** Observed in animal experiments, cisplatin treatment caused tissue volume shrinkage and reduced GFP fluorescence in a concentration-dependent manner. Recovery from male reproductive toxicity was also dependent on the concentration of cisplatin received. These results demonstrated that this novel *in vitro* system can be a faithful replacement for animal experiments to assess the male reproductive toxicity of candidate pharmaceuticals and their reversibility, providing a useful method for drug development.

O. Simsek¹, L. Altintas², A. Koker¹, E. Y. Gurle Albayrak¹, M. Albayrak¹, and F. Kalkir¹.
¹Burdur Mehmet Akif Ersoy University, Burdur, Turkey; and ²Ankara University, Ankara, Turkey.

Background and Purpose: Spinosad, a naturally derived bioinsecticide widely used in agriculture, is considered a reduced-risk pesticide. Although it can induce oxidative stress in various biological models, its effects on the oxidative balance of mammalian ovarian cells remain unclear. This study examined the time- and dose-dependent effects of spinosad on the total antioxidant capacity (TAC) of bovine granulosa cells *in vitro*. **Methods:** Bovine granulosa cells were isolated from abattoir-derived ovaries, pre-incubated in medium containing 10% newborn calf serum for 24 hours, and then exposed to spinosad (0.1 μ M, 1 μ M, or 10 μ M) in serum-free medium for an additional 96 hours. Subsequently, the culture media were collected at 48 and 96 hours to determine TAC (in mmol/L) using a colorimetric assay. This study was financially supported by the Scientific and Technological Research Council of Turkey (TÜBİTAK, TOVAG-1240439). **Results:** At 48 hours, TAC levels in the 1 μ M dose group were significantly higher than those in the control group ($p < 0.05$). However, neither the lower-dose (0.1 μ M) nor the higher-dose (10 μ M) groups differed significantly from the control. By 96 hours, TAC levels in the 1 μ M group had significantly decreased compared with its 48-hour value ($p < 0.05$). **Conclusions:** Spinosad exposure induced a nonlinear, transient antioxidant response in cultured bovine granulosa cells, characterized by a short-term enhancement of total antioxidant capacity at 48 hours that was not sustained at 96 hours. The 1 μ M dose significantly increased antioxidant capacity at 48 hours, indicating early activation of the antioxidant defense system, whereas both lower (0.1 μ M) and higher (10 μ M) doses produced minimal changes. These findings highlight a possible dose-sensitive adaptive mechanism in granulosa cells under spinosad exposure, warranting further investigation into its reproductive toxicological relevance.

PS 3201 Human extravillous trophoblasts exhibit circadian rhythms responsive to molecular clock regulators and select environmental chemicals

G. Chimino¹, J. Moeller¹, A. Zevallos-Morales¹, C. Murga-Zamalloa¹, A. Yaw², H. Hoffmann², and A. Veiga-Lopez¹. ¹University of Illinois Chicago, Chicago, IL; and ²Michigan State University, East Lansing, MI.

Background and Purpose: The circadian system coordinates daily timing of cellular and physiological functions; in pregnancy, its dysregulation has been associated with preeclampsia and preterm birth. In placenta trophoblasts, core clock components are rhythmically expressed, and perturbation of clock genes alters extravillous trophoblasts (EVTs) invasiveness. However, whether environmental chemicals, known to impair EVT invasion, disrupt circadian regulation in placental cells remain unknown. Thus, we examined two chemical classes: one linked to circadian disruption in insects (neonicotinoids) and one targeting a central placental pathway (benzotriazole UV stabilizers (BUVs)). Neonicotinoids, widely used insecticides, act at nAChRs receptors, involved in regulating circadian pacemaker activity in invertebrates, whereas BUVs, widely used in sunscreens, affect the epidermal growth factor receptor (EGFR), a major regulator of EVT proliferation and invasion. Because both receptor systems are expressed in EVTs, we hypothesize that exposure to either of these chemicals classes will decrease the circadian clock rhythmicity in EVTs. **Methods:** A stable Period 2::Luciferase (PER2::LUC) reporter was generated in HTR-8/SVneo EVTs to enable real-time tracking of molecular clock dynamics. Cells were first synchronized by serum shock (metabolic cue) or by thymidine block (cell cycle cue), rhythmic expression of PER2::LUC was recorded from circadian time (CT) CT0 to CT96, and evaluated for two known circadian clock modulators: dexamethasone (DEX; 100 nM) and CK1 ϵ / δ inhibitor PF-670462 (10 μ M) was assessed at CT0, CT18, and CT24. Next, thymidine block synchronized cells were exposed to environmentally relevant concentrations of the neonicotinoid 3-OH-imidacloprid (2 μ M and 20 μ M), acetylcholine (a nAChR agonist; 2 μ M and 20 μ M), or BUVs (UV-326 and UV-327; 1 μ M and 10 μ M). All bioluminescence traces were assessed for goodness of fit prior to rhythm parameter (amplitude, period, and phase) analysis. **Results:** Both synchronization methods yielded robust rhythms in HTR8/SVneo EVTs for up to 72 h. In serum shock synchronized EVTs, DEX had no effect on rhythm output when applied at CT0 but caused a slight phase delay at CT18 and increased amplitude with tighter phase clustering at CT24. In thymidine block synchronized cells, DEX disrupted the rhythmicity when applied at CT24 in 75% of the recordings. PF-670462 increased period length at CT0 in both synchronization methods, and at CT18 in serum shock synchronized EVTs, and led to tighter phase clustering at CT24. In thymidine block synchronized cells, PF-670462 induced a 12 h phase delay at CT0. Exposure to 3-OH-imidacloprid, acetylcholine, and UV-326 in thymidine block synchronized EVTs at CT0 yielded rhythms that passed goodness of fit criteria and showed no changes in amplitude, period, or phase. However, exposure to 10 μ M dose of UV-327 showed a trend towards phase advancement at CT0. **Conclusions:** This study demonstrates that EVTs possess robust circadian rhythms, modulated by clock regulators in a time- and synchronization-dependent manner. Most environmental chemicals tested did not alter rhythm parameters, though UV-327 showed a potential phase-shifting effect. Chemical exposures were assessed under thymidine block synchronization, which may yield more tightly phased rhythms, based on differential responses to DEX

and PF-670462, warranting future evaluation under serum shock conditions. Overall, these findings suggest that select environmental chemicals may influence placental clock function and merit further investigation. Funded by R01ES035691 to A.V.-L.

PS 3202 Hormone Secretion and Membrane Transporter Regulation in Human Placental Explants Under Standard and Accelerated Culture Conditions

C. Kuwata^{1,2,3}, M. J. Campbell^{1,2}, O. Paul^{1,2}, C. Jiang^{1,2}, J. K. Fallon⁴, J. B. Tiley⁴, N. P. Illsley^{2,5}, M. Goedken², E. Rosenfeld^{6,7}, and L. M. Aleksunes^{1,2}. ¹Environmental and Occupational Health Sciences Institute, Rutgers University, Piscataway, NJ; ²Department of Pharmacology and Toxicology, Ernest Mario School of Pharmacy, Rutgers University, Piscataway, NJ; ³Medicinal Safety Research Laboratories, Daiichi Sankyo Co. Ltd., Tokyo, Japan; ⁴Eschelman School of Pharmacy, University of North Carolina, Chapel Hill, NC; ⁵Placental Research Group, Maplewood, NJ; ⁶Division of Maternal-Fetal Medicine, Department of Obstetrics, Gynecology, and Reproductive Sciences, Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ; and ⁷Division of Biostatistics and Epidemiology, Department of Obstetrics, Gynecology, and Reproductive Sciences, Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ.

Background and Purpose: *Ex vivo* culturing of human placental explants is a physiologically relevant model as cell-cell communication remains intact. During explant culture, syncytiotrophoblasts partially detach during the first 2 days and regenerate through cytotrophoblast fusion to form a new syncytial layer over a period of 5-7 days. Previous studies have suggested that treatment of explants with trypsin accelerates this process by inducing early shedding. However, there has been little investigation into how this accelerated protocol affects hormone secretion, morphological changes, and the expression of nutrient and xenobiotic membrane transporters. Therefore, this study sought to profile the dynamic changes that human placental explants undergo over a 7-day period, with or without trypsin treatment, with a focus on the regulation of hormone production, structure, and transporter enrichment. **Methods:** Six healthy, term placentas (N=3 male; N=3 female) were collected during scheduled Cesarean sections. Placental villous tissue samples were dissected and washed with PBS to remove maternal blood. Villous explants (~8 mm³) were prepared and cultured in 24-well dishes. For the trypsin-treated group, explants were incubated in 0.25 mg/mL trypsin for 20 minutes at 37 °C before replacement with standard culture media on Day 0. Cultures were maintained at 37 °C with 5% CO₂ and 20% O₂ for up to 7 days. Media was collected daily for measurement of human chorionic gonadotropin (hCG) and lactate dehydrogenase (LDH). Fresh media was added each day. Explants were imaged daily using a light microscope. Quantitative Targeted Absolute Proteomic (QTAP) analysis of transporters by liquid chromatography-mass spectrometry and histopathological analyses of explant morphology on Days 0, 1, 2, 3, 5, and 7 are ongoing. **Results:** In the control group, explants appeared similar under a light microscope until around Day 3 to 4 when gradual aggregation occurred, and tissue density increased. In the trypsin-treated group, on Day 0, the extracellular matrix (ECM) was degraded and became gelatinous. By Day 1, the degenerated ECM had disappeared, and the explants aggregated and became smaller in size. In both control and trypsin-treated groups, the hCG concentration peaked on Day 1 and gradually declined over Days 2 and 3. Notably, trypsin-treated explants had 70% higher hCG levels on Day 1 compared to the non-treated group ($p < 0.001$), but no differences were observed on Day 2 or later. LDH levels were also the highest on Day 1, gradually decreased toward Day 3, and stabilized at a low level until Day 7. No significant differences in LDH levels were observed between control and trypsin-treated explants. **Conclusions:** Delineating the morphological and biochemical profiles of human placental explants with and without trypsinization provides a foundation for establishing appropriate and time-efficient models for placental toxicology studies. Supported by Daiichi Sankyo Co. Ltd. and the Integrated Transporter Elucidation Center funded by NIH UC2HD113039.

PS 3203 The Effects of Iodoacetic Acid on Oxidative Stress Markers in the Mouse Ovary

A. Fields¹, A. Varella Gonsioroski², R. Santacruz Marquez¹, M. J. Laws¹, and J. Flaws¹. ¹University of Illinois Urbana Champaign, Urbana, IL; and ²Michigan State University, East Lansing, MI.

Background and Purpose: The incorporation of water disinfectants into the main water supply has significantly decreased the incidence of waterborne diseases such as cholera. However, the interaction between disinfectants and organic material generates water disinfection byproducts (DBPs). Iodoacetic acid (IAA) is an unregulated DBP that has been reported as a reproductive toxicant. Our previous studies show that IAA inhibits follicular growth and alters the expression of steroidogenic factors *in vitro*, but its underlying mechanisms of action were unknown. Thus, we tested the hypothesis that IAA exposure causes ovarian toxicity through oxidative stress pathways. **Methods:** Adult CD-1 mice were dosed with vehicle control (reverse osmosis water) or IAA (2.7- 2,695.7 μ M) for 35 days. Following this, ovaries were collected when the mice were in diestrus, and either antral follicles were isolated from the ovary, or the ovary was kept whole. Both antral follicles and whole ovaries were subjected to RNA extraction, reverse transcription, and quantitative polymerase

chain reaction (qPCR) to analyze the expression of several enzymes that regulate oxidative stress (*Gpx1*, *Gpx2*, *Gsr*, *Gss*, *Gsta1*, *Gstm1*, *Gsto1*, *Gstp1*, *Gstt1*, *Sod1*, *Sod2*, and *Cat*). In other experiments, ovarian antral follicles were collected from CD-1 mice between 40 and 42 days of age. The follicles were incubated in individual wells within a 96-well plate in media containing vehicle control $\pm$ the antioxidant Trolox or IAA (2-15 μ M) $\pm$ the antioxidant Trolox for 96 hours. Follicle growth was measured every 24 hours and media were collected for estradiol measurements at 96 hours. **Results:** IAA decreased *Cat*, *Sod1*, *Gss*, *Gsta1*, *Gstp1*, and *Gstt1* and increased *Gstm1* expression in whole ovaries compared to control *in vivo*. IAA decreased *Sod2* and *Gpx2* and increased *Gstp1* expression in antral follicles compared to control *in vivo*. IAA increased *Gpx1* and *Gsto1* expression in antral follicles compared to control *in vitro*. **Conclusions:** IAA inhibited follicle growth and reduced estradiol levels, whereas Trolox rescued follicles from IAA-induced inhibition of follicle growth and estradiol levels *in vitro*. Collectively, these data indicate that IAA exposure causes ovarian toxicity by altering oxidative stress pathways in the mouse ovary. Supported by NIH R21 ES028963.

PS 3204 SILDENAFIL CREAM, 3.6%: VAGINAL DOSE STUDY ON EMBRYOFETAL DEVELOPMENT TOXICITY AND TOXICOKINETICS IN RATS

D. R. Friend, and A. Thurman. Dare Bioscience, San Diego, CA. Sponsor: D. Jacobson-Kram

Background and Purpose: The purpose of this study was to investigate the effects of sildenafil cream, 3.6% on embryofetal development in rats when administered via vaginal route from Gestation Day (GD) 6 to up to and including GD 17 and to characterize the dose response relationship to any observed toxicity. In addition, the toxicokinetics (TK) in mated females were determined. Sildenafil cream, 3.6% is being developed for treatment of female sexual arousal disorder. **Methods:** 157 mated female rats were randomly assigned to 5 groups with 29 animals in the sham dose control and placebo control groups (25 animals/group in the main study and 4 animals/group in TK study) and 33 animals in the three test article treatment groups (25 animals/group in the main study and 8 animals/group in TK study). Test article groups were administered sildenafil cream, 3.6% at the dose volume of 0.1 mL/animal (once daily), 0.2 mL/animal (once daily) or 0.2 mL/animal (twice daily), equivalent to 3.77, 7.54 or 15.08 mg sildenafil/animal/day. The placebo control group was administered Placebo Cream at the dose volume of 0.2 mL/animal (twice daily). The sham dose control was not administered any test article, but all other procedures were performed as with test article groups or placebo control group. The dose duration was from GD 6 to GD 17 for main study animals and from GD 6 to GD 20 for TK animals. The ovaries and uteri were examined for determination of litter data. The uteri without visible implantations were placed in ammonium sulfide solution for detection of early resorptions. The placentae of live fetuses were examined macroscopically. All the live fetuses were weighed and examined for external abnormalities; their crown-rump lengths were measured, and sexes were determined. Approximately 1/2 of the live fetuses in each litter were fixed with modified Davidson's fixative for soft tissue examination and the remaining fetuses were stained with Alcian blue and Alizarin red solution for subsequent skeletal examination. The visceral and skeletal examination of fetuses was conducted for the high dose and two control groups. In addition, frozen vagina samples were collected from all TK animals at scheduled necropsy. **Results:** In the main study, there were 24/25, 24/25, 23/25, 23/25, and 23/25 pregnant animals in sham dose control, placebo control, low, mid, and high-dose groups, respectively. There were no unscheduled deaths noted in this study. All animals survived to the scheduled necropsy. Test article-related changes were restricted to the transient and slight decreases in food consumption at high dose (7.0%, relative to sham dose control group) mainly during GD 6-12 when compared to the control groups. The changes were reversible during the following period and were considered non-adverse. TK analyses were conducted for dams on GD 6 and 17. For analyte of sildenafil, T_{max} values were observed between 0.5 and 8.0 hours post first dose. The systemic exposure increased dose-proportionally in females on GD 6 and GD 17 as the dosage increased from 3.77 to 7.54 mg sildenafil/animal/day. Generally, no marked drug accumulation in systemic exposure was observed at any dose level. For analyte of *N*-desmethyl sildenafil, T_{max} values were observed at 8.0 hours post first dose. The systemic exposure increased dose-proportionally in females on GD 6 and GD 17 as the dosage increased from 3.77 to 7.54 mg sildenafil/animal/day. There were no test article-related changes on mortality, clinical signs, body weight, macroscopic observation, litter data (number of corpora lutea, implantation sites, live fetuses, fetal death, and death fetuses, resorptions, pre- and post-implantation loss), sex ratio, placental examination, fetal weight and crown-rump length, and fetal external, visceral and skeletal examinations. **Conclusions:** Based on the above results, the No-Observed-Adverse-Effect-Level (NOAEL) of sildenafil cream, 3.6% for maternal and embryo-fetal developmental toxicity was considered to be 15.08 mg sildenafil/animal/day (corresponding maternal mean C_{max} and AUC_{0-24h} of sildenafil in plasma on GD 17 were 3970 ng/mL and 47200 h*ng/mL, respectively; maternal mean C_{max} and AUC_{0-24h} of *N*-desmethyl Sildenafil in plasma on GD 17 were 575 ng/mL and 5040 h*ng/mL, respectively; maternal mean vaginal tissue concentration of sildenafil on GD20 were 30700 ng/g; maternal mean vaginal tissue concentration of *N*-desmethyl sildenafil on GD 20 were 954 ng/g).

PS 3205 Lifelong Exposure to an Environmentally Relevant Endocrine Disruptor Mixture Promotes Preneoplastic Lesions and Reveals Molecular Markers Linked to Poor Survival in Prostate Cancer

L. O. Mendes¹, A. R. Gorzoni¹, T. C. Sousa¹, K. D. Hinokuma¹, M. S. Ricardo¹, A. Y. Yoshigae¹, A. M. de Aquino², E. A. Mareco¹, W. R. Scarano³, and A. d. Castilho¹. ¹Western Paulista University - UNOESTE, Presidente Prudente, Brazil; ²Henry Ford Cancer Institute, Detroit, MI; and ³Sao Paulo State University, Botucatu, Brazil.

Background and Purpose: Endocrine disruptors (EDs) are environmental contaminants capable of interfering with hormone-regulated tissues, including the prostate. While most toxicology studies evaluate single compounds and short exposure periods, humans are chronically exposed to mixtures. This study investigated molecular and histopathological alterations in the ventral prostate of male rats exposed to a mixture of 12 environmentally relevant EDs from intrauterine life to adulthood. **Methods:** Pregnant Sprague-Dawley rats received either vehicle (corn oil) or an EDs mixture (phthalates, pesticides, UV filters, bisphenol A, and butylparaben; 32.11 mg/kg/day) from gestational day 7 to postnatal day (PND) 21. Male offspring continued exposure until PND 220. Ventral prostates were processed for histopathology (hematoxylin and eosin) and RNA-seq (HiSeq-2500). All procedures were approved by the Animal Ethics Committee at UNOESTE (CEUA 6034) and complied with ARRIVE guidelines. Differential expression was assessed using DESeq2 ($\log_2FC \geq |1.5|$; adj. $p \leq 0.05$), followed by Gene Ontology enrichment and protein-protein interaction (PPI) network analysis (STRING). Prognostic value of selected genes was evaluated using TCGA prostate cancer datasets. **Results:** The EDs mixture induced prostatic intraepithelial neoplasia (PIN) in 80% of exposed animals, characterized by loss of epithelial polarity, prominent nucleoli, and stromal and luminal inflammatory foci, indicating early neoplastic transformation. Transcriptomic profiling identified 48 differentially expressed genes, predominantly downregulated. GO enrichment highlighted disruptions in cellular response to stimulus and intracellular transport, suggesting endoplasmic reticulum stress and impaired vesicular trafficking. PPI network analysis revealed *VCP*, *HSPA5*, *NPM1*, and *ARCN1* as central regulatory nodes, consistent with roles in protein quality control, proliferation, and stress adaptation. Survival analysis demonstrated that high expression of *ARCN1*, *CD55*, *CRIP2*, and *MFSD4A* was significantly associated with reduced overall survival in prostate cancer patients, indicating translational relevance and biomarker potential. **Conclusions:** Lifelong exposure to an environmentally relevant mixture of EDs compromises prostate homeostasis, inducing pre-neoplastic lesions and transcriptional reprogramming involving stress response and proliferative signaling networks. These findings provide mechanistic evidence linking environmental ED exposure to increased prostate cancer susceptibility and identify candidate molecular biomarkers for disease monitoring and risk assessment. (Funding: FAPESP - 2018/24044-0 and CNPq - 305205/2022-6).

PS 3206 Diisononyl phthalate disrupted microRNA regulation of the placental transcriptome

S. Lapehn¹, E. J. Firsick¹, M. Parenti¹, J. MacDonald², T. Bammler², S. Sathyanarayana^{1,2}, and A. G. Paquette^{1,2}. ¹Seattle Children's Research Institute, Seattle, WA; and ²University of Washington, Seattle, WA.

Background and Purpose: The placenta is a fetal organ that regulates oxygen, nutrient, and waste exchange; immune protection; hormone production; and maternal-fetal communication. We have demonstrated relationships between phthalates and placental mRNA and microRNA (miRNA) expression via epidemiological and toxicological methods. Diisononyl phthalate (DINP) is a high molecular weight phthalate that is metabolized into primary metabolite mono-isononyl phthalate (MINP), then secondary metabolite mono-carboxy-isoctyl phthalate (MCIOP). Our previous human cohort studies have highlighted MCIOP as the phthalate metabolite most associated with both mRNA and miRNA expression in bulk placental tissue. However, there are limited studies of MCIOP or its precursors using *in vitro* models and toxicological methods. The goal of this project is to evaluate miRNA expression in the placental HTR-8/SVneo cell line and investigate the effects of DINP and its metabolites on mRNA and miRNA expression. **Methods:** HTR-8/SVneo cells were treated with DMSO (0.05%) or 90 μ M of DINP, MINP, or MCIOP for 24 hours with 6 samples per treatment. Total RNA was isolated and sequenced to quantify global miRNA and mRNA expression. Differentially expressed genes (DEGs) and miRNAs (DEMs) were evaluated by fitting linear models in EdgeR and using a significance threshold of $FDR < 0.05$. DEGs were assessed for pathway and transcription factor (TF) enrichment through overrepresentation analysis with KEGG pathways and a placental transcriptional regulatory network. The resulting DEGs and DEMs were then mapped onto an existing placenta-specific miRNA-mRNA network based on human data. Global HTR-8/SVneo miRNA expression was compared to bulk placental tissue to determine the utility of this cell line for analyses of placental miRNA expression. **Results:** MCIOP altered both mRNA (4,508 DEGs) and miRNA (68 DEMs) expression, including 9 miRNAs that were part of the placenta-specific C14 miRNA cluster (C14MC). There was no evidence that DINP affects mRNA or miRNA expression, while MINP modestly altered the mRNA transcriptome (23 DEGs). Three DEMs (miR-27a-5p, miR-199b-5p, and miR-30b-5p) and 3 DEGs (*ZNF616*, *KRT10*, and *CPZ*) were also associated with prenatal urinary concentrations of MCIOP in a human cohort study. MCIOP DEGs were enriched for pathways related to DNA replication and repair, protein processing, and oxidative phosphorylation. MCIOP DEGs were also overrepresented as target genes for 57 transcription factors (TFs), of which 6 were nuclear hormone receptors.

Using our placental miRNA-mRNA network, 49 of the MCIOP DEMs are predicted to target 5,607 genes expressed in HTR-8/SVneo cells, of which 2,025 were MCIOP DEGs. Twelve of these miRNAs targeted genes that were enriched within 12 KEGG Pathways related to catabolism and protein processing. HTR-8/SVneo cells and bulk placental tissue both expressed 439 miRNAs; however, 188 miRNAs were exclusively expressed in placental tissue, and 303 miRNAs were exclusively expressed in HTR-8/SVneo cells. Placental-specific miRNAs from the C19 miRNA cluster (C19MC) were not expressed in HTR-8/SVneo cells, but all C14MC miRNA present in the bulk tissue were also expressed in HTR-8/SVneo cells with 19 additional C14MC miRNAs, which could be specific to the extravillous trophoblast. Overall, the expression of shared miRNAs was comparable between bulk tissue and HTR-8/SVneo with an R^2 of 0.64 for all 439 shared miRNAs and 0.83 for overlapping C14MC miRNAs. **Conclusions:** We demonstrated that MCIOP, but not its precursors (DINP and MINP), causes substantial changes to the placental transcriptome at the level of miRNA and mRNA, emphasizing that metabolites, but not parent compounds are responsible for transcriptomic effects, which has important implications for toxicology studies. Overall, HTR-8/SVneo cells demonstrated good coverage of miRNAs expressed in bulk placental tissue with the exception of C19MC, highlighting their potential use for validation of epidemiological studies. Future directions include incorporating proteomics data, expanding the phthalate concentration range, and using placental cell lines representative of other trophoblast phenotypes.

PS 3207 Profiling the novel impacts of the organochlorine compounds tris(4-chlorophenyl)methane (TCPM) and tris(4-chlorophenyl)methanol (TCPMOH) on human placental cells

G. Romo¹, M. Drellichman², A. Trappe¹, C. Cellini¹, F. Stein¹, S. Campbell¹, K. Sant³, and E. R. Elkin¹. ¹School of Public Health, San Diego State University, San Diego, CA; ²School of Public Health, San Diego State University, San Diego, CA; and ³Department of Pharmacology and Toxicology, College of Veterinary Medicine, Michigan State University, East Lansing, MI.

Background and Purpose: Tris(4-chlorophenyl)methane (TCPM) and tris(4-chlorophenyl)methanol (TCPMOH) are anthropogenic environmental pollutants that are believed to be byproducts of the organochlorine pesticide dichlorodiphenyltrichloroethane (DDT). TCPMOH is thought to be a metabolite of TCPM. These chemicals persist in the environment, and have been found to accumulate in aquatic mammal tissue and in human breast milk. They are also potential endocrine disruptors, yet no studies evaluating potential toxic effects have been conducted in the placenta, a transient organ with many endocrine functions critical for fetal development. In this study, TCPM and TCPMOH were screened for their cytotoxic effects, differential gene expression, and invasion capacity. **Methods:** For cell viability and cytotoxicity, HTR-8/SVneo cells were treated with medium plus DMSO (control) or TCPM or TCPMOH (1 μ M - 100 μ M) for 24-hours and cytotoxicity was measured using Multiplex Multitox Cytotoxicity Assay. RNA sequencing of HTR-8/SVneo cells was used for differential gene expression after being treated with medium plus DMSO (control), TCPMOH (1 μ M or 10 μ M), or TCPM (1 μ M or 10 μ M). Differential gene expression was analyzed using DESeq2 in R. For invasion capacity, HTR-8/SVneo cells treated with medium plus DMSO (control) or TCPMOH (1 μ M or 10 μ M). For cell cycle determination, HTR-8/SVneo cells treated with medium plus DMSO (control) or TCPMOH (1 μ M or 10 μ M). **Results:** Placental cells significantly decreased in cell viability when exposed to TCPMOH concentrations of 50 μ M or greater, while TCPM did not show a significant decrease in cell viability. Differential gene expression when exposed to TCPMOH for 1 μ M and 10 μ M concentrations yielded 3 shared significantly upregulated pathways: Inflammatory response, Interferon gamma, and KRAS signaling. Invasion capacity for 1 μ M concentrations reduced cell count by 38%, and for 10 μ M concentrations cell count was reduced by 62%. **Conclusions:** Placental cell viability was significantly reduced by concentrations of TCPMOH 50 μ M and greater, while TCPM did not display significant cytotoxicity. Differential gene expression showed an upregulation of pathways related to inflammation as well as cell proliferation at sublethal concentrations. Low concentrations of TCPMOH also affected the invasion capacity of the placental cells.

PS 3208 Effects of S - (1,2-dichlorovinyl) - L - cysteine (DCVC) exposure on mitochondrial respiration in BeWo Cells

A. Trappe, M. Drellichman, G. Romo, and E. R. Elkin. School of Public Health, San Diego State University, San Diego, CA.

Background and Purpose: Trichloroethylene (TCE) is a widely used industrial solvent and recognized environmental pollutant, present in spray adhesives, paint removers, tool cleaners, and other common household products. It has remained persistent in the environment globally, causing a risk to human health. TCE can be metabolized into the reactive and toxic metabolite S-(1,2-dichlorovinyl)-L-cysteine (DCVC), which induces mitochondrial-mediated apoptosis in trophoblast cells, known to play a crucial role in the early stages of pregnancy and placental development. Mitochondrial metabolism plays a crucial role in trophoblast differentiation, and little is known about how DCVC exposure affects this process. **Methods:** The current study aims to investigate the effects of different environmentally relevant DCVC concentrations on inducing mitochondrial stress and disruptions to the fusion

process, known as syncytialization, in BeWo syncytiotrophoblast cells. To assess the effects of DCVC on the BeWo cell line, we measured live-cell metabolic function using the Agilent Seahorse XF HS Mini Analyzer, conducting a Mito Stress Test assay. This test measures key parameters such as the oxygen consumption rate (OCR) of cells, allowing for real-time monitoring of plate-based live assays. Prior to the assay, BeWo cells were exposed to 10 and 20 μ M DCVC and incubated for 24 hours. **Results:** Following the exposure period, oxygen consumption rate (OCR), proton efflux rate (PER), extracellular acidification rate (ECAR), and seven other parameters were measured via the Seahorse XF Analyzer. A one-way ANOVA was conducted for the basal respiration results for the three trials to assess changes in mitochondrial activity. So far, preliminary data have shown no significant results identified in the DCVC-treated BeWo cells. **Conclusions:** DCVC remains a significant concern in both public health and environmental toxicology. Ongoing studies aim to further characterize its effects, including upcoming experiments that will use polymerase chain reaction (PCR) to quantify mitochondrial copy number and gene expression. Additional work with the fused version of these cells is also underway to provide deeper insight into the mitochondrial dysfunction induced by DCVC in this placental cell line.

PS 3209 Toxicity assessments of perfluorobutane sulfonic acid (PFBS) in two in vitro human placental models

M. G. Drellichman¹, S. Campbell¹, G. Romo¹, A. Trappe¹, C. Cellini¹, A. Bhattacharya², J. Huang³, and E. R. Elkin¹. ¹School of Public Health, San Diego State University, San Diego, CA; ²MD Anderson Cancer Center, Houston, TX; and ³Department of Public Health Sciences, University of Hawai'i at Mānoa, Honolulu, HI.

Background and Purpose: Perfluorobutane sulfonic acid, PFBS, is a compound belonging to the class of human made chemicals, per- and polyfluoroalkyl substances, PFAS, with its greatest source of exposure through drinking water. In humans, maternal PFBS exposure can be associated with adverse birth outcomes and complications for mothers-to-be. Prior studies associate PFBS exposure with preeclampsia, a pregnancy-specific disease characterized by shallow trophoblast invasion and subsequent placental ischemia. **Despite epidemiological evidence, the toxicological mechanisms underlying this association and its effects on the placenta is not clearly known.** The aim of the research is to understand a dose-response threshold and gene expression results related to reproductive toxicity in two *in vitro* human placenta models exposed to PFBS. This research generates a characterization of a toxicity profile for preliminary studies. **Methods:** We measured cell viability in the HTR-8/SVneo cell line using the Promega MultiTox-Glo Cytotoxicity Assay at 0, 0.1 μ M, 1 μ M, 10 μ M, 20 μ M, 50 μ M, 100 μ M PFBS. Transcriptomic via RNAseq analysis was performed in two models: the HTR-8/SVneo cell line and in third trimester tissue explant. RNA sequencing was processed using the R package DESeq2. Pathway analysis was executed through gene set enrichment analysis, GSEA, programming using ranked Log2FC values. **Results:** The cell viability assay showed no dose-response relationship in the live-dead cytotoxicity assay in the cell model. The RNA sequencing results demonstrated concentration dependent effects in the third trimester tissue model, as evidenced by the magnitude of altered gene expression with 20 μ M versus 5 μ M versus 0 μ M PFBS ($FDR > 0.05 + |\log_{10}FC| > 1$ [$FC > 2$]). Gene set enrichment pathway analyses identified upregulation in cell cycle proliferation in cells with 5 μ M treatment and both 5 μ M and 20 μ M treatments in third trimester tissue. Gene set enrichment pathway analyses identified downregulation in inflammation and immune response across all models and doses. **Conclusions:** This study advances understanding of potential risks of PFBS exposure during pregnancy by identifying differentially expressed genes and subsequent pathways in placental cells and tissues.

PS 3210 Chromium(VI) Exposure During Pregnancy Disrupts Placental Development and Fetal Growth by Altering the Epigenome and Transcriptome of the Placental Labyrinth zone

I. P. Saravanan¹, V. Kolla¹, J. Cai¹, S. Kluaihanngam¹, J. A. Arosh¹, T. K. Lamon², R. E. Rose², D. J. Boland³, S. Krothapalli¹, S. Azzi¹, E. Miller¹, O. Mohr¹, E. Quinones¹, and S. K. Banu¹. ¹Department of Veterinary Integrative Biosciences, Texas A&M University, College Station, TX; ²Comparative Medicine Program, Texas A&M University, College Station, TX; and ³Texas A&M University Institute of Genomics and Society, Texas A&M University, College Station, TX.

Background and Purpose: Hexavalent chromium [(Cr(VI))] has been detected in groundwater across the United States due to industrial and military operations, including plating, painting, cooling-tower water, and chromate production. Cr(VI) is a mutagen, teratogen, carcinogen, and a reproductive toxicant and it causes lung cancer, along with evidence of Cr(VI)-induced genetic alterations. Environmental and occupational exposure to Cr(VI) in women adversely affects their reproductive health, causing premature birth (PTB), preeclampsia and fetal growth restriction (FGR). The actual molecular mechanism underlying Cr(VI)-induced FGR is unknown. The placental labyrinth zone (LZ) in rats (which closely resembles the chorionic villi in human placenta) is the primary site for nutrition and gas exchange between the mother and the developing fetus. Disruption of LZ leads to compromised nutritional exchange potentially causing FGR. According to the Developmental Origin of Adult Health and Diseases (DOHAD) theory, exposure to endocrine disruptors during early

life can have serious impact on the offspring's health in later life. We hypothesized that exposure to Cr(VI) induces FGR by altering the gene expression profiles of the LZ, disrupting placental function and fetal development. **Methods:** Timed-pregnant rats were exposed to 0 or 5 ppm Cr(VI) (as potassium dichromate) in drinking water from gestational day (GD) 9.5 to 12.5, representing environmentally relevant exposure levels (eg. drinking water Cr(VI) in Midland, TX is 5.28 ppm). Animals were euthanized on GD 18.5, and pregnancy outcomes, fetal growth indices, and placental morphology were evaluated. Histological, immunohistochemical (IHC), and quantitative RT-PCR analyses were conducted to assess apoptosis, cytotrophoblast (CTB) cells fusion into syncytiotrophoblast (STB), inflammation, oxidative stress, and anti-oxidants expression were determined. In addition, bulk RNA-sequencing of micro-dissected LZ tissues was performed to identify global transcriptomic changes and regulatory pathways using bioinformatics tools. Pathway enrichment and network analyses were visualized through volcano plots, heatmaps, and KEGG/GO functional clustering. **Results:** Cr(VI) exposure significantly increased fetal resorption rates and decreased live birth index and fetal weight compared to controls. Histological evaluation revealed disrupted trophoblast architecture and the affected fusion of CTB leading to abnormal formation of syncytium in the LZ, increased expression of pro-inflammatory and oxidative stress proteins, and downregulation of anti-inflammatory proteins and antioxidants, compared to control. RNA-seq analysis revealed extensive dysregulation of genes involved in oxidative phosphorylation, extracellular matrix organization, angiogenesis, and epigenetic regulation (including DNA methylation and histone modification pathways). Integration of transcriptomic and molecular data demonstrated that Cr(VI) perturbs the epigenomic landscape of trophoblasts, leading to aberrant gene expression profiles associated with trophoblast differentiation, placental pathologies, restricting fetal growth and increasing fetal death. **Conclusions:** Our findings demonstrate that prenatal exposure to Cr(VI), recapitulating the human exposure levels, disrupts placental development by reprogramming the epigenomic and transcriptomic networks of the trophoblasts in the labyrinth zone. These changes compromise placental development and function, resulting in restricted fetal growth and increased fetal loss. This study provides novel mechanistic insights into how developmental exposure to Cr(VI) causes placental perturbations through epigenomic modulation, advancing our understanding of metal-induced reproductive and developmental disorders.

PS 3211 Effects of Prenatal BaP Exposure on Spindle Quality in MII Mouse Oocytes

N. Vaddella, K. L. Parada, and U. Luderer. University of California, Irvine, Irvine, CA.

Background and Purpose: Benzo[a]pyrene (BaP) is a by-product of the incomplete combustion of organic material and a known endocrine disrupting chemical. Previous studies of the Luderer Laboratory found that gestational BaP exposure induced DNA damage and mitochondria-mediated apoptosis in F1 metaphase II (MII) mouse oocytes. Prenatal BaP exposure is heavily prevalent amongst the general population but the extent of damage to female fertility is not fully understood, specifically on the quality of F1 MII mouse oocytes exposed to human relevant doses. At ovulation, oocytes are arrested at MII during which the meiotic spindle aligns chromosomes in the center of the cell. Errors in chromosome segregation lead to aneuploidy in resulting daughter cells which is linked to miscarriage and increased cancer risk. **Methods:** C57BL/6J F0 pregnant mice were orally dosed with 0 (sesame oil control), 0.033, or 2 mg/kg/day BaP during F1 embryonic ovarian development, E6.5-15.5. The 0.033 mg/kg/day dose over 10 days is roughly 1/3 of the estimated exposure to BaP during pregnancy of a highly exposed woman and 2 mg/kg/day is used for the comparative higher dose. F0 dams were humanely euthanized and F1 MII oocytes were extracted from the fetal ovaries; immunofluorescence was carried out using antibodies against alpha-tubulin and CREST to visualize the meiotic spindle and kinetochores and DAPI to visualize chromosomes. Z-stack images of eggs were collected and IMARIS software was used to analyze spindle width, the distance from the top-most and bottom-most spindle, and spindle disorganization, classified as spindles deviating from the metaphase plate. Spindle intensity was also measured based on the signal of segments from the surface created in IMARIS. **Results:** There was a significant increase in spindle width (GEE, $p < 0.001$) and the prevalence of spindle disorganization (Kruskal-Wallis: $p = 0.033$) in mice exposed to BaP compared to control. Spindle intensity, an indirect measurement of spindle quantity was not altered by BaP exposure (GEE, $p = 0.073$). **Conclusions:** Greater spindle width and disorganization at MII pose a risk for aneuploidy as the likelihood of non-disjunction, or errors in chromosome segregation into daughter cells, drastically increases in the presence of stray spindles. If an egg that underwent non-disjunction were to be fertilized, the resulting zygote may have the improper number of chromosomes leading to developmental defects like Trisomy 21. Given the non-replenishable nature of the ovarian reserve, any environmental factors that reduce oocyte quality are detrimental to overall reproductive health and fertility. In light of recent drops in fertility rates, this research will be important for understanding the extent of BaP-mediated meiotic damage and contribute to standardized precautions against environmental toxins.

PS 3212 Sexually Dimorphic Immune Response in Placentas of Nano-Titanium Dioxide Exposed Rat Dams

T. D. Gluth^{1,2}, A. C. Dunn^{1,2}, K. M. Seman^{1,2}, M. S. Springer^{1,2}, R. P. Hunter^{1,2}, and E. C. Bowdridge^{1,2}. ¹Department of Physiology, Pharmacology, & Toxicology, West Virginia University School of Medicine, Morgantown, WV; and ²Center for Inhalation Toxicology, West Virginia University School of Medicine, Morgantown, WV.

Background and Purpose: The placenta plays a vital role for the developing fetus by providing nutrient and waste exchange, hormone production, and a protective barrier. Two major zones of the placenta include the junctional zone (JZ), which generates hormones and growth factors, and the labyrinth zone (LZ), which is the site of nutrient exchange. Poor placental protection or nutrient delivery can have more immediate effects such as preeclampsia, fetal growth restriction, and fetal mortality, and/or lifelong health effects on the offspring, as described by the Developmental Origins of Health and Disease hypothesis. Therefore, disturbances to the placenta through maternal toxicant exposure can have lasting implications to the baby. In Sprague Dawley (SD) rat dams, gestational inhalation of titanium dioxide nanoparticles (nTiO₂) leads to placental insufficiency, intrauterine growth restriction, and sexually dimorphic metabolic and endocrine dysfunction in adult offspring. These sex differences begin *in utero*, with fewer males being born to nTiO₂ exposed dams, and female fetuses experiencing more growth restriction. Exposed female placentas also had greater changes to relative placental zone mass and Hofbauer cell (placental macrophage) presence. Because immune responses are known to differ significantly by sex, and placental cells have sex chromosomes, we sought to determine if placentas exposed to nTiO₂ have sexually dimorphic and zone-specific immune responses. **Methods:** Female SD rats ($n = 4-6$ per group), approximately 8-week-old, were acclimated for 48 hours before handling and provided standard chow and water *ad libitum*. Females were randomly assigned to be exposed to either nTiO₂ (12 mg/m³) or HEPA-filtered air (25 mL/min) for 6 hours per day for 6 non-consecutive days between GD12 and 19. Dams were euthanized on GD20 for tissue collection and evaluation of litter size, implantation count, pup weight, and placental weight. Placentas were divided by fetal sex, and placental zones (JZ and LZ) were isolated. One male and female placenta per dam was fixed in 4% paraformaldehyde for immunofluorescence of Hofbauer cell polarization. At least one male and female placenta per dam were snap frozen for subsequent protein and RNA analysis. A cytokine proteome array was used to screen whole placentas for changes in 79 cytokines by exposure and sex. Phosphorylation of JNK and NFκB in placental zones was measured by western blot. Relative mRNA levels of cytokines, chemokines, and pro-inflammatory ER stress pathways were determined RT-qPCR. **Results:** In general, nTiO₂ exposure resulted in more cytokine upregulation in the female placenta and more downregulation in the male placenta, as measured by the proteome array. Proteins increased in the exposed female placenta include Galectin-1, Neprilysin, IL-2, IL-3, IL-6, IFNγ, and CCL2, and in the male placenta include Neprilysin and ICAM-1. Proteins decreased in the female placenta include RAGE and IGFBP-3, and in the male placenta include FGF, IGF-1, IL-1β, and CCL2. The mRNA expression of TNFα, IL-1β, IL-10, and IFNγ were all higher in the JZ compared to the LZ in both males and females. However, trends in these cytokines differed by nTiO₂ exposure in the LZ, but not in the JZ. Exposed male JZs had more IL-10 (355%, $p = 0.06$, $n = 3$) and IFNγ (305%, $p = 0.06$, $n = 3$), while female JZs had a trending increase in IL-10 (487%, $p = 0.1$, $n = 3$). Further RT-qPCR analysis will be utilized to further evaluate changes in cytokines, chemokines, and apoptotic pathways by nTiO₂ in placental zones. Western blot of female JZs showed a trending increase ($p = 0.1$, $n = 3$) in JNK phosphorylation by nTiO₂, indicating an increase in apoptosis. **Conclusions:** Altogether, these data demonstrate sexually dimorphic and zone-specific immune responses in placentas of gestational nTiO₂ exposure. In general, the female placenta had higher protein concentrations of cytokines when exposed to nTiO₂, which may contribute to the growth restriction and placental zone adaptations seen in female pups. Furthermore, while the JZ had higher mRNA expression of cytokines, changes due to nTiO₂ occurred more in the LZ. Better understanding the sex differences in placental responses can help us to identify mechanisms, pharmacological targets, and markers of poor pregnancy outcomes specific to the fetal sex.

PS 3213 Thyroid dysregulation secondary to hepatic enzyme induction underlies altered ovarian cyclicity in rats exposed to PF-06835919, a KHK inhibitor

S. N. Campion, C. J. Bowman, C. Houle, J. Cook, and J. Zhou. Pfizer Inc., Groton, CT.

Background and Purpose: PF-06835919, a ketohexokinase (KHK) inhibitor being developed for the treatment of non-alcoholic fatty liver disease (NAFLD), caused decreased or absent corpora lutea in the ovary and cornified squamous epithelium in the vagina in a 6-month repeat dose toxicology study in rats. These findings occurred in the presence of liver and thyroid effects that were consistent with PF-06835919-related hepatic enzyme induction. Given that there are numerous reports in the literature indicating that thyroid function is associated with the female reproductive cycle, it was hypothesized that the increased incidence of decreased/absent corpora lutea in the ovary was a result of hypothyroidism secondary to PF-06835919-related UGT (UDP-glucuronosyltransferase) enzyme induction in the rat. **Methods:** An investigative study was conducted to further characterize the ovarian findings and to investigate this potential mechanism. In this study the duration of dosing required prior to onset of estrous cycle disruption and the duration of time needed for the animals

to return to normal cycling following suspension of dosing were evaluated following daily oral administration of 100 mg/kg/day PF-06835919 to female Wistar Han rats. TSH (thyroid stimulating hormone), T3, and T4 levels were also measured. All procedures performed on animals were in accordance with regulations and established guidelines and were reviewed and approved by an Institutional Animal Care and Use Committee or through an ethical review process. **Results:** Estrous cycle disruption (persistent estrus) was noted in 10 of 15 females with onset of disruption occurring between days 33 and 81. Higher TSH (3.8x control) and altered T3/T4 were noted on day 37, indicating that thyroid hormone dysregulation preceded the estrous cycle disruption. This aligns with the thyroid hormone effects with longer dosing in the 6-month rat toxicity study, in which elevations in TSH (7.09x), and a reduction in T3 (0.59x) were observed at 100 mg/kg/day. Consistent with these observations, UGT enzyme induction, including UGT1A1, were confirmed to be induced in a separate 2-week study. Recovery of the estrous cycle disruption occurred in 30% of the animals before the study was terminated due to the onset signs of natural reproductive senescence in several animals, including control animals. **Conclusions:** While a direct link has not been established, all data support the hypothesis that PF-06835919 induction of one or more UGT enzymes and consequent thyroid dysregulation is the cause of altered ovarian cyclicity observed in rat. Although dysregulation of thyroid hormones can result in female reproductive effects in both humans and rats, the mechanism underlying PF-06835919-induced thyroid dysregulation (induction of UGTs leading to altered thyroid hormone levels) is rat specific and therefore not relevant to humans.

PS 3214 The effects of a combination of western diet and phthalate exposure on gene expression levels in the ovary

M. J. Laws¹, S. Kramer¹, Z. Bomstein², A. Deviney¹, K. Lee³, A. Jayaraman⁴, K. Allred², C. Allred², and J. A. Flaws¹. ¹University of Illinois Urbana-Champaign, Urbana, IL; ²University of North Carolina Greensboro, Greensboro, NC; ³Tufts University, Medford, MA; and ⁴Texas A&M University, College Station, TX.

Background and Purpose: Phthalates are a diverse group of chemicals commonly used in a wide range of products, including food packaging, children's toys, and plastic containers. These compounds have been shown to negatively impact female reproductive health, but their effects on the ovary in conjunction with a western diet—characterized by high fat and processed foods prevalent in the United States—are not well understood. Thus, this study tested the hypothesis that combined exposures to a western diet and phthalates affect the ovarian expression of regulators of immune, steroidogenic, and aryl hydrocarbon receptor signaling pathways (*Il-1α*, *Il-1β*, *Il-1r1*, *Il-1r2*, *Il-4*, *Il-6*, *Il-10*, *Tnf-α*, *17β-Hsd*, *3β-Hsd*, *Cyp17a1*, *Cyp11a1*, *Esr1*, *Esr2*, and *Ahr*) and impair production of estradiol levels. **Methods:** To test this hypothesis, female C57BL/6 mice were divided into six experimental groups: control diet, control diet + di(2-ethylhexyl) phthalate (DEHP), control diet + diisononyl phthalate (DiNP), western diet, western diet + DEHP, and western diet + DiNP. RNA was extracted from the ovaries of these mice and subjected to qPCR for measurement of regulators of immune, steroidogenic, and aryl hydrocarbon receptor signaling pathways. Sera was subjected to estradiol ELISA to measure estradiol levels. **Results:** The results indicate that DiNP exposure significantly increased *Il-1β* and *Cyp17a1* expression in the ovary compared to control, irrespective of whether the mice were on a control or western diet. Furthermore, DiNP exposure + control diet and DiNP exposure + western diet significantly decreased *Il-1r2* and *3β-Hsd* expression in the ovary compared to control. DEHP exposure + western diet significantly decreased expression of *Cyp11a1* and *3β-Hsd* compared to control. In contrast, control diet + DEHP, control diet + DiNP, western diet, western diet + DEHP, and western diet + DiNP did not significantly affect the expression of *Il-1α*, *Il-1r1*, *Il-4*, *Il-6*, *Il-10*, *Tnf-α*, *17β-Hsd*, *Esr1*, *Esr2*, or *Ahr* compared to controls. None of the phthalate or diet treatments significantly affected estradiol levels compared to control, but statistical analysis indicated an interaction between phthalates and diet on estradiol levels. **Conclusions:** Overall, these findings indicate that DiNP and western diet exposure alter the expression of some inflammatory and steroidogenic markers in the mouse ovary. Supported by NIH R01 ES034112.

PS 3215 Single Cell Transcriptomics Reveals that Hexavalent Chromium [Cr(VI)] Exposure During Pregnancy Disrupts Uterine Artery Remodeling by Altering the Extracellular Matrix Network.

V. V. Kolla¹, I. P. Saravanan¹, S. S. Romero¹, S. Gupta¹, S. Kluaihanngam¹, S. Azzi¹, S. Krothapalli¹, E. Miller¹, O. Mohr¹, E. Quinones¹, T. K. Lamont², R. E. Rose², D. J. Boland³, J. N. Stallone⁴, J. Arosh¹, J. Cai¹, and S. K. Banu¹. ¹Department of Veterinary Integrative Biosciences, College of Veterinary Medicine & Biomedical Sciences, Texas A&M University, College Station, TX; ²Comparative Medicine Program, Texas A&M University, College Station, TX; ³Texas A&M Institute of Genome Sciences & Society, Texas A&M University, College Station, TX; and ⁴Department of Veterinary Physiology & Pharmacology, College of Veterinary Medicine & Biomedical Sciences, Texas A&M University, College Station, TX.

Background and Purpose: Hexavalent chromium [Cr(VI)] is a heavy metal endocrine disruptor (EDC). Occupational exposure to Cr(VI) affects about half a million industrial workers in the U.S. and several million globally. Significant Cr(VI) contam-

ination has been detected in roughly 30% of drinking water sources in California. According to the U.S. Environmental Protection Agency, the safe level of Cr(VI) in drinking water is 0.01 PPM. However, in some severe pollution incidents in the U.S., including Hinkley, CA, and in developing countries, levels of Cr(VI) in drinking water or groundwater have exceeded the EPA limit by 50 to 500 times. For instance, water in Midland, TX, contains 5.28 PPM Cr(VI). Women exposed to Cr(VI) through occupational or environmental sources experience adverse reproductive outcomes such as preterm labor, miscarriage, and fetal growth restriction (FGR). The molecular mechanisms underlying Cr(VI)-induced FGR remain unclear. Trophoblast remodeling of the uterine artery (UA) is a crucial process during pregnancy, where fetal extravillous trophoblasts (EVTs) invade the maternal uterine spiral arteries. This invasion replaces the endothelial cells of the arteries with trophoblasts, transforming them from high-resistance/low-flow vessels into low-resistance/high-flow ones to ensure adequate blood flow to the developing fetus. Failure of proper remodeling can lead to complications such as preeclampsia and FGR. We hypothesize that Cr(VI) exposure disrupts uterine artery remodeling (UAR) by altering the gene network underlying UAR, leading to arterial thickening or stiffness. **Methods:** Pregnant Sprague-Dawley rats were exposed to 5 PPM Cr(VI) (as potassium dichromate) via drinking water from gestational day (GD) 9.5 to 12.5. On GD 18.5, uterine arteries were collected for histology (H&E, Verhoeff-Van Gieson) and immunohistochemistry (Collagen IV, α-smooth muscle actin [α-SMA]). Single-cell RNA-seq was used to define transcriptional changes in fibroblasts and vascular smooth muscle cells (VSMCs). Differentially expressed genes (DEGs) were visualized using volcano plots, and Gene Ontology enrichment identified dysregulated biological pathways. **Results:** Cr(VI)-exposed arteries displayed thickened vessel walls, reduced luminal diameter, and increased elastin and Collagen IV deposition, consistent with structural stiffening. IHC showed elevated α-SMA expression, indicating heightened vascular contractility. Single-cell transcriptomics revealed fibroblast downregulation of vasodilatory and signaling genes (*Ramp3*, *C1qa*, *Cd74*) and VSMC upregulation of ECM and contractile genes (*Col1a1*, *Col3a1*, *Mgp*, *Gsn*). Enrichment analyses demonstrated activation of ECM organization, collagen fibril formation, angiogenesis, and vasculature development, alongside suppression of cell migration, intracellular signaling, and apoptotic regulation. These data indicate that Cr(VI) exposure reprograms both fibroblast and VSMC gene networks governing matrix homeostasis and vessel elasticity. **Conclusions:** These cellular and molecular alterations indicate that Cr(VI) exposure disrupts vascular remodeling by dysregulating ECM, inducing oxidative stress, and increasing arterial stiffness, leading to restricted blood flow and FGR.

PS 3216 Characterization of tight junctions in a JEG3 cell-based human placental model, widely used in reproductive and developmental toxicity studies

R. Hayashi, Y. Niwa, K. Ikeda, and M. Kondoh. The University of Osaka, Suita, Japan. Sponsor: M. Kondoh, American Society for Pharmacology and Experimental Therapeutics

Background and Purpose: In development of medical products, animal tests have begun to be replaced by *in vitro* and *in silico* tests. Indeed, the U.S. Food and Drug Administration just announced "Roadmap to Reducing Animal Testing in Preclinical Safety Studies" in April 2025. Toxicity results from animal testing poorly predict human toxicity, particularly in reproductive and developmental toxicity. Notably, in perinatal medicine, reliable means for extrapolating to human toxicity are limited. Therefore, cell-based models that accurately mimic the human placental barrier are required for toxicity assessment. However, the structural and functional components of the human placental barrier, particularly tight junctions (TJs), have not been fully characterized. In this study, we investigated the contribution of TJs to barrier properties in an *in vitro* human placental model by examining changes in barrier function following treatment with TJ modulators. **Methods:** Human choriocarcinoma JEG3 cells were used as an *in vitro* human placental model. Cells were cultured on polycarbonate Transwell inserts to form a confluent monolayer for eight days. To evaluate how TJ modulators influence barrier integrity, the monolayer was treated with claudin (CLDN) modulators—including CLDN3/4 binder C-CPE 194, broad CLDN binder C-CPE m19, CLDN5 binder C-CPE mt, and a mutant lacking CLDN affinity C-CPE YL—as well as angulin modulators, including angulin-1/3 binder angubindin-1 and a mutant lacking angulin affinity angubindin-1 4ADE. Trans-epithelial electrical resistance (TEER) was monitored at defined intervals during the 24-hour treatment period, and recovery was further assessed for 24 hours after modulator removal. To assess paracellular permeability, the apparent permeability coefficients (P_{app}) for fluorescein and fluorescein isothiocyanate (FITC)-dextran of different molecular weights (4, 10, 40 and 150 kDa) were determined 24 hours after modulator treatment. Baseline permeability of a small molecule drug, metformin, was also evaluated under non-treated conditions. **Results:** C-CPE 194 and m19 significantly reduced TEER to approximately 20 % of baseline, while C-CPE mt lowered it to 34 %. Angubindin-1 moderately decreased TEER to 75 %. In contrast, C-CPE YL and angubindin-1 4ADE showed no effect, consistent with their lack of binding affinity for CLDNs or angulins, respectively. Recovery of TEER was observed 24 hours after removal of the modulators. Permeability assay demonstrated that the apparent permeability coefficients (P_{app}) of all fluorescent tracers increased in association with TEER reduction. Compared with control, P_{app} values increased by 2.0-3.5-fold in C-CPE 194 and C-CPE m19 groups, 1.5-2.4-fold in C-CPE mt group, and 1.1-1.3-fold in angubindin-1 group. No significant changes were observed in C-CPE YL and angubindin-1 4ADE groups. The P_{app} of metformin after 30 minutes was approximately 2.4-fold higher than that

of fluorescein. **Conclusions:** These findings indicate that CLDN3 and CLDN4 play key roles in maintaining the JEG3 monolayers integrity, as shown by the marked barrier modulation following C-CPE 194 and m19 treatment. Angulin-1 and angulin-3 may also contribute to tricellular TJ integrity, as suggested by the moderate TEER reduction induced by anguibindin-1. Considering the gene expression profile of JEG3 cells, CLDN4 and angulin-1 likely constitute the major structural components of the intercellular TJ seals. Permeability data indicate that TJs restrict paracellular influx of molecules; however, the higher permeability of metformin compared with fluorescein—despite their similar molecular size—implies that active transport mechanisms may also contribute. Overall, these results highlight the importance of characterizing both TJ and transporter functions to enhance the physiological relevance and predictive value of *in vitro* human placental models for reproductive and developmental toxicity testing.

PS 3217 Prenatal and Postnatal PFAS Exposure Induces Sex-Specific Hepatic and Reproductive Organ Hypertrophy in CD-1 Mice

O. N. Avenbuan, M. Watt, T. Tzendzalian, E. Mattingly, and R. C. Fry. University of North Carolina, Chapel Hill, NC.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are ubiquitous in the environment. In line with the developmental origins of health and disease (DoHaD) hypothesis, PFAS exposure early in life (e.g., *in utero*) has been associated with adverse health outcomes such as delayed puberty later in life in both human populations and animal models. During pregnancy, placental and fetal endocrine communication governs hypothalamic-pituitary-gonadal (HPG) axis development. Although the mechanisms underlying these adverse health outcomes are not precisely established, they may include disruption of placental hormones such as leptin, progesterone, estradiol, and human chorionic gonadotropin. This study evaluated the effects of prenatal and postnatal PFAS exposure on organ weight in a CD-1 mouse model. **Methods:** Time-mated CD-1 dams were exposed to perfluorooctanoic acid (PFOA; 0.1, 0.3, 0.5 mg/kg/day), perfluorohexane sulfonate (PFHxS; 0.15, 0.4, 0.65 mg/kg/day), or control water throughout gestation and lactation. Offspring were either sacrificed at postnatal day (PND) 23 or maintained on the same drinking water until pubertal timepoints (males: PND 27, 43; females: PND 40, 56). Body and organ weights were collected, including liver, kidneys, brain, testes (males), uterus & ovaries (females), adrenal glands, and mammary glands (females), and subsequently normalized to body weight. Tissues were collected for subsequent gene-expression and hormone assays. **Results:** PFAS exposure produced sex-specific, dose-dependent effects on organ weights normalized to body weight (expressed as g/g). At PND 56, the combined uterus + ovary weight (g) relative to body weight (g) was significantly elevated in 0.65mg/kg PFHxS (mean $\pm$ SEM = 1.93 ± 0.06 ; $n = 5$) compared all other exposure groups ($p < 0.0001$). This represents an approximate twofold increase in weight relative to the control and lower-dose groups, consistent with uterine and ovarian hypertrophy following chronic PFAS exposure. The hypertrophy effect was specific to 0.65mg/kg PFHxS. Male offspring exhibited no significant differences in relative testis weights across exposure levels or time points, highlighting a female-specific sensitivity to PFAS-mediated endocrine disruption. In the liver, PFAS exposure induced consistent, dose-dependent hypertrophy across developmental stages. At PND 23, females in exposed to 0.3 mg/kg PFOA displayed higher relative liver weights (mean = 9.0 ± 2.59) than those in the control (mean = 5.7 ± 0.296 ; $p < 0.05$). By PND 56, females with all PFOA exposures had livers with weights that remained significantly elevated (means = 6.9 - 9.7) compared to the control (mean = 5.1 ± 0.73 ; $p < 0.05$). Males showed similar trends at PND 43, with relative liver weights in 0.5mg/kg and 0.3 mg/kg PFOA (11.5 ± 0.7 and 10.4 ± 1.07 , respectively) exceeding those in the control (6.4 ± 0.56 ; $p < 0.05$). These findings align with PFAS-induced hepatic hypertrophy, a phenotype associated with PPAR α activation and altered lipid metabolism. **Conclusions:** In summary, pre- and postnatal exposure to PFAS in drinking water was associated with liver hypertrophy in both male and female offspring and reproductive organ hypertrophy in female offspring specifically. Future research will investigate changes in the expression of key puberty-related genes in critical organs such as the liver and gonads.

PS 3218 Cross-Laboratory Reproducibility and Age-Adapted Strategies for Learning and Memory Assessment in Rodents Using Morris and Biel Water Maze Paradigms

D. S. Harischandra¹, S. Beck², J. Proctor-Clarke³, A. Hedge³, and P. Bushdid¹. ¹Labcorp, Greenfield, IN; ²Labcorp, Eye, United Kingdom; and ³Labcorp, Harrogate, United Kingdom.

Background and Purpose: Learning and memory (L&M) assessments are often considered among the least sensitive endpoints in regulatory safety evaluations. However, cognitive integrity is essential for survival, adaptation, and overall neurological health. As regulatory agencies increasingly emphasize the importance of higher-order cognitive function in developmental neurotoxicity (DNT) and general neurobehavioral assessments, the need for reliable and reproducible testing strategies has grown. Standardization of behavioral assays, including room setup, apparatus, visual cues, and harmonized protocols is critical to achieving consistency across laboratories. This study aimed to (1) evaluate inter-laboratory reproducibility

of Morris Water Maze (MWM) performance across geographically distinct sites, and (2) explore age-adapted strategies for dual L&M testing using MWM and Biel Water Maze (BWM) paradigms within the same animals. **Methods:** Sprague Dawley rats were tested under control and scopolamine-treated conditions across four laboratories: GRN (Greenfield, IN, USA), and Eye, Huntingdon, and HAR (Harrogate, UK). All sites followed harmonized protocols for MWM testing, including standardized visual cues and apparatus. Behavioral endpoints included path length, latency to platform, and probe trial performance. To assess cross-laboratory reproducibility, control data from GRN ($n=498/\text{sex}$) and HAR ($n=139/\text{sex}$) were compared. In a separate study arm, age-adapted testing was conducted using MWM in weanling rats (Postnatal Day [PND] 25) and BWM in adolescent rats (PND 60-70), or vice versa. Scopolamine was used as a positive control to evaluate sensitivity of both paradigms. Animals were tested sequentially in both mazes to assess feasibility, performance trends, and potential carryover effects. **Results:** MWM data revealed consistent acquisition and probe trial outcomes across all four sites, demonstrating strong inter-laboratory reproducibility, with statistically significant L&M impairments specifically associated with scopolamine treatment, which served as the positive control to validate assay sensitivity. Analysis of Historical Control Data from GRN and HAR showed highly comparable performance across all key parameters, including path length and latency to platform, despite differences in sample size and geographic location. Probe trial metrics such as platform zone crossings and time spent in the target quadrant were also aligned, supporting the robustness of standardized MWM protocols. In the age-adapted testing arm, weanling rats successfully completed MWM tasks with performance trends similar to older cohorts. These same animals were then tested in BWM, demonstrating reliable egocentric navigation and sensitivity to scopolamine-induced deficits. Reversing the sequence, BWM at weaning and MWM in adulthood was also feasible, with no impact on task acquisition or memory recall. Across both paradigms, scopolamine produced statistically significant impairments in learning and memory, validating the sensitivity of the assays. **Conclusions:** This study confirms that standardized protocols enable robust cross-laboratory reproducibility of MWM outcomes, reinforcing the reliability of behavioral data in safety evaluations. Furthermore, age-adapted dual testing strategies using MWM and BWM offer flexible, developmentally appropriate approaches for assessing spatial and egocentric navigation in rodents. These findings support the integration of multiple cognitive assays into regulatory studies, aligning with evolving expectations for comprehensive neurobehavioral assessment. The ability to reuse animals across paradigms while maintaining data quality enhances study efficiency and animal welfare, while expanding the scope of cognitive evaluation in toxicology.

PS 3219 The Functional Observational Battery in Rats - Results from a Positive Control Study to Support Crop Protection and Chemical Safety Studies

S. A. Beck¹, A. Froud¹, S. Edwards¹, A. Hedge², and S. Renaut¹. ¹Labcorp, Eye, United Kingdom; and ²Labcorp, Harrogate, United Kingdom. Sponsor: D. Harischandra

Background and Purpose: Regulatory guidelines from agencies such as the US EPA and OECD require laboratories conducting neurotoxicity and developmental neurotoxicity studies to periodically validate their procedures using positive control substances. These studies confirm the sensitivity and reliability of the testing methods, equipment, and personnel, especially when key elements change. Guidelines including EPA OPPTS 870.6200, 870.6300, OECD 424, OECD 443, and OECD Guidance Document No. 43 emphasize the need to detect both increases and decreases in behavioral performance. Positive control studies also help demonstrate technician expertise and inter-observer reliability. This study aimed to validate the Functional Observational Battery (FOB) for regulatory neurotoxicity assessments and to confirm its suitability for detecting chemically induced behavioral changes across rat strains. **Methods:** The FOB is a structured assessment of an animal's appearance, behavior and responses to stimuli, performed in a sequence from least to most interactive. It includes a home cage observation, a handheld assessment, an arena evaluation and a series of elicited and quantitative tests such as pupil response, landing footsplay and grip strength. Female Sprague Dawley (SD) and Han Wistar (HW) rats were administered either 3 mg/kg D-Amphetamine or 4/4.3 mg/kg Di-isopropylfluorophosphate (DFP) one hour prior to FOB testing. Animals were at least 42 days old at dosing. These substances were selected for their known neuro-behavioral effects and ability to produce observable changes in behavior and physiology. Observations were recorded using standardized scoring criteria to ensure consistency and inter-observer reliability. Animal care and use was conducted in alignment with animal welfare regulatory requirements in an AAALAC accredited facility and AWERB approved. **Results:** Rats treated with D-Amphetamine exhibited an increased incidence of rearing, fast respiration and an absence of eyelid closure in the home cage. Handheld assessments showed an increase in exophthalmos and increased avoidance behavior when removed from the cage. Arena evaluations showed abnormal high-stepping gait, piloerection, elevated tail posture and increased levels of alertness alongside increased ambulation and rearing counts. Elicited tests revealed excessively dilated pupils, slow or incomplete pupil constriction in response to light and impaired righting reflex. These effects were consistent across both SD and HW strains. Rats treated with DFP exhibited an increased incidence of lying down, jaw chomping, gaping mouth movements and tremors in the home cage and felt cold when held. Arena evaluations showed flattened or hunched posture, gait abnormalities including flattened, high stepping, slow and deliberate, splayed, and ataxic. Alertness was reduced as were the ambulation and rearing counts. Abnormal

motor movements such as jaw chomping and excessive licking were observed and tremors continued. Elicited tests showed a reduced response to stimuli, pupil abnormalities, low body weight and temperature, and increased landing footsplay. These findings were more pronounced in HW rats but observed in both strains. **Conclusions:** Following administration with positive control chemicals, the FOB procedure effectively detected both increases and decreases in behavioral performance. The results confirm the sensitivity of the FOB and its suitability for regulatory neurotoxicity and developmental neurotoxicity studies. The use of standardized scoring and trained technicians supports inter-observer reliability and consistency across strains. These findings underscore the importance of periodic validation using positive controls to maintain the integrity and reliability of behavioral assessments in safety evaluations.

PS 3220 Exploratory Assessment of Preconception Phthalate Exposure and its Impacts on Pregnancy and Offspring Health Outcomes in Mice

M. Afghah, A. C. Elkins, P. C. Powell, M. E. Mulligan, M. C. Boland, A. P. Suggs, M. A. Walker, Z. J. Padgett, and K. D. Rock. Clemson, Clemson, SC.

Background and Purpose: Infertility impacts approximately 10-15% of couples globally and is attributed to environmental exposures disturbing endocrine function. Among endocrine-disrupting chemicals (EDCs), *phthalates* are particularly concerning for their widespread use in consumer products, including cosmetics and feminine hygiene items, and their ability to leach into the environment, resulting in near-universal human exposure. Studies link phthalates with menstrual irregularities, anovulation, and adverse pregnancy outcomes, yet mostly focusing on *gestational* or *postnatal* exposure periods. The *preconception* window, spanning puberty through early adulthood, represents an understudied period when endocrine homeostasis governs oocyte maturation, estrous cyclicity, and uterine receptivity. Preconception perturbations can alter maternal physiology before pregnancy, thereby influencing implantation, placentation, and offspring health. We hypothesized that preconception exposure to a human-relevant phthalate mixture would perturb hormone-dependent processes such as estrous cyclicity and implantation, leading to altered placental architecture, endocrine signaling, and offspring metabolic programming. **Methods:** Female CD-1 mice were orally dosed daily from PND 30-60 with either corn oil or a six-component phthalate mixture (BzBP, DiBP, DiNP, DBP, DEHP, DEP) at 200 µg/kg bw/day, a human-relevant dose based on biomonitoring data. Following a 24-h washout, females were paired with untreated males; sperm plug detection marked embryonic day (E) 0.5. Dams were assigned to three experimental cohorts: (1) implantation (E4.5, via Chicago Blue dye injection), (2) placental/fetal development (E14.5, fetal body weight and placental histology, morphometrics, RNA-seq), and (3) offspring outcomes (PND 60, body weight, reproductive cycling, and liver transcriptomics). A biomarker of hypothalamic-pituitary-gonadal (HPG) axis function was provided monitoring daily maternal estrous cyclicity. Placentas underwent hematoxylin and eosin staining and blinded quantitative ImageJ analysis. Total RNA from E14.5 placentas and PND 60 offspring livers (both sexes) was sequenced on the Illumina platform. Differential expression was analyzed with DESeq2 and edgeR, and GO/KEGG enrichment identified disrupted pathways. **Results:** Preconception exposure modestly altered estrous cyclicity, prolonged preestrus, shortened metestrus, without affecting implantation or litter size. At E14.5, fetuses displayed increased bodyweights accompanied by expansion of the placental junctional zone in males ($\eta^2 = 0.57$). Placental RNA-seq revealed 518 DEGs in females (mostly down-regulated) versus 9 in males. Female placentas showed suppression of immune and steroid-metabolic genes (*SerpinA6*, *Gstm1*, *Cyp21a1*, *Tph1*) and enrichment of complement/coagulation, and lipid homeostasis pathways. Male placentas exhibited limited transcriptional changes but expanded trophoblast layers. In adult offspring, maternal exposure induced sex-specific hepatic reprogramming: females showed down-regulation of *Cyp7a1*, *Mthfr*, and *H2-DMB1* (impaired bile acid and one-carbon metabolism), whereas males up-regulated *Elf4*, *Tnfrsf22* and down-regulated *Adm2*, *Ly6a*, consistent with reduced stress adaptability. Growth trajectories inverted from fetal overgrowth to adult growth restriction, aligning with developmental-origins "thrifty phenotype" programming. **Conclusions:** Preconception phthalate mixture exposure produces subtle but biologically meaningful endocrine disruption, modifies placental structure and transcriptomes, and reprograms offspring metabolic gene networks in a sex-specific manner. These findings identify the preconception period as a critical, previously overlooked window of EDC susceptibility with implications for reproductive success, placental resilience, and intergenerational health. Future work will quantify hormone and metabolite profiles to define the placenta-liver signaling axis underlying these outcomes.

PS 3221 Investigating the molecular mechanism of reproductive dysfunction caused by transgenerational BPA exposure

I. Olaya, L. Truong, and P. Allard. University of California, Los Angeles, Los Angeles, CA.

Background and Purpose: Toxicants can alter the epigenome and cause changes in gene expression. Changes in the epigenome caused by ancestral exposure to toxicants can exhibit transgenerational inheritance, indicating molecular effects on the germline and meiosis. The nematode, *C. elegans*, is a valuable research model

to study the transgenerational molecular and epigenetic effects of toxicants due to its fast reproduction cycle (3 days), utility in toxicological research, well-established distribution of histone marks, and broad conservation of chromatin regulation with humans. Bisphenol A (BPA) is a reproductive toxin associated with recurrent miscarriages in humans and male and female infertility. Ancestral BPA exposure in *C. elegans* causes a transgenerational reduction in repressive histone modifications and an increase in germline apoptosis and embryonic lethality. However, the molecular mechanism of how BPA causes reproductive dysfunction and which processes during meiosis are impaired is not fully understood. **Methods:** Worms were ancestrally exposed to BPA (100 µM) in liquid culture for 48 hours from the L4 stage. After BPA exposure, worms were maintained on plates through the F3 generation without any additional BPA exposure. F3 germlines were used for immunofluorescence to characterize defects in meiotic recombination and synaptonemal complex formation. Genetic analyses were done to assess whether the transgenerational increase in germline apoptosis can be rescued by inactivation of the recombination checkpoint (*spo-11*) and/or synapsis checkpoint (*pch-2*) by counting the number of apoptotic nuclei per germline from ancestral BPA exposure. **Results:** Ancestral BPA exposure causes a significant change in the frequency of crossovers in F3 germlines resulting in nuclei with fewer or excess crossovers than the typical six crossovers that form in *C. elegans* nuclei. Genetic ablation of the synapsis checkpoint after ancestral BPA exposure rescues apoptosis (mean 3.27 apoptotic nuclei) to similar levels as control *pch-2* worms (mean 2.67 apoptotic nuclei), indicating defects in synaptonemal complex formation. We are currently investigating the presence and extent of synapsis defects and whether synapsis defects colocalize with epigenetic aberrations of repressive histone marks. **Conclusions:** Our work can inform our molecular understanding on how BPA can have lasting reproductive effects on generations that were not directly exposed and could provide insight into how other related bisphenols could affect fertility.

PS 3222 Acute Exposure to Perfluorooctanoic Acid (PFOA) Disrupts Steroidogenesis and Mitochondrial Function in Granulosa Cells

D. Um, M. J. Laws, A. E. Dean, R. Santacruz Márquez, and J. A. Flaws. University of Illinois at Urbana-Champaign, Urbana, IL.

Background and Purpose: Perfluorooctanoic acid (PFOA) is a legacy Per- and polyfluoroalkyl substances (PFAS) classified as a long-chain perfluoroalkyl acid and historically employed in various industrial and commercial applications. Due to its bioaccumulative nature arising from the chemical structural characteristics, PFOA has been linked to various toxicological effects, including liver and kidney toxicity. Moreover, recent studies indicate that PFOA exposure contributes to reproductive dysfunction such as hormonal imbalance, reduced birth weight, infertility, and immune toxicity in fetuses. Recent studies further indicate that PFOA exposure induces ovarian dysfunction through disruptions in folliculogenesis, steroidogenesis, and oocyte quality *in vivo*. Despite these findings, the cellular pathways through which PFOA exerts its effects remain insufficiently characterized. Follicular development begins with the primordial follicle containing an oocyte surrounded by a single layer of flattened granulosa cells. As maturation progresses, granulosa cells proliferate and form multiple layers to create the secondary follicle. During this stage, theca cells emerge and cooperate with granulosa cells to synthesize steroid hormones that are essential for follicular growth. Beyond steroidogenesis, granulosa cells supply metabolic substrates and paracrine signals regulating oocyte growth and meiotic competence while maintaining the follicular microenvironment through gap junctions and growth factor secretion. In the preantral and antral stages, granulosa cells produce estrogen and facilitate bidirectional communication between the oocyte and theca cells, thereby supporting oocyte maturation, antrum formation, and overall follicular integrity. Given these key roles, assessing PFOA induced toxicity in granulosa cells can serve as an appropriate model to investigate how PFOA exposure affects female reproductive health. This study investigated how PFOA affects granulosa cell function as a potential mechanism underlying female reproductive toxicity. Specifically, this study tested the hypothesis that PFOA exposure impairs granulosa cell viability and function by inducing oxidative stress, disrupting steroidogenesis, and causing mitochondrial dysfunction. **Methods:** Granulosa cells were collected from antral follicles isolated from ovaries of six-week-old CD-1 mice and cultured *in vitro*. The cells were treated with PFOA at concentrations of 1, 10, 25, 50 and 100 µg/mL for cell viability assays and 50 and 100 µg/mL for oxidative stress and gene expression analyses. Dimethyl sulfoxide (DMSO) was used as the vehicle control for all treatments, which were conducted for up to 72 hours. Cell viability was assessed using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, while reactive oxygen species (ROS) levels and gene expression related to steroidogenesis and mitochondrial function were analyzed by ROS assay and quantitative polymerase chain reaction (qPCR). **Results:** PFOA exposure significantly reduced granulosa cell viability in a dose-dependent manner compared to DMSO vehicle control. It also increased the level of reactive oxygen species and suppressed *Sod1* antioxidant expression. PFOA also decreased *Cyp11a1* and increased *Cyp19a1* expression, indicating that PFOA may alter steroid hormone synthesis. In addition, PFOA exposure increased *Aifm1* and decreased *Ppargc1a* expression, suggesting that PFOA exposure may induce mitochondrial dysfunction and apoptosis activation. **Conclusions:** These results suggest that the PFOA impairs granulosa cell function by inducing oxidative stress, disrupting steroid hormone synthesis, and impairing

mitochondrial function. These cellular alterations may contribute to PFOA-induced ovarian dysfunction and reduce female fertility. Supported by NIH R01 ES034112, T32 ES007326, and T32 HD108075

PS 3223 Differences in placental gene expression by maternal demoralization

A. R. Grayon^{1,2}, E. C. Di Giuseppe², K. W. Riley², M. Caria², H. Hu², J. B. Herbstman², and M. A. Deysenroth². ¹NYU Grossman School of Medicine, New York, NY; and ²Columbia University, New York, NY.

Background and Purpose: Poor maternal mental health has previously been associated with adverse childhood health - including neurodevelopment, metabolic, and immunological issues - through impaired fetal development. The placenta oversees fetal development through several biological pathways and is influenced by maternal health. Emerging evidence has shown that maternal stress can alter placental gene expression, but prior studies primarily focus on changes in expression of individual genes which can limit the mechanistic insight from these findings. Studying the co-expression of genes in the placenta can potentially highlight biological pathways that are implicated with poor maternal mental health. The objective of this study is to explore differences in placental gene networks related to maternal demoralization. **Methods:** Pregnant individuals were enrolled into the Siblings-Hermanos cohort in New York City, and during their prenatal visit they completed a demoralization questionnaire (PERI-D scale). Demoralization has been previously characterized by nonspecific psychological distress and disempowerment. A subset of the cohort had placental biopsies collected (n=89), and sixty-eight of those participants also had maternal demoralization data. RNA was extracted from placental biopsies, and RNA sequencing was conducted to generate transcriptome-wide gene expression levels. Using weighted gene co-expression network analysis (WGCNA), genes were grouped into distinct modules based on the clustering of their expression profiles. Multivariable regression analyses were performed to assess associations between maternal demoralization and module eigengene values. Additionally, we assessed correlations between gene module membership and gene significance with maternal demoralization scores. **Results:** We found that maternal demoralization was positively associated with membership in one of the twenty-two identified modules. The correlation of gene module membership and demoralization gene significance was moderately positive ($r=0.530$, $p=2.32 \times 10^{-15}$). The genes most strongly correlated with demoralization were involved in cellular structure, proliferation, energy production, immune signaling, and other homeostatic processes. **Conclusions:** Maternal demoralization during pregnancy could have implications on placental development, morphology, and signaling. Due to its role in coordinating fetal development through nutrient, hormonal, immune, and inflammatory pathways, the placenta is an important structure to understand how risk factors during pregnancy can lead to adverse outcomes in childhood. These findings provide insight into possible pathways through which maternal demoralization may affect placental physiology and potentially impact fetal development. Future, larger studies can further investigate the relationship between maternal mental health, placental molecular profiles, and associated postnatal outcomes.

PS 3224 Influence of *in utero* and/or lactational exposure to the antidepressant venlafaxine: late repercussions on reproductive and behavioral parameters in male Wistar rats.

B. de Matos Manoel, S. Tawany Caetano Dos Santos, L. Cardoso Valente, L. Trippie Nagaoka, J. Stein, B. Campos Jorge, J. de Castro e Horta Júnior, and A. Arena. São Paulo State University, Botucatu, Brazil. Sponsor: W. Scarano

Background and Purpose: Clinical depression is commonly found in women of child-bearing age, especially during pregnancy and postpartum. Venlafaxine, classified as a Serotonin Norepinephrine Reuptake Inhibitor (SNRI), is one of the main options for the treatment of pre and postnatal depression. As serotonin plays an important role in central nervous system development, *in utero* and lactational exposure to SNRIs may affect hormone-dependent processes such as the hypothalamic sex differentiation process. Additional data comparing exposure to this drug at different critical periods of development are needed. The objective of this study was to evaluate the effects resulting from maternal exposure during pregnancy and/or lactation to the antidepressant venlafaxine on sexual development and possible late repercussions on reproductive and behavioral parameters in male rats. **Methods:** Female Wistar rats were treated daily, via gavage, with distilled water or venlafaxine (4.5 mg/kg/day) during pregnancy and lactation (CGL and VENGL) or only during lactation (CL and VENL). On the 5th day of lactation, the dams underwent maternal behavior assessment. Male offspring were evaluated at different ages (postnatal day - PND-21, 50 and 90) using the following parameters: evaluation of sexual development, play behavior, fertility testing, sexual behavior, quantification of Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA) volume, organ weight, sperm parameters, reactivity of vas deferens and hormonal dosages. **Results:** Females treated with venlafaxine during lactation had a lower weight gain compared to those treated during gestation and lactation. In the male offspring, exposure to venlafaxine in both periods increased anogenital distance at PND1, with an increase in offspring weight in VENGL. On PND 50, animals exposed during gestation and lactation had lower serum

testosterone concentrations. In adulthood, male offspring showed a decrease in liver weight (VENGL), an increase in testis and vas deferens weight (VENGL and VENL), a greater epididymal weight (VENGL) and a smaller SDN-POA volume (VENGL). In the reactivity of the vas deferens, the animals exposed to venlafaxine showed a lower potency of response to the stimulus, as well as a lower maximum response. **Conclusions:** Maternal exposure to venlafaxine during pregnancy and/or lactation altered male offspring development, affecting sexual differentiation, hormone levels, reproductive organ morphology and function. These findings suggest that early-life exposure to venlafaxine may disrupt hormone-dependent developmental processes with lasting reproductive effects.

PS 3225 Novel detection of legacy and emerging per- and polyfluoroalkyl substances (PFAS) in the follicular fluid of *in vitro* fertilization (IVF) patients from North Carolina

S. S. Boney¹, C. Christen², B. A. Wetmore², A. S. Murr², D. Raburn³, S. L. Young³, C. Abraham³, and T. E. Stoker². ¹NIEHS, Durham, NC; ²EPA, Durham, NC; and ³Duke Fertility Center, Durham, NC.

Background and Purpose: North Carolina (NC) has per- and polyfluoroalkyl substances (PFAS) contamination, including the Cape Fear region, as shown by detection in drinking water and serum. However, little is known about PFAS accumulation in human follicular fluid (FF), a critical microenvironment for oocyte maturation. Prior work has shown that PFAS can traverse the blood-follicle barrier, yet no studies have evaluated FF PFAS levels in NC, a region with complex exposure mixtures. Given the key role of FF in oocyte maturation and ovarian hormone regulation, measuring PFAS in this compartment is necessary to better define potential reproductive risks among exposed individuals. The objective of this study was to quantify PFAS in the FF of a cohort of women undergoing *in vitro* fertilization (IVF) in NC. **Methods:** Using targeted PFAS analysis, we measured 23 analytes in the FF collected from 86 IVF patients. At oocyte retrieval, FF from multiple follicles was combined into a pooled sample for each patient, centrifuged at 500 x g for 15 minutes and supernatant stored at -80° until analysis. Patient demographics and basic clinical data were collected. Legacy compounds, alternatives, and emerging ether compounds were measured using UPLC-MS/MS. Detection frequencies and concentrations were evaluated across chemical classes, and cumulative PFAS load was compared between patients with and without an infertility diagnosis and between types of infertility diagnoses using a Kruskal-Wallis rank sum test. Additional correlation analyses were used to compare PFAS load and patient characteristics, as well as to assess associations between analyte detection. **Results:** PFAS were detected in all FF samples. Perfluoroalkyl sulfonic acids (PFSA), particularly PFHxS and PFOS, were measured at the highest concentrations (2.36 and 1.28 ng/mL). Legacy PFCA and PFSA were detected more frequently than emerging alternatives. Notably, hexafluoropropylene oxide dimer acid (GenX) was detected in 88% of samples at relatively low concentrations despite being infrequently reported in human serum. Across patients, 3-16 analytes were present within a concentration range of 0.5-12.8 ng/mL. Cumulative PFAS load did not differ significantly between patients, with and without an infertility diagnosis or between types of diagnoses, although substantial inter-individual variability was observed. Several of the highest detected PFAS analytes were significantly correlated with one another, including PFOS with PFOA, PFNA and PFDA and GenX with PFDS, PFHpS, PFDA and 4:2 FTS. **Conclusions:** This is the first study to characterize PFAS in FF in NC and demonstrates that both legacy and alternative PFAS, including PFDS, PFTrA, and GenX, can cross the blood-follicle barrier and accumulate in FF. These findings expand current understanding of PFAS exposures in reproductive microenvironments and highlight the presence of several compounds not previously reported in NC serum. The detection of multiple PFAS classes in this biologically sensitive compartment supports the need for further evaluation of ovarian PFAS transfer, potential implications for oocyte development, endocrine function, and fertility outcomes. Although we did not detect statistically differences by infertility diagnoses, our findings are important with increasing reports of various PFAS effects on ovarian and reproductive target sites.

PS 3226 Reproductive System Effects in Male C57Bl/6 Mice Exposed to Diesel Exhaust Particulate (DEP) and/or Desert Sand Dust (DSD)

K. MacDonald, L. Schneider, and T. Brown. Defense Centers for Public Health—Aberdeen, Aberdeen Proving Grounds, MD.

Background and Purpose: Warfighters on deployment are often exposed to airborne particulate matter (PM) such as diesel exhaust particulate (DEP) from engine emissions and/or desert sand dust (DSD) that is carried by the wind or kicked up by vehicles—often at levels exceeding exposure rates of the average population. These particulates can enter the lungs when breathed in by the service members, and over time these exposures have been linked to several detrimental health outcomes including respiratory, cardiovascular, and neurodegenerative diseases. Cascading effects beyond the lungs have been known to occur, however DEP and/or DSD effects on the reproductive system are scarcely researched. Therefore, this study investigates several elements of the reproductive systems of male C57Bl/6 mice exposed to DEP, DSD, or a combination of DEP+DSD. **Methods:** Over a 60-day study period, 7-8-week-old male and female C57Bl/6 mice were exposed twice a

week to either sterile saline (control) or a low, medium, or high dose of DEP, DSD, or DEP+DSD suspended in 0.9% sterile saline. The mice were anesthetized with 3-4% isoflurane, prior to exposure via nasal instillation. Mice were euthanized with Euthasol® followed by exsanguination 14-16 hours after their last exposure. Sperm analysis was performed on male mice immediately upon harvest of the epididymis. Sperm was prepared for analysis by slicing open the cauda in warmed M199 buffer and incubated for 5 minutes. The resulting sperm solution was pipetted onto a 2-chamber 100 µm slide and analyzed by the Hamilton ThorneIVOS® II system using the Animal Motility program. Endpoints collected included sperm count, motile cells, progressive cells, percent motile cells, percent progressive cells, and sperm per gram cauda. **Results:** Epididymides were frequently red and inflamed among the low combination exposure group, with occurrences happening less frequently among other groups such as the control, low DSD, medium combination, and high combination. Average sperm counts were significantly lower in the low combination exposure group compared to the medium combination and medium DSD exposure groups; while average motile cell counts and percentage were significantly lower in the low combination group compared to the medium DSD and control groups; and average progressive cell counts were significantly lower in the low combination group compared to the medium DEP and control groups. Other notable differences were found for progressive cell counts and percentage including significantly lower averages for the high DEP, low DSD, high DSD, low combination, and high combination exposure groups relative to the control group. No significant differences were found among any exposure groups for sperm per cauda weight. These findings may suggest interesting toxic effects exhibited by inflamed epididymides correlating with decreased sperm quality/production in the low combination exposure group, as well as potential compound-related effects attributed more to DSD and combination exposures than DEP exposures. **Conclusions:** Further investigation and analyses are currently ongoing; however, these data suggest the combined effect of DEP and DSD have some level of reproductive toxicity in male C57Bl/6 mice. This was evident in the percentage of progressive cells, where five of the ten dose groups had significantly lower average progressive cell percentages relative to the control group. Progressive cells are spermatozoa that achieve forward motion, which facilitates fertility by movement of the sperm towards female eggs during reproduction—without this contact, fertilization cannot occur. Also, several mouse epididymides presented as red and inflamed, most commonly in the low combination exposure group, which is also the group that tended to have the lowest averages for each sperm endpoint compared to the other exposure groups. This suggests some relationship between inflammation and sperm quality/production as a consequence of DEP/DSD reproductive toxicity. Studies testing the reproductive toxic effects of DEP and DSD are limited, and these results support the need for more research to determine if these observed effects can be attributed to compound-related toxicity. DISTRIBUTION A. Approved for public release: distribution unlimited.

PS 3227 Pituitary Hormone Alterations and Inflammatory Responses Associated with Chronic Phthalate Exposure in Female Reproductive Aging

Y. V. Ojo, M. J. Laws, R. Santacruz Márquez, J. A. Flaws, and L. T. Raetzman. University of Illinois, Urbana, IL.

Background and Purpose: Exposure to phthalates, a group of ubiquitous endocrine-disrupting chemicals used in plastics and consumer products, has been associated with a decline in female reproductive health in both human and animal studies. Chronic exposure to phthalates disrupts hypothalamic-pituitary-gonadal signaling, but the mechanism behind this disruption is yet unknown. Focusing on the pituitary gland, we hypothesized that exposure to common phthalates, di(2-ethylhexyl) phthalate (DEHP) and diisononyl phthalate (DiNP), increases pituitary gonadotropins, aryl hydrocarbon receptor (AHR) signaling, and inflammatory markers in aging female mice. **Methods:** To investigate this, adult female CD-1 mice were orally dosed with corn oil or increasing concentrations of DEHP and DiNP for 9 months and 15 months. Pituitary tissues were collected immediately after dosing and analyzed by quantitative PCR (qPCR), cytokine array analysis, and immunohistochemistry. **Results:** Our results showed that chronic phthalate exposure over 9 months did not affect gonadotropin mRNA levels compared to controls. However, exposure to DEHP alone for 9 months showed a borderline increase in *Ahr* mRNA levels, while exposure to both DEHP and DiNP significantly elevated the mRNA expression of the AHR transcriptional target, *Cyp1a1*, compared to controls. Unlike the 9-month phthalate exposure, continuous phthalate dosing for 15 months increased the mRNA levels of gonadotropin and pituitary reproductive hormones compared to controls. DEHP exposure resulted in a borderline increase in *Fshb*, *Lhb*, *Cga*, *Esr1*, and *Gnrhr* mRNA levels, and DiNP exposure increased *Lhb*, *Cga*, *Esr1*, and *Pgr* mRNA levels, compared to controls. Immunohistochemistry revealed that after 9 months, exposure to DiNP alone reduced the number of LH- and FSH-positive cells; however, no changes were observed at 15 months following exposure to either DEHP or DiNP. Additionally, 9 and 15-month phthalate exposure did not alter the mRNA expression of proinflammatory cytokines—*Il1b*, *Il18*, *Tnfa*, but cytokine array analysis showed that the protein levels of other inflammatory markers associated with endothelial cell inflammation were altered. **Conclusions:** Together, these findings suggest that long-term phthalate exposure alters the expression of pituitary hormones and inflammatory markers, which could impact the process of reproductive aging. Supported by NIH R01 ES034112 and a Toxicology Scholar Fellowship from the University of Illinois Urbana-Champaign.

PS 3228 Analyzing the Effects of Charged Oxygen Particle Radiation on the Ovaries of Female Mice

A. Pore¹, K. N. Leon Parada¹, G. Lawson², and U. Luderer¹. ¹University of California, Irvine, Irvine, CA; and ²University of California, Berkeley, Berkeley, CA.

Background and Purpose: As human space exploration pushes beyond Earth's magnetosphere, astronauts face increased exposure to galactic cosmic radiation (GCR). These particles originate from explosions involving supernovae, black holes, and other cosmic events. GCR consists mostly of protons (~85%) and helium nuclei (~14%). Approximately 1% of GCR consists of high charge and energy (HZE) particles, which are unstable ions that travel at high speeds. HZE particles have high linear energy transfer (LET), which causes significant DNA damage. Our previous research has shown that exposure to iron or oxygen (O) radiation causes ovarian damage by reducing the ovarian reserve of oocytes, which are enclosed in ovarian follicles, just one week after exposure. While prior work effectively established that O ions can cause ovarian failure, the long-term histopathological effects of this exposure remain unknown. Understanding all aspects of the biological effects of GCR is increasingly vital, especially for female astronauts, who are underrepresented in research. We hypothesized that ovaries from mice exposed to 50 centigray (cGy) of O ions would have fewer ovarian follicles at all stages (primordial, primary, secondary, and antral), as well as higher tumor prevalence of smooth muscle and theca cell origin compared to controls exposed to 0 cGy of O ions. **Methods:** Female B6C3F1 mice were exposed to 0 or 50 cGy of O ions at three months of age. Ovaries were collected 14-15 months post-exposure, fixed in Bouin's fixative and washed, then stored in 70% ethanol until embedded in paraffin. Every fifth 5-micron paraffin section was stained with hematoxylin and eosin (H&E) for ovarian follicle counts. Follicles were categorized based on established morphological criteria. Corpora lutea and presence of oviductal ovulated eggs were also evaluated. Immunohistochemistry was conducted to identify tumor type using the markers actin, alpha 2, smooth muscle, aorta (α-SMA) for smooth muscle tumors, and cytochrome P450, family 17, subfamily a, polypeptide 1 (CYP17A1) for theca cell tumors. **Results:** Compared to controls, exposure to 50 cGy O ions caused significant and long-lasting ovarian damage, which was seen by an overall decrease of total healthy follicles ($p < 0.001$, Student's T-Test) and presence of tumors. Specifically, there was a significant difference between 0 and 50 cGy irradiated ovaries with primordial ($p = 0.016$, Mann-Whitney U Test), primary ($p = 0.008$), and secondary ($p = 0.008$) follicles. Antral follicles ($p = 0.31$), fresh corpora lutea ($p = 0.056$), and old corpora lutea ($p = 0.151$) did not differ significantly, which is consistent with age-related declines in the numbers and quality of these ovarian components in older mice. Although no smooth muscle tumors were observed, tumors of theca cell origin appeared in irradiated ovaries. **Conclusions:** This research contributes to safeguarding astronaut health during deep space missions and highlights the importance of addressing sex-specific risks as human space exploration expands. Understanding the biological impacts of space radiation on female reproductive health is essential, not just for astronaut safety, but also for the development of effective shielding technologies and medical countermeasures to enable safe human exploration of Mars and beyond.

PS 3228a Diisononyl phthalate exposure increases Cyp1a1 transcript localization in the antral follicle

A. E. Dean, R. Santacruz-Marquez, M. J. Laws, T. A. Seaton, and J. A. Flaws. University of Illinois Urbana-Champaign, Urbana, IL.

Background and Purpose: Phthalates are chemicals commonly used as plasticizers and known endocrine disrupting chemicals (EDCs). Humans are exposed to di(2-ethylhexyl) phthalate (DEHP) and its replacement diisononyl phthalate (DiNP) daily. Exposure to these chemicals over a person's lifetime is a concern because phthalate exposure can accelerate reproductive aging, causing early menopause. Recently, we have shown that phthalates alter aryl hydrocarbon receptor (AHR) signaling in ovarian cells *in vitro*. However, it is not known how phthalates affect AHR signaling in the ovary and throughout reproductive aging *in vivo*. The AHR is a transcription factor that plays a role in ovarian follicle development, function, and xenobiotic metabolism. Once a ligand is bound, the AHR can promote transcription of its downstream targets such as *Cyp1a1* and *Cyp1b1*. We hypothesized that DEHP and DiNP exposure alter the expression of genes in the AHR signaling pathway in the ovary throughout reproductive aging. **Methods:** We treated adult female CD-1 mice with varying doses (0 ppm, 0.15 ppm, 1.5 ppm, or 1500 ppm) of DEHP and DiNP in the diet for 1 and 6 months. The 0.15 ppm and 1.5 ppm doses correspond to human daily exposure and occupational exposure, respectively. We also included a high dose (1500 ppm) to examine dose-response effects. We collected ovaries at each time point and then examined expression of *Ahr*, *Cyp1a1*, and *Cyp1b1* using quantitative polymerase chain reaction (qPCR) for the whole ovary and localization of these transcripts in the antral follicles using RNAscope. **Results:** Since how transcripts in the AHR pathway change throughout reproductive aging has not been characterized, we first determined the expression and localization of transcripts for *Ahr*, *Cyp1a1*, and *Cyp1b1* by comparing the control samples collected at 1 and 6 months. At 6 months, we observed decreased expression in *Cyp1b1* in the whole ovary compared with 1 month samples, but did not observe changes in expression of *Ahr* or *Cyp1a1* over time. However, at 6 months, we observed an increase in *Cyp1a1* transcript, but not *Cyp1b1*, localized in the antral follicle compared to the 1-month time-point. Further, DEHP and DiNP did not alter expression of *Ahr* in the whole ovary at either

time point. DEHP (1500 ppm) increased expression of *Cyp1a1* only after 6 months of exposure compared to control in the whole ovary. DiNP did not alter *Cyp1a1* expression in the whole ovary. Conversely, DEHP did not alter *Cyp1a1* localization in the antral follicle at either time point. However, DiNP (1.5 ppm and 1500 ppm) increased the amount of *Cyp1a1* transcript localized in the antral follicle compared to controls after 6 months of exposure. We did not observe changes in transcript in the whole ovary or localized in the antral follicle for *Cyp1b1* after phthalate exposure at either time point. **Conclusions:** Overall, changes observed in the whole ovary do not reflect the changes observed in the antral follicle over time or with phthalate exposure. Within the antral follicle, DiNP exposure appeared to promote the greatest amount of changes in the *Cyp1a1* transcript in the antral follicle. As *Cyp1a1* plays a role in estrogen metabolism, the observed changes in *Cyp1a1* transcript may have greater implications regarding how DiNP affects estrogen metabolism in the antral follicle. Supported by NIH T32 ES007326, NIH R01 ES034112, the Wanda Haschek-Hock Travel Award, and the Department of Comparative Biosciences Travel Award.

PS 3229 Investigating the Involvement of Pyroptosis in Cutaneous Nitrogen Mustard Induced Toxicity

Z. Kelly, A. Roney, K. Murphy, A. Stammersky, and N. Tewari-Singh. Michigan State University, East Lansing, MI.

Background and Purpose: Sulfur mustard (SM) is a vesicating agent used in chemical warfare. It most readily affects several organs including the exposed skin causing blistering, erythema, edema, and inflammatory consequences. It remains a potential chemical threat today, yet its complete effects on cellular toxicity mechanisms are poorly understood. Its laboratory safe alternative nitrogen mustard (NM) has been shown to induce apoptosis, ferroptosis, and necrosis, but other mechanisms like pyroptosis, a pro-inflammatory programmed cell death process, have not been investigated. The canonical pyroptosis mechanism is a gasdermin-D mediated pathway triggered by the activation of the NOD-like receptor family pyrin domain containing 3 (NLRP3) inflammasome. NLRP3 activation can occur via diverse stimuli including reactive oxygen species (ROS) generation which leads to activation of caspase-1 (casp-1) and activation of gasdermin-D N-terminal which forms membrane pores. Casp-1 also activates pro-inflammatory mediators interleukin-18 (IL-18) and interleukin-1 β (IL-1 β) which are subsequently released through the gasdermin-D pores along with other cellular contents. NM toxicity produces a pro-inflammatory response, oxidative stress, innate immune response, and long-term inflammatory lesions like psoriasis. Since pyroptosis is involved in such responses and may be a cell death pathway involved in NM toxicity, the purpose of this study was to identify if pyroptosis is a cell death mechanism induced by cutaneous NM exposure. **Methods:** To study pyroptosis following cutaneous NM exposure we used an *in vivo* model composed of male C57BL/6 mice (n=5), 7-9 weeks of age. They were exposed to 1 mg of NM or acetone vehicle via topical application to shaved dorsal skin, and groups were euthanized at various time points post-exposure (1, 3, and 8 days) with subsequent skin tissue collection and RNA extraction. We also used an *in vitro* model composed of the skin epidermal human HaCaT cells. Cells were exposed to 50 μ M NM for 2 hours before replacement with fresh media and incubation for an additional 22 hours. Following incubation, cells were collected and RNA was extracted. The skin tissue and HaCaT cells were analyzed for increased expression of pyroptotic genes (NLRP3, Casp-1, and IL-18) via qPCR. **Results:** In the *in vivo* model, our results showed a significant increase in relative fold gene expression of NLRP3, Casp-1, and IL-18 at 1 day and trends at 8 days post NM exposure. Data collection and analysis of these genes and mechanistic studies are underway in our *in vitro* model to confirm pyroptotic cell death following NM exposure. **Conclusions:** Increased expression of pyroptosis related genes 1 day post-exposure indicates that pyroptosis plays a role in acute NM induced skin injury. On going studies aim to further study and confirm the presence of pyroptosis via further molecular and protein analysis at other NM exposures and time points. We will further investigate pyroptosis as a potential target for therapeutic development to counter acute NM induced toxicity that can lead to long-term inflammatory consequences.

PS 3230 NOD1/UPR Signaling Axis in the Pathogenesis of Acute Kidney Injury Following Inhalation of Arsenic Gas Exposure

R. K. Srivastava, A. M. Traylor, J. Khan, S. Muzaffar, S. Esman, R. H. Soliman, J. Akhter, J. J. DeBerry, S. Bolisetty, A. Agarwal, and M. Athar. University of Alabama at Birmingham, Birmingham, AL.

Background and Purpose: Arsenic (military designation SA) gas is the extremely toxic from of inorganic arsenic. During World War II, arsenic was developed as a chemical weapon for its possible use in the battlefield. Fortunately, no evidence exists of its actual use in the combat zone. However, accidental occupational exposure of arsenic is known among industrial workers. The ease with which such a highly toxic gas is prepared may also attract terrorists for its intentional use in small-scale public meetings or concerts. Inhalation of arsenic causes severe red blood cell (RBC) destruction, leading to the release of hemoglobin and heme, which then accumulate in renal tubules and contribute to acute kidney injury (AKI). However, the exact underlying molecular mechanisms of its renal toxicity are poorly understood. Absence of an appropriate animal model that can recapitulate the exact pathogenesis of

arsenic gas is an important gap that needs to be addressed. In this study, we establish and validate a mouse model that manifests arsenic-induced hemolysis-mediated AKI. In addition, we also developed a surrogate model of hemolysis-induced AKI. This model demonstrates similarities with arsenic-exposed murine model and can be used for the screening of potential drug candidates for abrogating arsenic toxicity. **Methods:** A dose-dependent study of arsenic gas (10-25 ppm for 1 hour) was conducted using 10-week-old C57BL/6 mice under nose-only exposure conditions at MRIGlobal (Kansas City). In a parallel, another group of mice received phenylhydrazine (PHZ; 1.5 mg/10 g, intraperitoneally), a well-established hemolytic agent. Mice were euthanized at 24 and 72 h post-exposure and blood, serum, and kidney samples were collected to evaluate hematology and AKI biomarkers of the kidneys. Furthermore, utilizing human proximal tubular kidney cells (HK-2), we investigated a novel molecular signaling axis underlying arsenic gas-induced hemolysis and its role in AKI. **Results:** Inhalation of arsenic gas significantly induces intravascular hemolysis as observed by dark red plasma and bloody urine in our mouse model. These observational changes were associated with a significant decline in RBC count, hemoglobin and hematocrit levels with concomitant increase in urinary heme content at 24 h. These changes accompanied marked increases in biomarkers of AKI, namely NGAL and KIM-1 in both urine and kidneys following arsenic exposure. A significant increase in levels of arsenic in blood and kidney tissue were also prominent. Histopathological analysis revealed tubule injury identified by brush border loss, cytoplasmic vacuolation and appearance of intracytoplasmic iron deposition. Parallel to arsenic-associated AKI, our PHZ treated surrogate model also exhibited similar pathotoxicological responses. In this PHZ model, kidney injury was characterized by hemolysis-induced upregulation of KIM-1 and NGAL in the urine and kidney, with reduced glomerular filtration rate (GFR), a functional marker for renal damage. We found that hemolysis-induced AKI in both models was linked with the activation of nucleotide-binding oligomerization domain 1 (NOD1) and unfolded protein response (UPR) signaling pathway. Western blot analysis demonstrated a significant upregulation of NOD1/2, pRIPK2 and UPR regulated PERK/ATF4/CHOP proteins in the kidney of both arsenic and PHZ exposed mice. In addition, there was a substantial increase in levels of serum and kidney cytokines. Utilizing human proximal tubular kidney cells (HK-2) *in vitro*, we tested the protective effects of ML130 and GSK2656157, a specific inhibitor of NOD1 and PERK, respectively. We found that blocking NOD1 or PERK significantly attenuated expression of inflammatory cytokine (IL-6, IL-8) and cell death markers (cleaved caspase-3 and DR4) along with reduced expression of hemin-induced KIM-1, NOD1 and PERK signaling proteins. **Conclusions:** Our findings reveal that NOD1/UPR signaling pathway axis underpins hemolysis-induced AKI and may serve as a potential therapeutic target for treating arsenic toxicity and perhaps other hemolytic diseases.

PS 3231 Phenylarsine Oxide Disrupts Mitochondrial Function and Redox Signaling in Human Keratinocytes

Y. Jan¹, B. B. Michniak-Kohn², L. B. Joseph³, and J. D. Laskin¹. ¹Department of Environmental and Occupational Health and Justice, School of Public Health, Rutgers University, Piscataway, NJ; ²Department of Pharmaceutics, Ernest Mario School of Pharmacy, Rutgers University, Piscataway, NJ; and ³Department of Pharmacology and Toxicology, Ernest Mario School of Pharmacy, Rutgers University, Piscataway, NJ.

Background and Purpose: Phenylarsine oxide (PAO), a structural analog of the chemical warfare agent Lewisite, is a highly toxic organoarsenic compound and a potential threat to both civilian and military populations. Human skin is particularly vulnerable to PAO. Depending on the dose and exposure duration, it can cause inflammation, edema, and blistering. As a trivalent arsenical, PAO exerts its toxicity primarily through covalent binding to sulfhydryl groups on cysteine residues, thereby disrupting protein structure and function and promoting oxidative stress. These molecular events can alter cellular redox homeostasis, impair metabolic activity, and trigger programmed cell death. In this study, we analyzed the effects of PAO on mitochondrial function and redox signaling in human keratinocytes. **Methods:** Human keratinocytes (HaCaT cells) were maintained in DMEM supplemented with 10% fetal bovine serum. Cells were treated with 0.1-0.4 μ M PAO or vehicle control in serum-free DMEM prepared immediately before use. Protein expression was assessed by western blotting and mitochondrial respiration and glycolysis using an Agilent Seahorse. Production of reactive oxygen species was measured by flow cytometry using dichloro-dihydro-fluorescein diacetate (DCFH-DA). HaCaT bioenergetics, Nrf2 signaling, and ROS production were analyzed up to 4 hr post PAO treatment. Protein expression was assessed 24 hr post PAO treatment. **Results:** PAO treatment inhibited mitochondrial oxidative phosphorylation in HaCaT cells in a concentration- and time-dependent manner, reducing basal, ATP-linked, and maximal respiration; glycolytic activity was also impaired as reflected by reduced basal glycolysis, glycolytic capacity, and glycolytic reserve, indicating that PAO disrupts overall cellular bioenergetics. Western blot analysis revealed that PAO downregulated SIRT1 and SIRT3, key regulators of mitochondrial function and antioxidant defense. Expression of the antioxidants SOD2, catalase, and GPx4 was also reduced by PAO. This correlated with a concentration-dependent increase in intracellular ROS, confirming oxidative stress. PAO also promoted nuclear localization of Nrf2 and upregulated its downstream target HO-1 in a concentration- and time-dependent manner, indicating activation of the Nrf2-mediated antioxidant response. Additionally, PAO increased LC3-II and p62 levels, suggesting induction of autophagy in response to sustained oxidative and metabolic stress. **Conclusions:** Together, these results indicate that

PAO disrupts keratinocyte bioenergetics by impairing both mitochondrial respiration and glycolysis, while simultaneously promoting oxidative stress and activating adaptive antioxidant and autophagic responses. This coordinated dysregulation of metabolic and redox pathways likely underlies the cytotoxic effects of PAO in human skin cells and highlights potential targets for mitigating its toxic impact. This work was supported by National Institute of Environmental Health Sciences (grant/award numbers: P30ES05022 and National Institute of Arthritis and Musculoskeletal and Skin Diseases (grant/award number: U54AR055073).

PS 3232 The Effect of Chemical Threat Agents on Corneal Nerve Injury and Related Biomarkers

A. Stammersky, E. Okoyeocha, C. McGreer, Y. Mohammad, S. Marks, S. Lundback, and N. Tewari-Singh. Michigan State University, Lansing, MI.

Background and Purpose: Chloropicrin (CP) is a potent chemical threat agent (CTA) resulting in severe ocular injury. The eye is the most sensitive organ to CP-induced injury, especially the cornea, due to its tear film acting as a reservoir and anterior location. Exposures can lead to photophobia, dry eye, corneal ulcerations, scarring, and blindness. In recent years, CP has been deployed in warfare in Russia and used as a fumigant for agriculture posing as an additional risk for injury. However, there are still no effective treatments, only symptomatic management. Phosgene Oxime (dichloroform oxime; CX), is another highly toxic vesicant/irritant CTA and penetrates tissues faster than other CTAs with high mortality. We have recently published that CP and CX ocular exposures lead to inflammation and cell death in the cornea. However, very little is known regarding CP and CX toxicity on corneal nerve tissue. Ocular nerves, especially in the cornea, are vital to maintain tissue homeostasis, regeneration, and restore sight. They release key mediators that interplay with immune cells to provide a healthy ocular microenvironment. In this study, we aim to investigate the corneal nerve morphology, function, and related biomarkers of nerve injury post CP and/or CX ocular exposure at time-points vital for injury and regeneration. This in turn will provide further insight into the underlying mechanisms of CP and CX-induced ocular injury and potential targets to develop treatments. **Methods:** CX-exposure was induced in male and female WT (C57BL/6) mice (5-9 weeks) by placing 10 μ l (liquid) for 15 seconds (short duration) and 30 seconds (long duration) using a vapor cap placed on the eye with filter paper. CP-exposure was carried out in male BALB/c mice (5-9 weeks) by placing 2 μ l (liquid) in DMSO at either 2.5% (low dose) or 10% (high dose) for 1 minute. For controls, sham and DMSO were used, respectively. Clinical assessment for corneal sensitivity using a Cochet Bonnet Aesthesiometer (centimeters, cm) was performed. Eyes were collected for corneal flatmount or paraffin-embedded sectioning, staining (B3 Tubulin), and analysis for nerve density (mean fluorescent intensity, MFI), substance P (SP) MFI, nerve length (um), and number of nerve branches. The mRNA was extracted from control and CP-exposed eyes followed by cDNA synthesis and quantitative PCR to determine nerve injury related gene expression (*Tubb3*, *Sp*, *Cgrpr*, *Ngf*). The delta-delta CT method was used to calculate relative gene expression fold change compared to the control housekeeping gene. **Results:** The results demonstrate significantly reduced nerve density at 30 seconds post CX-exposure compared to controls at 24 hr. At day 1 post CP-exposure, there was observed greater expression of substance P (SP) for nerve function and more co-localization with varicosities for 2.5% CP compared to controls and 10% CP. At day 7 post CP-exposure, significantly greater nerve branching and length was observed for 2.5% CP compared to 10% CP, indicating that 10% CP induces greater nerve damage over time. Additionally, corneal sensitivity was significantly reduced for both CP doses, yet 2.5% CP showed recovery by 7 days compared to 10% CP. Currently, the gene expressions of nerve injury related biomarkers are being analyzed. **Conclusions:** These findings strongly suggest CTA exposure, CP and CX, induce corneal nerve damage and higher doses reduce the ability for nerve regeneration and function. These effects may explain the prolonged ocular tissue damage seen post CP and CX-exposure. Additionally, the nervous system and its related nerve injury biomarkers are a promising mechanism to identify therapeutic targets to treat CTAs.

PS 3233 Colony stimulating factor 1 receptor (CSF1R) inhibition mitigates the development of spontaneous recurrent seizures and alleviates neuropathology in adult female rats acutely intoxicated with diisopropylfluorophosphate (DFP)

Y. Tsai, P. M. Andrew, M. A. Munoz, C. M. Unkel, B. P. Davis, J. A. MacMahon, P. N. Bernardino, D. A. Bruun, and P. J. Lein. University of California, Davis, Davis, CA.

Background and Purpose: Acute intoxication with organophosphate (OP) cholinesterase inhibitors can trigger a cholinergic toxidrome that includes seizures that rapidly progress to life-threatening *status epilepticus*. Individuals who survive the acute cholinergic crisis are susceptible to long-term adverse neurological effects, including spontaneous recurrent seizures (SRS) even when standard of care treatment for acute OP poisoning is administered within an optimal therapeutic window. Neuroinflammation is widely posited to contribute to SRS associated with acute OP intoxication; however, attempts to modify neuroinflammatory responses following OP-induced SE have yielded equivocal therapeutic results. However, it is not clear that the inflammatory status of the innate immune cells in the brain changes with

time post-exposure, suggesting that the timing of anti-inflammatory agents is critical. **Methods:** We assessed whether pharmacological deletion of microglia using the CSF1R inhibitor PLX5622 (PLX) administered at varying times post-exposure modified SRS development in a rat model of acute intoxication with the OP diisopropylfluorophosphate (DFP). Adult female Sprague Dawley rats were instrumented for cortical electroencephalography (EEG) and allowed 10 d recovery. Animals were administered DFP (4 mg/kg, s.c.) followed by atropine sulfate (2 mg/kg, im) and 2-PAM (25 mg/kg, im) given 1 min post-DFP, and midazolam (0.65 mg/kg, im) administered at 40 and 50 min post-DFP. Seizure behavior during the first 4 h post-DFP was scored using a modified Racine scale and video-EEG recordings. Animals that exhibited robust SE were randomly assigned to receive vehicle (VEH, 5% DMSO in 20% Kolliphor EL/80% 0.9% saline) or PLX (50 mg/kg, ip, twice daily) from 1-3 or 4-6 days post-exposure (DPE). Animals were euthanized at 28 DPE to collect brain tissues for quantitative immunohistochemical (qIHC) analysis. The amygdala, somatosensory and piriform cortices, hippocampus, and thalamus were immunostained for (1) IBA1 and iNOS or arginase-1, biomarkers of pro- and anti-inflammatory microglia, respectively; (2) GFAP with C3 and S100A10, biomarkers for pro- and anti-inflammatory astrocytes, respectively; and (3) NeuN, a biomarker of mature neurons. **Results:** PLX administration from 1-3 DPE, but not 4-6 DPE, prevented the development of SRS over 28 DPE. Animals that received PLX5622 from 4-6 DPE developed SRS at the same rate with comparable average seizure duration as VEH controls. qIHC indicated that PLX treatment from 1-3 DPE or 4-6 DPE decreased iNOS+ microglia specifically in the piriform cortex ($p < 0.05$), but PLX treatment from 4-6 DPE increased the density of arginase-1+ microglia ($p < 0.05$). PLX did not influence overall astrocyte density; however, DFP animals treated with PLX from 4-6 DPE trended towards a higher density of S100A10+ astrocytes compared to DFP animals treated with PLX from 1-3 DPE. Lastly, treatment with PLX 1-3 DPE increased neuronal cell density at 28 DPE in multiple brain regions when compared to VEH controls or DFP animals treated with PLX from 4-6 DPE. **Conclusions:** Collectively, our results revealed that CSF1R inhibition at specific times following acute OP intoxication may modify epileptogenesis. While PLX treatment doesn't significantly alter the overall density of microglia and astrocytes at 28 DPE, it altered microglial and astrocytic inflammatory responses and was neuroprotective. In conclusion, our data suggest that microglia depletion is a potential therapeutic strategy for mitigating SRS following acute OP-induced SE but that timing of administration is a critical determinant of therapeutic efficacy. This work is supported by the NIH CounterACT Program (U54 NS127758).

PS 3234 Mast Cells Shape Early Pulmonary Inflammation and Regulate the Abundance and Localization of Dendritic Cells after Chloropicrin Exposure

M. Gibb, A. Reinert, A. K. Bauer, and J. M. Brown. CU Anschutz Medical Campus, Aurora, CO.

Background and Purpose: Chemical threat agents remain a significant pulmonary hazard, yet the mechanisms by which they trigger inflammation and modulate immune networks are poorly defined. Chloropicrin (CP; trichloronitromethane) is a highly toxic pulmonary irritant that disrupts the alveolar-capillary barrier, promotes neutrophilic infiltration, and may lead to long-term lung remodeling. Mast cells, strategically positioned near airway epithelium and vasculature, rapidly release cytokines, proteases, and bioactive lipids upon injury, influencing both innate and adaptive immunity. We hypothesized that mast cells are central mediators of CP-induced lung injury, orchestrating neutrophil recruitment, dendritic cell (DC) dynamics, macrophage polarization, and oxylipin metabolism leading to an exacerbation of injury when present. **Methods:** Wild-type C57BL/6J, c-Kit-dependent mast cell-deficient $\text{Kit}^{\text{W-sh}}$, and c-Kit-independent mast cell-deficient $\text{Cpa3-Cre}; \text{Mcl1}^{\text{fl/fl}}$ mice were exposed via oropharyngeal aspiration to 0.1-20 mg/kg CP. Lung injury was assessed via histology (H&E), bronchoalveolar lavage (BAL) cellular differentials, immunohistochemistry, and high-parameter flow cytometry to quantify T cells, neutrophils, cDC1/cDC2 subsets, alveolar (AM) and interstitial macrophages (IM), and cKit+ cells. Immune cell localization relative to the airway epithelium was measured. Semi-targeted UHPLC-MS lipidomics quantified oxylipins in BAL fluid. Statistical analyses employed two-way ANOVA with post hoc testing. **Results:** Wild-type mice displayed pronounced alveolar injury, edema, and inflammatory cell infiltration, whereas $\text{Kit}^{\text{W-sh}}$ mice exhibited preserved alveolar architecture and reduced neutrophilic influx. BAL analysis revealed elevated total cell counts in both strains post-CP exposure, but significantly lower neutrophil percentages in $\text{Kit}^{\text{W-sh}}$ mice (1 mg/kg: 31% vs 15%; 20 mg/kg: 61% vs 46%). cDC1 and cDC2 densities decreased in C57BL/6 lungs (12.7→2.3 and 7.7→4.3 cells/mm²) but increased in $\text{Kit}^{\text{W-sh}}$ mice (4.3→23.7 and 2.0→92.7 cells/mm²). Following CP exposure, cDC1 cells moved closer to the lung epithelium in wild-type mice (~61%) while cDC2 moved closer to the epithelium in $\text{Kit}^{\text{W-sh}}$ (~35%), highlighting MC-dependent spatial redistribution. $\text{Kit}^{\text{W-sh}}$ mice displayed attenuated T cell responses, increased cDC1/cDC2 populations, and preserved Ly6C+ monocytes compared to wild-type mice, indicating a shift toward tissue repair and diminished acute inflammation. Lipidomic profiling revealed near-absent α -linolenic acid and suppressed linolenic acid pathway metabolites (GLA, DHLA, AA) in $\text{Kit}^{\text{W-sh}}$ mice, with diminished EPA/DHA and leukotriene B4/E4 production. Pro-resolving mediators, including 15-keto-PGE₂ and (S)-H₂PE₂, were significantly elevated in wild-type BALF but blunted in mast cell-deficient mice, demonstrating that MCs coordinate both pro-inflammatory and resolution-phase lipid mediator responses. Validation in c-Kit-independent $\text{CPA3-Cre}; \text{Mcl1}^{\text{fl/fl}}$ mice recapitulated these findings, confirming MC-specific effects. **Conclusions:** Mast cells are central regulators of CP-induced

pulmonary injury, promoting neutrophil and T cell recruitment, exacerbating epithelial damage, and suppressing reparative dendritic cell and Ly6C⁺ monocyte/macrophage populations. They coordinate oxylipin metabolism, integrating pro-inflammatory and pro-resolving lipid signaling, which is critical for initiating and resolving lung inflammation. These findings identify mast cells as key drivers of acute chemical-induced lung injury and highlight their potential as therapeutic targets for mitigating inflammation and preventing long-term remodeling.

PS 3235 Comparison of Established and Experimental Skin Decontaminants Against the Nerve Agent VX in Rat Skin and a Three-Dimensional Bioartificial Human Skin Model

A. Schwab¹, D. Steinritz^{1,2}, T. Wille¹, and N. Amend^{1,2}. ¹Bundeswehr Institute of Pharmacology and Toxicology, Munich, Germany; and ²Walther-Straub-Institute of Pharmacology and Toxicology, Faculty of Medicine, Ludwig-Maximilians-Universität München, Munich, Germany.

Background and Purpose: The Chemical Weapons Convention prohibits the development, production, stockpiling, and use of chemical weapons. Nevertheless, nerve agent exposure remains a persistent threat. Given the limited efficacy of currently approved antidotes, effective skin decontamination following percutaneous exposure is critical to prevent systemic uptake. In this study, rat skin (shaved, without connective and adipose tissue) and a full-thickness, three-dimensional bioartificial human skin model were used to evaluate the efficacy of various decontamination protocols on the dermal penetration and diffusion of the nerve agent VX using Franz diffusion cells. **Methods:** Decontamination was initiated 5 or 30 minutes after exposure to VX (10% v/v; 10 µL applied to 1.5 cm²) at 35°C. Samples were collected every 30 minutes for 5 hours (mean, n=5). The decontamination efficacy of Reactive Skin Decontamination Lotion (RSDL), potassium salt of acetohydroxamic acid (AHAK; 880 mg/mL, 250 µL), sodium hypochlorite (NaOCl; 2%, 250 µL), and tap water (250 µL) was assessed. RSDL was applied using fully soaked sponge disks (0.8 cm diameter) with 10 circular motions in alternating directions, left for 2 minutes, and then removed with gauze. NaOCl and water were applied for 2 minutes and similarly removed. AHAK was applied for the full experimental duration (5 hours) according to a previously published protocol (Bloch-Shilderman et al., *Arch. Toxicol.* 2023, 97:2771-2783) to neutralize agent within the dermal depot. VX penetration into the acceptor chamber was quantified using a modified Ellman enzymatic assay, and results were expressed as percent reduction of inhibitory activity relative to untreated controls. **Results:** RSDL, an FDA-approved skin decontaminant, achieved substantial efficacy in rat skin (99.7% after 5 min; 95.0% after 30 min) and comparable results in the human model (96.2% and 85.5%, respectively). NaOCl (2%) reduced VX penetration by 94.0% and 79.0% in rat skin and by 92.5% and 81.0% in human skin at 5 and 30 minutes, respectively, without causing visible tissue damage. In contrast, 10% NaOCl caused macroscopic damage to the human model. Tap water showed moderate efficacy after 5 minutes (84.8% in rat; 91.2% in human skin) but poor performance at 30 minutes (0.8% and 49.6%). AHAK achieved excellent decontamination in both models (rat: 99.5% and 97.9%; human: 99.9% and 99.6% at 5 and 30 min, respectively). Moreover, prophylactic AHAK application, whether removed or left in place before VX exposure, provided near-complete protection (99.9%) in the human skin model. **Conclusions:** In summary, both models demonstrated consistent trends in VX penetration and decontamination efficacy. Hydrophilic agents (water, NaOCl 2%) were less effective, particularly when decontamination was delayed. RSDL and the experimental compound AHAK showed superior performance, with AHAK exhibiting comparable efficacy to RSDL. These findings highlight AHAK as a promising, cost-effective candidate for both post-exposure skin decontamination and prophylactic protection against VX.

PS 3236 Evaluation of novel oximes as antidotes for an organophosphate requiring bioactivation in rats.

E. Meek, N. Busby, and J. Chambers. Center for Environmental Health Sciences, College of Veterinary Medicine, Mississippi State University, Mississippi State, MS.

Background and Purpose: Organophosphates (OP) are a group of synthetic chemicals that include nerve agents and some insecticides. The mechanism of toxic action for OPs is the inhibition of the enzyme, acetylcholinesterase (AChE). Many of the insecticidal OPs must be bioactivated, via cytochrome P450s (CYPs), to an active metabolite(s) to inhibit AChE. One such OP is phorate, an insecticide that can be bioactivated to multiple anticholinesterase metabolites. Phorate is very toxic with acute exposures in rats resulting in a delay in toxic signs compared to OPs of similar structure. Once initiated, the progression of toxic signs is very rapid. Standard of care (SOC) for OP intoxication includes atropine (antimuscarinic) and an oxime to reactivate OP inhibited AChE. The currently approved oxime (pralidoxime, 2-PAM) can reactivate OP inhibited AChE but has very limited ability to cross the blood-brain barrier (BBB) and reactivate OP inhibited brain AChE. Our laboratory has synthesized and tested a series of novel pyridinium oximes (US Patent 9,227,937) that have previously been shown to cross the BBB, reactivate OP inhibited brain AChE and enhance survival following lethal exposures to OPs. These oximes have longer half-lives (several hours) than 2-PAM (about an hour) and can reactivate OP-inhibited plasma butyrylcholinesterase (BChE), converting it to a pseudo-catalytic OP scavenger. In

this project, we evaluated some of our oximes to provide greater survival efficacy than 2-PAM to lethal doses of phorate. **Methods:** Phorate and its major metabolites were tested *in vitro* for potency as inhibitors of rat brain AChE using a spectrophotometric assay. Bioactivation of phorate to its anticholinesterase metabolites was measured spectrophotometrically *in vitro* using both rat and human hepatic microsomes. A lethal dose (LD₅₀) *in vivo* phorate rat model was established to determine the therapeutic window for evaluating oxime efficacy. Male and female rats were challenged with phorate (LD₅₀) in a biocompatible solvent (multisol) followed by administration of novel oxime (IM) 146 µmol/kg (human 2-PAM molar equivalent dosage, HED) or 2-PAM. Atropine [0.65 mg/kg atropine (HED) in saline IM] and novel oxime in a biocompatible vehicle, 90% water and 10% benzyl alcohol were administered at the time of initiation of seizure-like behavior for phorate challenged rats. Brain and blood were collected at the time of death or in 24-hour survivors and brain AChE and serum BChE activities were determined spectrophotometrically. To evaluate the role of BChE, rats were administered Iso-OMPA, a specific BChE inhibitor, 1 mg/kg IM one hour prior to phorate challenge and compared to rats not administered Iso-OMPA. **Results:** *In vitro* potency (AChE IC₅₀s) of phorate-oxon metabolites was much greater (nanomolar) than the parent compound (molar). Phorate incubation with hepatic microsomes produced anticholinesterase activity that was NADPH-dependent (CYP bioactivation). An LD₅₀ challenge of phorate (12 mg/kg) in both male and female atropinized rats resulted in death occurring at about 3 hours for female rats and about 4.5 hours for male rats. Novel oximes were selected for efficacy (24-hour survival) testing based on *in vitro* AChE reactivation and *in vivo* pharmacokinetics (longer half-life in the blood, compared to 2-PAM). Oxime efficacy studies following a lethal phorate challenge resulted in greater than 70% survival compared to about 60% for 2-PAM. Limited results from the Iso-OMPA pre-treated rats indicate that survival is decreased in rats with non-functional BChE. **Conclusions:** Phorate exposure results in a delay in the cholinergic toxidrome, compared to many other OPs, making it a challenging compound to develop countermeasures against it. We have observed promising *in vivo* therapeutic efficacy of our novel oximes against phorate toxicity when administered at the signs of severe poisoning. Survival efficacy in the *in vivo* experiments seem to be enhanced with the novel oxime's longer half-life. The ability of the novel oximes to reactivate OP-inhibited BChE plays a significant role in increased survival following phorate challenge, as evidenced by improved survival in rats exposed to phorate with functional BChE. These data are important in the continued development of these novel oximes as a treatment for OP poisoning. Supported by NIH R21NS131159-01 and U01 NS123255-03.

PS 3237 Soluble epoxide hydrolase as a therapeutic target for mitigating the adverse neurological consequences of acute organophosphate intoxication

M. A. Muñoz, J. A. MacMahon, D. A. Bruun, Y. H. Tsai, C. M. Unkel, B. P. Davis, N. H. Saito, D. J. Harvey, B. D. Hammock, and P. J. Lein. University of California Davis, Davis, CA.

Background and Purpose: Acute intoxication with OP cholinesterase inhibitors, which include pesticides and nerve agents, can cause a cholinergic crisis that rapidly progresses to status epilepticus. Survivors can develop long-term neurological consequences, including persistent brain injury, epilepsy and cognitive impairment. Current standard of care (atropine, oxime and a benzodiazepine) increases survival, but does not effectively protect against chronic adverse neurological outcomes, highlighting the urgent need for more effective therapeutic strategies. We are investigating the pharmacological inhibition of sEH, which catalyzes the conversion of the anti-inflammatory lipid epoxyeicosatrienoic acid (EET) to pro-inflammatory lipid derivatives. Using a rat model of acute intoxication with the OP diisopropylfluorophosphate (DFP), we previously showed that EET is reduced in the brain of male rats during the first 3 d post-DFP, coincident with increased levels of pro-inflammatory lipids. Here, we tested whether administration of the sEH inhibitor 1-(1-propionylpiperidin-4-yl)-3-(4-trifluoromethoxy) phenyl) urea (TPPU) improved neurological outcomes. **Methods:** Adult female Sprague Dawley rats were randomly divided into groups for immunohistochemical (IHC) or electroencephalographic (EEG) analyses and within these, randomly assigned to vehicle (VEH) or TPPU (DFP+VEH vs. DFP+TPPU) groups. For EEG analyses, animals were implanted with telemetry devices 10 d prior to experimentation. In all experiments, animals were intoxicated with DFP (4 mg/kg, sc) followed 1 min later with atropine sulfate (2 mg/kg, im) and 2-pralidoxime (25 mg/kg, im) then two sequential doses of midazolam (0.65 mg/kg, im) at 40 and 50 min post-DFP. TPPU (1 mg/kg, ip) or an equal volume of VEH (20% PEG400, ip) were given once daily from 1 - 7 d post-exposure (DPE). Animals implanted with EEG telemeters were continuously monitored up to 36 DPE to quantify seizure frequency, and underwent behavioral tests (open field, fear conditioning) starting 1 mo post-DFP. Non-surgerized animals were euthanized at 3, 7 and 21 DPE to collect brain tissue for IHC analyses. Tissue sections were immunostained for GFAP, an astrocytic biomarker, or stained with Fluoro-Jade-C to visualize degenerating neurons. IHC data were analyzed using two-way ANOVA and mixed effects modeling; seizure data, repeated measures ANOVA; behavior data, unpaired t-test and two-way ANOVA. **Results:** DFP triggered acute status epilepticus as determined electrographically or behaviorally. There were no significant group differences in the % area of GFAP immunoreactivity in the dentate gyrus or piriform cortex nor in number of FJC-immunopositive cells in the somatosensory and piriform cortices, amygdala, thalamus and hippocampus at any timepoint (p < 0.05; n=6-10 animals/group). No significant group differences were detected in the number of seizures

up to 3 weeks post-DFF, the velocity or distance moved in the open field test, or the average motion index in the fear conditioning task ($p < 0.05$; $n=8-9$ animals/group). **Conclusions:** These data do not support sEH as a therapeutic target in female rats acutely intoxicated with DFP. However, whether this is because the lipid profile after OP intoxication differs in the female vs. male brain or whether a different therapeutic window or dose of TPPU would be efficacious remains to be determined. Supported by the NIH CounterACT program (U54 NS127758). MM was supported by the Northern California Achievement Rewards for College Scientists (ARCS); BD by a predoctoral fellowship (T32GM136559).

PS 3238 Exploration of Mechanisms Driving Nitrogen Mustard-Induced Injury in Mouse Skin

A. Roney¹, D. Goswami¹, E. Okoyeocha¹, K. Murphy¹, S. Lundback¹, O. Madadgar¹, E. Kim¹, Z. Kelly¹, S. Veluru¹, S. Ojha¹, A. Stambersky¹, S. Saha², E. Noland¹, J. Brown³, and N. Tewari-Singh¹. ¹Michigan State University, East Lansing, MI; ²University of Kansas Medical Center, Kansas City, KS; and ³University of Colorado Anschutz Medical Campus, Aurora, CO.

Background and Purpose: Sulfur mustard (SM) is the most widely used chemical warfare agent and belongs to the vesicant, or blister, agent class. SM causes debilitating blisters and inflammation in the acute phase of injury with psoriasis, fibrosis, and chronic inflammation developing in victims years later. SM was used extensively during World War 1 and its use was confirmed in the more recent Syrian Civil War. SM's ease of manufacture and its potency as a weapon make it highly attractive to terrorist groups. The threat of SM is exacerbated by our lack of effective targeted therapies. The development of such therapies is impaired by our lack of understanding of the mechanisms driving the toxic effects of SM, especially the long-term effects. We carried out a study characterizing the long-term dermal injury induced by nitrogen mustard (NM, an analog of SM) that heavily implicated mast cell activity and chemokine (C-C motif) ligand/receptor 2 (CCL2/CCR2) signaling in NM-induced dermal injury. Preliminary studies were then conducted to assess the role of these two potential drivers of NM-induced injury. **Methods:** Male C57BL/6 mice (age 5-6 weeks) were exposed on their dorsal skin to 0.5 mg NM dissolved in 100 μ L acetone or acetone alone. Mice were euthanized and skin samples collected at 1-, 7-, 14-, 29-, and 84-days post-exposure. The preliminary studies examining mast cells and CCL2 signaling utilized male C57BL/6 (WT), mast cell-deficient B6.Cg-Kit^{W-sh}/HnJrJaeBsmJ (MCD), and CCR2 knock-out B6.129S4-Ccr2tm1lf/J (CCR2KO) mice of the same age and given the same treatment as in the long-term study. Mice in the MCD study were sacrificed at day 14 post-exposure and mice in the CCR2KO study were sacrificed at day 63 post-exposure. Clinical analyses were made throughout the study and skin samples were flash frozen for PCR analysis or fixed for sectioning and histological analyses. **Results:** NM induced significant and persistent mast cell activation and upregulation of CCL2/CCR2 expression in C57BL/6 mice. CCR2KO mice had less severe weight loss, reduced mast cell activity, and reduced expression of inflammatory markers compared to WT mice following NM exposure. MCD mice had improved survivability and reduced expression of CCL2 and other inflammatory markers compared to WT mice following NM exposure. **Conclusions:** These observations indicate significant roles for mast cell activity and CCL2/CCR2 signaling, and the interactions between these pathways, in mustard agent-induced dermal injury. Further studies and analyses will need to be performed to better clarify the role of these pathways in mustard agent-induced injury and how these pathways synergize with each other to produce said injury. These studies will influence future studies exploring the efficacy of therapies targeting these pathways in counteracting mustard agent toxicity.

PS 3239 Characterization of Circulating miRNAs in Rodents after Pulmonary Exposure to Nitrogen Mustard

C. J. Rogers¹, J. D. de Leon¹, L. Uechi¹, T. A. Miller¹, K. N. Vayas², E. Abramova², R. Rancourt², P. Zhou², V. R. Sunil², J. D. Laskin², and D. L. Laskin². ¹ChromoLogic, Monrovia, CA; and ²Rutgers, The State University of New Jersey, Piscataway, NJ.

Background and Purpose: Acute exposure to ionizing radiation (IR) or chemical warfare agents including mustard vesicants such as sulfur mustard and nitrogen mustard (NM) can lead to chronic lung disease, resulting in long-term morbidity and mortality months to years after the initial insult. Both IR and NM exert their harmful effects primarily through DNA damage. Notably, the DNA-damaging effects of NM were recognized as "radiomimetic" 75 years ago, highlighting their mechanistic similarity to radiation-induced injury. Both IR and NM cause DNA single- and double-strand breaks; NM alkylates DNA, causing inter- and intra-strand crosslinking. DNA damage from both agents leads to cell cycle arrest, apoptosis, oxidative stress, and inflammation. We observed conserved miRNA responses in plasma from mice, non-human primates and humans following exposure to IR leading to pulmonary fibrosis. Dysregulation of miRNAs included increases in miR-34 family members and decreases in miR-155-5p and miR-199 family members. Changes in these miRNAs were linked to pathways associated with fibrosis, within the first 30 days post exposure. In the present studies, we analyzed the effects of NM exposure on plasma miRNAs with the overall goal of identifying a common repertoire of miRNAs that could be used to pre-symptomatically predict the onset of pulmo-

nary fibrosis. **Methods:** Male Wistar rats (225-250 g) were treated intratracheally with NM (0.125 mg/kg) or PBS control using a 22-gauge gavage needle (1.25 mm ball diameter). Animals were euthanized 1, 3, 7, 14, or 28 days later and plasma collected ($n = 3-6$ per time point). Small RNAs were extracted, sequencing libraries prepared, and mature miRNA sequences quantified using next-generation sequencing. Longitudinal miRNA profiles for PBS and NM-treated animals were fit to a regression spline model using 3 degrees of freedom (df) that assumes miRNA expression changes smoothly over time. A moderated F-test was conducted on each miRNA on 3 df to detect differences between treatment and control groups. miRNA with FDR-corrected p-values < 0.05 were considered significant. **Results:** The top four plasma miRNAs altered by NM exposure (miR-126a-3p, miR-199a-5p, miR-155-5p, and miR-34c-5p) corresponded to those identified in plasma after IR exposure. These miRNAs regulate signaling pathways linked to fibrogenesis. Plasma levels of these miRNAs increased rapidly following NM exposure reaching a peak at 3 d; this was followed by a decrease at 14 d. By 28 d post-NM, miR-126a-3p, miR-199a-5p, and miR-155-5p were at control levels, while miR-34c-5p remained reduced. **Conclusions:** The relative abundance of miRNAs in plasma is increasingly recognized as a reflection of tissue-specific physiology. Importantly, changes in circulating miRNA profiles have been shown to indicate organ damage prior to the onset of clinical symptoms, offering a window for early detection and timely medical intervention. Our findings that two well characterized pulmonary toxicants known to cause fibrosis, NM and IR, induce similar preclinical changes in circulating miRNAs suggest that selective groups of miRNAs may be useful as predictive biomarkers for the development of this chronic lung disease.

PS 3240 Verapamil Protects Neurons Via NADPH Oxidase Inhibition in A Rat Model of Organophosphate DFP-Induced Status Epilepticus

Y. Paudel, R. Blair, E. Hawkins, S. Kulkarni, and L. Deshpande. Virginia Commonwealth University, Richmond, VA.

Background and Purpose: Exposure to organophosphate (OP) compounds at high doses leads to status epilepticus (SE) and rapid death. Current standard-of-care therapy aimed at controlling cholinergic response and SE has improved mortality outcomes. However, OP-SE survival is associated with long-term neurological morbidities, including recurrent seizures and memory deficits. Targeting neuronal injury pathways and inflammatory mechanisms has produced beneficial outcomes in rat models of OP-SE. Verapamil (VPM) is a calcium channel blocker used clinically to manage blood pressure. VPM has been reported to reduce cell death and ameliorate inflammation in animal models of CNS injuries. In this study, we tested whether adjunct treatment with VPM could exert neuroprotective and anti-inflammatory effects following OP toxicity. **Methods:** Rats (SD; male and female; 250-300g) were injected with DFP (4 mg/kg, S.C.). One minute later, atropine sulfate (0.5 mg/kg, IM) and 2-PAM (25 mg/kg, IM) were injected. Rats immediately developed SE, which was then controlled with midazolam (1.78 mg/kg, IM) at 1 h post-SE onset. Rats were then treated with VPM (10 mg/kg, IM) *b.i.d.* for 3 days. On the fourth day, rats were perfused, and brains were post-fixed for sectioning. A separate cohort of rats was euthanized and brains freshly dissected, and brain regions were flash frozen and stored at -80°C. Neuronal injury was assessed using the FJC staining. Activation of microglia and astrocytes, and NADPH oxidase expression, were detected by immunohistochemistry using their respective markers IBA1, GFAP, and gp91phox. Cytokine expression was assessed using antibody-specific western blotting. **Results:** DFP exposure produced a rapid onset of SE. VPM combined with atropine, 2-PAM, and midazolam therapy was well tolerated, and no significant increase in mortality was observed compared with rats treated with the standard-of-care alone. Extensive FJC+ staining indicative of dying neurons was seen in multiple brain regions from DFP-SE rats, which was markedly reduced in VPM-treated DFP rats. Significant numbers of IBA1+ and GFAP+ cells were observed in DFP-treated rats, which were reduced upon VPM treatment. Western blotting studies showed a significant (7-fold) increase in the pro-inflammatory cytokine IL-6 and a significant (4-fold) decrease in the anti-inflammatory cytokine IL-4 expression in DFP rats compared to the control condition. Quantification of gp91phox and IBA1 colocalized microglial cells showed significant increases in % area colocalized in DFP-SE rats compared to SAL-SAL control. Upon VPM treatment, significant reductions in % area colocalized for gp91phox were noted in multiple brain regions (Two-way ANOVA (sex x treatment) followed by post-hoc Sidak test. $*p < 0.05$, $n = 6-8$ /group/condition). **Conclusions:** VPM delivered via the IM route post-OP-SE exerted significant neuroprotective and anti-neuroinflammatory effects compared with standard-of-care alone. VPM treatment significantly reduced the rise in IL-6 levels and restored IL-4 to control levels in DFP-VPM rats compared to DFP-SAL. VPM treatment was also associated with a significant reduction in the microglial gp91phox expression. Given NADPH oxidase's role in driving inflammatory response via oxidative stress, VPM exerts a potent anti-inflammatory effect by inhibiting NADPH oxidase in OP-SE. We anticipate that these protective effects of VPM would improve long-term neurological outcomes following DFP-SE.

PS 3241 Nitro-oleic Acid Mitigates Chlorine-Induced Lung Injury in Mice by Suppressing Pro-inflammatory Activity of Macrophages and Neutrophils

R. Malaviya¹, A. J. Gow¹, B. Freeman², R. C. Rancourt¹, J. Radbel¹, E. Abramova¹, K. N. Vayas¹, J. D. Laskin¹, and D. L. Laskin¹. ¹Rutgers University, Piscataway, NJ; and ²University of Pittsburgh, Pittsburgh, PA.

Background and Purpose: Chlorine (Cl₂) is a highly reactive gas which upon inhalation triggers extensive airway injury, including bronchiolar epithelial cell damage, disruption of epithelial barrier integrity, oxidative stress, accumulation of inflammatory cells within the lung, and impaired pulmonary mechanics. Nitrated fatty acids, such as nitro-oleic acid (OA-NO₂), are formed by the reaction of reactive nitrogen species and unsaturated fatty acids. Earlier studies demonstrated that nitrated fatty acids exert anti-inflammatory activity. In this study, we investigated the potential of OA-NO₂ to mitigate Cl₂-induced lung injury, oxidative stress and inflammation. **Methods:** Spontaneously breathing male C57BL/6 mice were exposed to air or Cl₂ (300 ppm, 25 min) in a whole-body exposure chamber; mice were treated i.v. with 50 µg OA-NO₂ or vehicle control 30-45 min later. Bronchoalveolar lavage (BAL) fluid and cells and lung tissue were collected 24 h later and analyzed for markers of injury, oxidative stress, and inflammatory cell activation. **Results:** Exposure of mice to Cl₂ resulted in peribronchial edema and inflammation, and necrosis of the bronchiolar epithelium. This was associated with an accumulation of bronchiolar epithelial cell debris in the alveoli, and upregulation of oxidative stress markers including heme oxygenase (HO)-1 and Ym-1. Cl₂ inhalation also increased levels of cells, IgM, total protein, and fibrinogen in BAL fluid indicating alveolar epithelial barrier dysfunction. BAL levels of surfactant protein (SP-D), soluble receptor for glycation end products (sRAGE) and matrix metalloproteinase (MMP)-9 also increased, consistent with pulmonary inflammation. Structural and inflammatory changes in the lung following Cl₂ inhalation were linked to functional alterations including a loss of elastic recoil properties, as reflected by a leftward shift in the pressure volume (PV) loops and significant increases in airway resistance and elastance in response to methacholine (12 mg/ml). Flow cytometric analysis of CD45⁺ lung cells showed significant increases in immature (CD11b⁺Ly6G⁺CD11c⁺ Ly6C^{hi}) and mature (CD11b⁺Ly6G⁺CD11c⁺ Ly6C^{lo}) pro-inflammatory macrophages, and CD11b⁺Ly6G⁺CD11c⁺ neutrophils in the lungs following Cl₂ exposure, with no effect on anti-inflammatory (CD11b⁺Ly6G⁺CD11c⁺ Ly6C^{lo}) macrophages, while CD11b⁺Ly6G⁺Ly6C⁺CD11c⁺Siglec F⁺ resident macrophages were reduced. This was correlated with increases in numbers of alveolar macrophages expressing cyclooxygenase (COX)-2 and inducible nitric oxide synthase (iNOS), markers of pro-inflammatory activation. Treatment of mice with OA-NO₂ mitigated Cl₂-induced peribronchial edema and inflammation, along with macrophage expression of HO-1 and Ym-1; alterations in pulmonary mechanics were also blunted. Numbers of immature pro-inflammatory macrophages and neutrophils were also reduced by OA-NO₂, a response associated with reduced expression of COX-2 and iNOS. Conversely, numbers of mature anti-inflammatory and resident macrophages were increased after OA-NO₂ administration to Cl₂ treated mice; macrophage expression of CD206 also increased. We also identified a population of immunosuppressive CD11b⁺Ly6G⁺CD11c⁺ neutrophils in the lungs of mice treated with Cl₂ and OA-NO₂. **Conclusions:** These findings demonstrate that OA-NO₂ reduces lung injury and oxidative stress following Cl₂ inhalation. We speculate that this is due to suppression of pro-inflammatory macrophages and neutrophils and activation of anti-inflammatory macrophages. Supported by NIH Grants U54AR055073 and P30ES005022.

PS 3242 Sulfur Mustard Alters Fatty Acid Synthase Expression During Rabbit Meibocyte Differentiation

L. B. Joseph¹, P. Zhou¹, C. R. Croutch², and J. D. Laskin¹. ¹Rutgers, The State University of New Jersey, Piscataway, NJ; and ²MRIGlobal, Kansas City, MO.

Background and Purpose: Sulfur mustard (SM; bis(2-chloroethyl)sulfide) is a cytotoxic vesicant known to induce chronic ocular injury. Characteristic long-term responses of the eye to SM include persistent inflammation, corneal opacity, and instability of the tear film. This is attributed, in part, to impaired tear film formation resulting from the dysregulation of conjunctival mucin secretion and meibomian gland (meibum) production, an oily secretion produced by differentiated meibocytes. Meibomian glands are a type of holocrine exocrine gland located along the tarsal plate of the eyelids; they play an essential role in maintaining corneal surface integrity and preventing tear film evaporation. Herein, we used the New Zealand white rabbit corneal exposure model to investigate the effects of SM on meibomian gland differentiation and lipid production. **Methods:** Experiments with rabbits and SM were conducted at MRIGlobal (Kansas City, MO) in an AAALAC-accredited facility, under protocols approved by the Institutional Animal Care and Use Committee (IACUC). The central cornea of the right eye of New Zealand white rabbits was exposed to 0.4 µL neat SM (5 mg; ~30 nmol) for 5 min and then flushed with sterile saline for 2 min. Left eyes served as controls and received only saline. Rabbits were euthanized 28 days later, eyelids excised, trimmed, fixed in paraformaldehyde/sucrose, and embedded in paraffin. Five-micron tissue sections were stained with hematoxylin and eosin (H&E) or Masson's trichrome for histopathology. For immunohistochemistry, sections were incubated with antibodies against fatty acid synthase (FAS), proliferating cell nuclear antigen (PCNA), and keratin 1 or IgG controls. Antibody binding was visualized using DAB Peroxidase Substrate. Tissue images were acquired using an Olympus

VS120 Virtual Microscopy System. **Results:** H&E and trichrome staining revealed distinct stages of meibocyte differentiation within the acini of the meibomian glands. Meibocytes in the basal region of the acini were proliferative and progressively enlarged as they accumulated lipid-rich material. As differentiation advanced, mature meibocytes underwent disintegration and released their contents into the glandular lumen, consistent with holocrine secretion. Rupturing cells were observed as they migrated toward the ductal opening. FAS was upregulated in lipid laden immature meibocytes, while downregulation was evident in mature and ruptured cells. In SM-exposed rabbit eyelids, expression of FAS, was markedly decreased, indicating disrupted lipid synthesis during meibocyte differentiation. PCNA expression was primarily confined to basal meibocytes at the gland periphery. SM increased PCNA expression of basal meibocytes, which is essential for the replacement of differentiated meibocytes. Keratin 1 was localized around individual meibocytes in control glands and glands from SM-treated rabbits, but was lost as the cells matured, consistent with differentiation-associated remodeling of the cytoskeleton. **Conclusions:** The tear film is essential for maintaining the integrity of the ocular surface, and its disruption leads to corneal epithelial damage, erosion, and dry eye, conditions known to result following SM exposure. Our findings demonstrate that SM alters meibomian gland architecture, specifically affecting meibocyte acini and reducing FAS expression, a key enzyme involved in lipid synthesis. Increased proliferation and keratinization of meibocytes were also observed following SM. These changes in FAS expression and meibomian gland secretion impair lipid composition and tear film stability. Together, these data indicate that SM-induced meibocyte dysfunction contributes to chronic ocular surface injury, underscoring the need to target meibocyte preservation and repair in the development of effective SM countermeasures.

PS 3243 Levels of novel oxime sufficient to counteract brain AChE inhibition by a sarin surrogate neither induce gene expression of nor inhibit metabolism by the human P450 isozymes CYP1A2, CYP2B6, and CYP3A4

M. Dail, O. Ajisafe, and J. Chambers. Mississippi State University, MS State, MS.

Background and Purpose: To counteract inhibition of brain AChE by organophosphate nerve agents or insecticides, our lab synthesized novel pyridinium oximes and has experimental evidence that some cross the BBB and reactivate rat brain AChE previously inhibited by a sarin surrogate (nitrophenyl isopropyl methylphosphonate: NIMP) or the active metabolite of the insecticide parathion (paraoxon). There is also evidence of attenuation of NIMP-induced seizure-like behavior and of brain neuropathology. Because of these positive results, several of our novel oximes have been down-selected for drug development. Oxime 20 is our lead candidate. FDA guidance recommends pre-clinical testing of lead drug candidates for potential interactions with the CYP 450 isozymes responsible for the majority of drug metabolism in humans. Inhibition or induction of CYP3A4, CYP2B6, CYP1A2 frequently results in drug-drug interactions (DDI) which influence therapeutic efficacy. **Methods:** Induction of CYP3A4, CYP2B6, and CYP1A2 gene expression was measured in induction qualified Gibco™ human plateable hepatocytes treated as per the manufacturer's instructions. Each well of a 24 well, collagen-coated tissue culture plate received 350,000 hepatocytes which were then grown for 24 hours at 37°C, 5% CO₂. The next day cells were exposed to either prototypical inducers [2 µM 3-methylcholanthrene (CYP1A), 1 mM phenobarbital (CYP2B), 10 µM rifampicin (CYP3A)], Oxime 20 from 1 nM to 1 µM, or the vehicle control (DMSO) and returned to the incubator for 48 hours. After 48 hours, hepatocytes were washed twice with iced HBSS which was then replaced with RLT Plus Lysis Buffer from the Qiagen RNeasy Plus Mini Kit. The cell lysates were stored at -70°C prior to RNA isolation using the same Qiagen kit. Gene expression was analyzed with RT-qPCR on the Agilent AriaMx system, using IDT PrimeTime assays and One-Step RT-qPCR Master Mix. Expression levels of CYP3A4, CYP2B6, and CYP1A2 mRNA were normalized to the housekeeping gene *Rplp1* and assessed using the ΔΔCT method. Inhibition of metabolism by CYP3A4, CYP2B6, CYP1A2 was studied using the Vivid® CYP450 screening kit from Life Technologies™ following the manufacturer's methods. The kits use CYP450 Baculosomes® Plus Reagents which are microsomes prepared from insect cells expressing a single human P450 isozyme. Different Vivid® substrates are metabolized by different CYP450 enzymes into fluorescent metabolites. Drugs are analyzed by their capacity to inhibit the fluorescent signal. Oxime 20 was combined with the CYP450 Baculosomes®, glucose-6-phosphate and glucose 6-phosphate dehydrogenase. After pre-incubation, the background fluorescence was measured. The enzymatic reaction was started with a mix of NADP+ and Vivid® substrate. The plate was read for 60 minutes on a Molecular Devices Spectramax M5 (EX=415 and EM=460) in Kinetic Assay Mode at 1-minute intervals. **Results:** Oxime 20 exposure at 1 nM, 10 nM, 100 nM and 1 µM, caused no statistically significant induction of CYP3A4, CYP2B6, and CYP1A2 gene expression compared to the DMSO vehicle (*p* ≥ 0.15). The prototypical inducers of CYP3A4, CYP2B6, and CYP1A2 did cause statistically significant induction compared to vehicle (*p* < 0.001). A minimal inhibition of CYP1A2 and CYP3A4 metabolism was observed at Oxime 20 concentrations below 50 µM. At this same concentration, however, CYP2B6 metabolism was more than 80% inhibited compared to the positive control. **Conclusions:** The lack of gene expression induction by Oxime 20 suggests a low risk of DDI due to increased metabolism by CYP1A2, CYP2B6 or CYP3A4. Our earlier pharmacokinetic study (Backer et al., 2022) indicated the maximum amount of Oxime 20 in the rat brain was 397.84 pM. This suggests that the biologically relevant concentration of Oxime 20 is much less than the 50 µM which caused 80% inhibition of CYP2B6 metabolism. Although effects at therapeutic

levels are minimal, given the significant inhibition of CYP 2B6, Oxime 20 may present a risk of interacting with drugs metabolized by this enzyme. This study supports Oxime 20's low DDI risk at therapeutic levels but necessitates further studies to assess its clinical impact, especially as a combination therapy.

PS 3244 Idebeneone Treatment Reduces Nitrogen Mustard Induced Mitochondrial Dysfunction in Lung Epithelial Cells

R. C. Canfield¹, M. Gibb¹, A. A. Date², and J. M. Brown¹. ¹University of Colorado Anschutz Medical Campus, Aurora, CO; and ²University of Arizona, Tuscon, AZ.

Background and Purpose: Sulfur and nitrogen mustards are bifunctional alkylating agents and vesicants developed in the early 20th century for use as chemical warfare agents. One prominent route of exposure is through inhalation where damage occurs in the lungs from DNA alkylation and reactive oxygen species generation (ROS). In this study we aimed to utilize the antioxidant quinone compound idebenone to reduce the ROS stress and toxicity from nitrogen mustard exposures. **Methods:** We utilized both primary and immortalized bronchial epithelial cells (HBEC and BEAS-2B cells respectively). Mitosox, Cellroxx and peroxiredoxin 1 and 3 westerns were used to determine the presence of oxidative stress in both lung epithelial cell models. Seahorse cell mito stress assay was used to determine mitochondrial dysfunction. We also utilized MTS and Calcein-AM to determine cell viability after pre-treatment of Idebeneone and exposure of nitrogen mustard. Cells were pretreated with idebenone at concentrations between 1uM and 50uM followed by treatment of nitrogen mustard at concentrations between 1uM and 100uM. **Results:** We observed a significant reduction in basal respiration, maximal respiration, and ATP production 6hrs following nitrogen mustard exposure in a dose dependent manner in both lung epithelial cell models. Pre-treatment with 10uM and 30uM of idebenone was able to recover the observed decrease in maximal respiration 6hrs following nitrogen mustard treatment. **Conclusions:** Idebeneone is an antioxidant drug which may be effective in reducing the toxicity of nitrogen mustard exposure by preventing the mitochondrial dysfunction in lung epithelial cells.

PS 3245 Sulfur Mustard Disrupts Epidermal and Dermal Structures in Hairless Guinea Pig Skin

K. Ozkuyumcu¹, D. Weinstock¹, P. Zhou¹, C. R. Crutch², J. D. Laskin¹, and L. B. Joseph¹. ¹Rutgers University, New Brunswick, NJ; and ²MRIGlobal, Kansas City, MO.

Background and Purpose: Sulfur mustard (SM; bis(2-chloroethyl) sulfide) is a highly reactive bifunctional alkylating agent and potent vesicant that causes severe damage to the skin. Following dermal exposure, SM induces erythema, inflammation, epidermal erosions, and blistering. In this study, we investigated the temporal progression of SM injury in the hairless guinea pig, a translationally relevant animal model for studying SM-induced cutaneous injury. Hairless guinea pig skin closely resembles human skin, possessing a thick epidermis and a well-developed dermis containing superficial microvessels and secondary appendages. Proteins essential for skin homeostasis were visualized following injury including elastin, a marker of skin elasticity, myeloperoxidase (MPO), a marker of inflammation, and keratin 5 (K5), an epithelial scaffolding protein. The objective of this work was to characterize the pathogenesis of SM-induced skin injury and the subsequent wound-healing responses in the hairless guinea pig. **Methods:** Exposures to SM were conducted using a vapor cap model at MRIGlobal (Kansas City, MO) under an IACUC-approved protocol. Air control or saturated SM vapor caps were applied to the dorsal flanks of 6-8 wk-old Hartley hairless guinea pigs for 20 min. Forty-eight hours post-exposure, SM-exposed sites were debrided daily for 4d using saline gauze soaks. Animals were euthanized 2d post-SM (prior to debridement) and at 20d and 66d post-SM exposure. Full-thickness skin biopsies from control and SM-treated animals were collected and processed for histopathology using hematoxylin and eosin (H&E) and Masson's trichrome staining. Elastic fibers were visualized using orcein stain. Immunohistochemistry was performed using antibodies against MPO and K5, with matched IgG controls. **Results:** The skin of control hairless guinea pigs displayed a well-developed, multi-layered epidermis overlying a dermis composed of an interwoven collagen network with abundant, branching elastic fibers. Two days post-SM skin was characterized by epidermal necrosis and dermo-epidermal clefts containing numerous necrotic heterophils. In the dermis, perivascular infiltrates and extravasated red blood cells surrounding degenerate vascular endothelial cells were observed. By 20d post-SM, moderate epidermal acanthosis and perivascular vacuolization were noted in the stratum granulosum and stratum spinosum. Elastic fibers within the edematous superficial dermis were fragmented and agglomerated. By 66d post-SM, there was a clear demarcation between the superficial and deep dermis, with the superficial dermis containing dense, highly compacted collagen fibers running parallel to the epidermis, which was devoid of elastic fibers and secondary appendages. MPO, a marker of azurophilic granules in neutrophils, was not expressed within the epidermis of control skin. Two days post-SM, MPO positive degenerate heterophils were observed within the dermo-epidermal cleft and throughout the necrotic epidermis. Epidermal MPO expression had decreased by 20d post-SM and was not evident 66d post-SM. K5, a protein essential for the structural integrity of epithelial cell attachment to the basement membrane, was expressed in basal keratinocytes in control skin. In epithelial cells along the basement membrane,

K5 was downregulated 2d post-SM. Twenty days post-SM, K5 expression within the basal layer had returned, approaching control levels by 66d. **Conclusions:** SM exposure in hairless guinea pig skin produced a well-defined sequence of injury and repair. Early lesions were characterized by extensive epidermal necrosis, dermo-epidermal separation, and an acute neutrophilic infiltrate, accompanied by vascular damage in the dermis. By 20d post-SM, partial re-epithelialization and remodeling of the epidermis were evident, though dermal elastic fibers remained fragmented and collagen organization was altered. At 66d, the skin exhibited structural remodeling marked by dense, compact collagen deposition with a loss of elastic fibers and adnexal structures, indicative of scar formation. The transient expression of MPO and restoration of K5 confirmed a shift from acute inflammation to tissue repair and re-establishment of epidermal integrity. Overall, these findings demonstrate a progressive transition from acute injury to chronic dermal remodeling following SM exposure.

PS 3246 Dexamethasone treatment alleviates lewisite-induced delayed proteomic dysregulations, inflammation, and fibrosis in the rabbit cornea in vivo

R. Kant, N. Mishra, L. Saba, C. Agarwal, and R. Agarwal. Department of Pharmaceutical Sciences, University of Colorado Anschutz Medical Campus, Aurora, CO.

Background and Purpose: Lewisite (Lew) emerged as a chemical warfare agent (CWA) during World War I and since then, it has been produced in large quantities and stockpiled. Eyes, particularly corneas, are extremely vulnerable to Lew exposure. However, in-depth analysis of corneal injury mechanism following Lew exposure has not been undertaken. Of interest are the delayed effects of Lew exposure on corneas. Moreover, British anti-Lew is the only approved therapeutic available, but it predominantly acts systemically, has several side effects, and is not recommended for ocular use. Thus, targeted ocular therapeutics that can be used in mass casualty situations are an immediate need. In this regard, dexamethasone (Dex), an FDA-approved steroidal anti-inflammatory, was used for treatment of ocular injuries following exposure to mustard vesicating CWA. Thus, in the present study, we assessed Dex efficacy for treatment of Lew induced corneal injuries at the delayed injury timepoint, leveraging high-throughput proteomic analysis, using an *in vivo* rabbit model. **Methods:** Male white rabbits (≤ 3 months old; 2-3 kg) were used for the study and procedures performed were approved by IACUC. Groups ($n=4$ /group) included: (1) control (2) Lew exposed (Lew); (3) Lew exposed and Dex treated (Lew+Dex). Lew vapor exposure was performed to achieve targeted mild to moderate corneal injuries ~ 0.2 mg/L; 300 ml/min; 8 min). Dex (0.1%; Bausch and Lomb) was delivered, starting 2 h post exposure, and thereafter every 8 h for 28 days. Samples were harvested at day 28 and divided into two fractions: 1) flash frozen and stored at -80°C until proteomic analysis (LC-MS/MS); and 2) formalin fixed paraffin-embedded, and sectioned (5 μm) for histopathological (H&E and Masson's trichrome staining) and molecular expression analysis (immunofluorescence). Statistical analysis was performed using R (ver 4.2.3; one-way ANOVA with pairwise post-hoc testing; unadjusted $p<0.05$; FDR <0.01) to identify the significantly dysregulated proteins between study groups. Pathway enrichment analysis of differentially expressed proteins was performed using Ingenuity Pathway Analysis (IPA, Qiagen). **Results:** Histopathological examination indicated that Lew exposure induced epithelial degradation, immune cell infiltration, and stromal collagen degradation. Molecular assessments revealed increased expression of cathepsin C and cell division cycle 42 (CDC42) in the epithelium and stroma, as well as increased expression of vimentin only in the stroma. Dex treatment prevented epithelial and stromal degradation. Furthermore, reversal of cathepsin C, CDC42, and vimentin elevation was observed with Dex treatment, thus preventing the prolonged inflammatory response observed in the untreated corneas. Proteomics analysis showed that the expression profiles for most proteins from control and Lew+Dex groups were similar but differed from the Lew group, with 1,163 proteins dysregulated in the three groups. Lew exposure led to the change in the expression profile of 1,045 proteins (Lew vs Control $p<0.05$), of which 575 were downregulated and 470 proteins were upregulated. Of the downregulated proteins, 479 were upregulated after Dex treatment (Lew+Dex vs Lew $p<0.05$). Further, of the upregulated proteins, 360 were downregulated after Dex treatment (Lew+Dex vs. Lew $p<0.05$). Dex treatment completely or partially reversed Lew-induced expression changes $\sim 80\%$ proteins. Top 20 canonical pathways were categorized into 5 groups based on biological functions: category 1, immune response and inflammation associated pathways; category 2, cytoskeletal remodeling and cell junction dynamics pathways; category 3, ECM organization and structural integrity mechanisms; category 4, intracellular transport, trafficking, and protein processing pathways; and category 5, pathways indirectly contributing to Lew injury and Dex efficacy. **Conclusions:** Lew-induced modulation on day 28 indicates persistent toxicity and delayed injury. Dex effectively reversed these molecular alterations, thus preventing activation of all top dysregulated pathways, with significant reversal in associated protein expressions. Dex is a potential therapeutic candidate that can be used as a countermeasure for treatment of Lew-induced corneal injuries. (Funding: U01 EY030405)

PS 3247 Post-exposure inhibition of IL-1 β signaling delays the onset of spontaneous recurrent seizures (SRS) and improves cognitive impairment in adult male Sprague-Dawley rats acutely intoxicated with the organophosphate (OP), diisopropylfluorophosphate (DFP)

C. Unkel, Y. Tsai, M. Munoz, B. Davis, D. Bruun, and P. Lein. University of California, Davis, Davis, CA.

Background and Purpose: Acute intoxication with organophosphorus (OP) cholinesterase inhibitors can cause life-threatening status epilepticus (SE), respiratory paralysis and death. When administered promptly following intoxication, standard of care therapeutics improve survival, but do not prevent long-term neurological sequelae, including spontaneous recurrent seizures (SRS) and cognitive deficits. Clinical and preclinical studies implicate the pro-inflammatory cytokine interleukin-1 β (IL-1 β) in epileptogenic processes and cognitive decline. We previously demonstrated that IL-1 β mRNA gene expression is upregulated immediately following acute DFP intoxication and during the epileptogenic period. Therefore, to determine the contribution of IL-1 β signaling in the pathogenesis of the long-term neurological sequelae resulting from acute DFP intoxication, we quantified the effects of administering Anakinra, an IL-1 β receptor antagonist, beginning 1 h post-exposure and continuing for 10 d post exposure (DPE) on electroencephalographic (EEG) activity in the brain and cognitive behavior. **Methods:** Adult male Sprague-Dawley rats were surgically implanted with cortical screws and an EEG telemetry unit 10 d prior to acute DFP intoxication. DFP (4.0 mg/kg, sc), or an equal volume of vehicle (PBS, sc) was administered followed 1 min later by atropine sulfate (2.0 mg/kg, im) and 2-PAM (25 mg/kg, im) (n=10 VEH / 12 Anakinra). Animals were administered midazolam (0.65 mg/kg, im) at 40- and 50-min post-DFP. At 60-min post exposure animals received Anakinra (33.3mg/kg, sc) or vehicle (saline) with repeated administration every 8 h for 10 d. Continuous EEG with time-locked video was recorded for 30 d (n=7 saline / 10 Anakinra). Animals underwent behavioral assays to evaluate cognitive function from 30-36 DPE (n=7 saline / 10-12 Anakinra). Animals were euthanized and brain tissue collected at 36 DPE. **Results:** Anakinra delayed the onset of SRS events during administration and reduced total convulsive seizure burden during the study period. During the novel object recognition task, DFP animals administered Anakinra had a significant increase in the number of interactions with a novel object compared to familiar objects; compared to DFP animals who were treated with saline that interacted with the familiar object and novel object comparably. DFP animals from both treatment groups underwent contextual fear conditioning, learned the task and performed at a comparable level during the context and cue tasks as indicated by significant decreases in the average motion index. **Conclusions:** Administration of Anakinra following acute DFP intoxication delayed the onset of SRS and moderately improved cognitive improvement compared to DFP-intoxicated animals who received saline. These findings are consistent with the hypothesis that IL-1 β plays a role in the pathogenesis of SRS and cognitive dysfunction associated with acute OP intoxication. These data provide evidence supporting the use of Anakinra as an adjunct therapy to standard of care to modify the long-term comorbidities associated with acute DFP intoxication. Supported by the NIH CounterACT Program (U54 NS127758) and predoctoral fellowships to Chelsea Unkel (T32 GM135741) and Brittany Davis (T32 GM136559).

PS 3248 Systemic and Pulmonary Effects of Acute Chlorine Exposure in a Preclinical Rat Model

G. Jadhav, A. J. Johns, W. Nasser, N. Fatima, I. A. Khalid, A. E. Faquih, I. Zafar, A. Ahmad, and S. Ahmad. University of Alabama at Birmingham, Birmingham, AL.

Background and Purpose: Chlorine is a highly reactive and toxic gas produced in large quantities in industry. Accidental exposures occur frequently, highlighting a need for effective countermeasures. Animal models provide important insights into the injury mechanisms and serve as preclinical models for drug development and advancement. Here we describe a rat model of chlorine inhalation using near lethal dose (LD₅₀) concentrations to characterize the physiological and systemic effects of exposure and to establish a platform for longitudinal therapeutic assessment. **Methods:** Sprague Dawley rats were exposed to 500 or 600 ppm of chlorine for 45 min and transferred to room air. Pulse oximetry was performed every 2h till 8h and then at 24h after exposure. At the predetermined timepoints (3, 6, and 24h), body weights were recorded and animals were euthanized for arterial blood collection from the descending aorta for arterial blood gas (ABG) measurements. Before bronchoalveolar lavage fluid (BALF) collection, the right upper lung (RUL) was clamped and excised for determination of lung wet-to-dry weight ratios. Lungs were then perfused, collected, and frozen. Additional endpoints included heart weight, spleen weight, complete blood cell count (CBC), BALF total cell counts, protein and lactate dehydrogenase (LDH) concentration in BALF supernatant. Cardiac injury markers, N-terminal pro-brain natriuretic peptide (NT-proBNP) was measured in the plasma. Separate animals were processed for histological evaluations. **Results:** A single acute chlorine (500 or 600 ppm) exposure caused about 50% mortality and excessive respiratory distress in survivors. Exposed animals exhibited increased clinical scores, reduced heart rate and decreased tissue oxygenation. ABG analysis revealed hypoxemia accompanied by respiratory and metabolic acidosis (or compensated respiratory acidosis) at all time points. Systemic inflammation was indicated by decrease in monocyte and lymphocyte counts along with increased eosinophils and neutrophils

in the blood. Lung injury and edema were confirmed by significantly increased BALF protein, LDH concentrations, higher lung wet-to-dry weight ratios, and increase in total BALF cell counts at all time points measured. Histopathological evaluation of lung hematoxylin and eosin (H&E) sections revealed marked injury to the airway and alveolar regions. Cardiac involvement was evident from increased heart-to-body weight ratios, increased plasma NT-proBNP, and ultrastructural damage observed by electron microscopy. **Conclusions:** This study establishes a robust preclinical rat model that reproduces the systemic and physiological effects of acute chlorine exposure. Using two near LD₅₀ concentrations we demonstrate severe respiratory distress, systemic inflammation, cardiopulmonary damage and altered pulmonary physiology in the exposed animals. This model provides a valuable platform that can guide future mechanistic studies and evaluation of novel therapeutics.

PS 3249 Phosgene inhalation in swine: reproducible ARDS phenotype and systems proteomics to guide countermeasure discovery

S. Achanta¹, M. Foster¹, G. Clair², V. Lin², S. Jordt¹, and W. Holmes³. ¹Duke University School of Medicine, Durham, NC; ²Pacific Northwest National Laboratory, Richland, WA; and ³United States Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.

Background and Purpose: Phosgene is one of the highly produced industrial gases and is an essential intermediate in polymer, pharmaceutical, and metallurgical synthesis. However, phosgene is highly toxic when inhaled. Phosgene inhalation causes a delayed onset of symptoms starting 8 hours post-inhalation. While phosgene inhalation-induced lung injury is consistent with acute respiratory distress syndrome (ARDS), pulmonary edema is the pathognomonic symptom. Due to its high propensity for toxicity, it was deployed as a chemical warfare agent during World War I. Currently, there are no mechanistic-based medical countermeasures for treating phosgene inhalation injuries. The treatment is mainly supportive and symptomatic. As the medical countermeasures are approved through the FDA's animal rule, there is a knowledge gap in non-rodent animal models that recapitulate human phosgene inhalation injuries and detailed proteomic profiling to identify potential drug targets and forensic diagnostic biomarkers. **Methods:** Sedated domestic Yorkshire swine were exposed to phosgene (40 ppm for 20 minutes) via a nose cone. Animals were recovered from sedation and observed in their home pens frequently. Animals were re-sedated at 8 or 24 hours post-phosgene exposure. Oxygenation, respiratory physiological, and pulmonary function testing parameters were recorded. At the end of the study, animals were euthanized, and lung tissues were collected. Lung tissues were processed for unbiased global proteomics using previously established mass spectrometry methods, and multiplex protein array assays were also performed to identify potential drug biomarkers and targets. **Results:** Phosgene inhalation resulted in hypoxemia and worsening of respiratory physiological parameters such as reduced compliance dynamics, elevated airway resistance and peak inspiratory pressure. Pulmonary function testing showed decreased tolerance to increasing concentrations of nebulized methacholine. Lung histopathology revealed neutrophilic alveolitis, hyaline membranes, and increased septal thickness consistent with ARDS. Unbiased global proteomics studies in phosgene-exposed lung tissues revealed >8,000 protein groups with good precision and accuracy based on quality control pool samples and internal spike-in standards. Prominent among the differentially-expressed proteins were plasma-derived and acute-phase proteins. Upregulated proteomic signatures included phospholipid efflux, lipoprotein metabolism, TGF β activation, and coagulation/complement pathways, while cilia-associated and epithelial barrier proteins were decreased. Extracellular matrix remodeling with altered collagen isoforms was evident. Multiplex protein array assays corroborated inflammatory changes. **Conclusions:** This acute porcine model recapitulates key features of human phosgene inhalation injury and is suitable for countermeasure testing. Differentially expressed proteome changes may serve as potential diagnostic biomarkers and drug targets. Extended observation and dose-response studies are underway.

PS 3250 Cytotoxicity screening in primary human epidermal keratinocytes and dermal fibroblasts

E. Hoffman¹, K. Grady², and A. Sharma¹. ¹Lonza Durham, Morrisville, NC; and ²Lonza Walkersville Inc., Walkersville, MD. Sponsor: K. Dunnick

Background and Purpose: The skin is the first protective barrier in the human body against damage caused by UV light and chemical substances as well as protecting internal structures against microorganisms and mechanical trauma. It is composed of three layers: the epidermis, containing keratinocytes as the most frequent cell type, the dermis, which consists mainly of connective tissue and fibroblasts, and the hypodermis, the deepest layer which is made up of adipose and connective tissue. Following damage, injury, or during the normal turnover of cells, the appropriate proliferation response of both fibroblasts and keratinocytes is essential for the regeneration and repair process to occur effectively. Delays in this process can lead to chronic wounds and an increased potential for bacterial colonization, while excessive and uncontrolled proliferation can lead to benign or malignant neoplasms. Despite the common clinical use of various antimicrobial agents to prevent delays in skin healing and the standard use of chemotherapy agents to treat skin cancers, these compounds can have adverse effects on healthy skin cell viability. Evaluation

of these cytotoxic effects during the drug discovery process is crucial to understanding how to achieve a balance between adequate clinically relevant outcomes and minimizing toxicity or off-target effects that could damage skin or prevent wound healing. Here we present a workflow for cytotoxicity assays targeting normal human epidermal keratinocytes (NHEK) and normal human dermal fibroblasts (NHDF). We validated this workflow by exposing both cell types to common antimicrobial or chemotherapy agents. **Methods:** Lonza NHEK and NHDF cells (n=3 donors for each cell type) were plated at 3500-5000 cells per cm² and cultured in KGM®-Gold or FGM®-2 medium, respectively. NHEK cells were exposed to eight concentrations of Doxorubicin (DOX; 0.1-2 µM) and Chlorhexidine (CHEX; 0.25-10 µM), while NHDF cells were exposed to eight concentrations of Camptothecin (CAMP; 0.001-2 µM) and Chloroxylenol (CHXY; 25-500 µM). DOX and CAMP are commonly used chemotherapy agents, while CHEX and CHXY are anti-microbials often employed in wound healing protocols and as antiseptics. Cells were exposed across acute (24 hours) or chronic (120 hours) timescales. Cells were cultured until 40-60% confluence before initiating exposure at the typical period of maximal proliferation. For chronic exposure, cells were cultured until reaching 10-20% confluence. This relatively low density was chosen to prevent over-confluence of cells by the experiment endpoint that itself could impact cell health. Cytotoxicity was measured by using total cellular ATP relative to untreated control cells as a proxy for viability, generating dose response curves and IC₅₀ values. **Results:** Cytotoxic effects were observed across all experiments. Across an acute timescale (24 hours), both NHEKs and NHDFs saw drop-offs in ATP activity, but only the highest dose of Chlorhexidine caused complete lethality (0% ATP activity). Across a chronic timescale (120 hours), lethal effects were observed for each compound tested at the highest concentrations. There was relatively low variation across donors in IC₅₀ values. Dose-response curves for all donors followed the same trajectories for each experiment and IC₅₀ values fell within 1.5 SD of the mean. In addition, mean IC₅₀ values for each compound tested were within range of those previously reported in the literature. Donor behavior was also consistent between acute and chronic timescales, as donors with higher IC₅₀ values at 120 hours also had higher IC₅₀ values at 24 hours. **Conclusions:** Our data shows that this cytotoxicity workflow generates robust and reproducible cytotoxicity results with calculated IC₅₀ values in line with previously published literature. The trajectory of the dose-response curves was near-identical across donors for each compound tested with overall minimal variation in IC₅₀ values between donors. This assay provides an excellent system for cytotoxicity screening of both epidermal keratinocytes and dermal fibroblasts, two cell types critical to the structure and function of human skin, capturing physiologically relevant data that accounts for the variability in patient populations while providing consistent, reliable results.

PS 3251 A retrospective study on the use of Local Lymph Node Assay EC3 values to derive doses for the Confirmation of No Induction in Humans test

M. A. Guttenberg¹, I. Lee¹, M. Na², M. Lavelle¹, I. Schember¹, and A. Api¹. ¹Research Institute for Fragrance Materials, Mahwah, NJ; and ²Estee Lauder Companies, Melville, NY.

Background and Purpose: Assessment of skin sensitization potential is a critical component of fragrance ingredient safety evaluation, as exposure to sensitizing substances can lead to allergic contact dermatitis. Weight-of-evidence analysis integrating *in silico*, *in vitro*, and *in vivo* data may be performed to determine a compound's sensitizing potential. This includes the use of predictive models, experimental data, historical animal and confirmatory human datasets. However, only historical animal studies are considered due to the ban on animal testing for cosmetics. Once a material is determined to be sensitizing, then quantitative risk assessment is required, which begins with determining the No Expected Sensitization Induction Level (NESIL). A key aspect to deriving a NESIL involves estimating the quantitative potency of a compound - historically achieved by using data from the Local Lymph Node Assay (LLNA) as the gold standard. Confirmatory human studies, also known as Confirmation of No Induction in Humans tests (CNIH) are conducted to confirm the NESIL. Previous studies have demonstrated that safe doses in human were closely aligned with LLNA EC3 values, showing a strong correlation between NESILs and LLNA EC3s without the need for additional uncertainty factors. This study builds on prior findings by expanding the dataset and reinforcing the relationship between LLNA EC3 values and CNIH-derived NESILs. Importantly, this retrospective analysis provides insight into how EC3 values can be leveraged when validating new *in vitro* methods, supporting the transition toward NAMs. **Methods:** Using expert judgement, historical LLNA studies, as well as CNIH studies were evaluated to ensure their sufficiency. They were then assessed and set to a potency category based on the LLNA EC3 or CNIH NESIL. If these categories were in discordance, all relevant data were evaluated through expert judgement. **Results:** Based on a preliminary assessment of an expanded dataset, 199 materials, the analysis confirms that LLNA EC3 values generally provide protective estimates for NESILs with only a few well-recognized exceptions. **Conclusions:** This study confirms the usefulness of the correlation between the historical LLNAs and the dosing strategy for CNIH tests. The analysis enables more accurate application of existing animal data in predictive models, which in turn supports the development of more human-relevant non-animal methods.

PS 3252 Outside the validated range: Performing a Weight of Evidence (WoE) assessment of the skin sensitization potential for fragrance chemicals positive at high concentrations in the Local Lymph Node Assay (LLNA)

M. M. Lavelle¹, A. Natsch², I. Lee¹, I. Schember¹, J. Muldoon¹, H. Moustakas¹, and A. Api¹. ¹Research Institute for Fragrance Materials, Inc., Mahwah, NJ; and ²Givaudan Suisse SA, Kempthal, Switzerland.

Background and Purpose: The Local Lymph Node Assay (LLNA) has been the gold standard for skin sensitization assessment for two decades. During its validation, most chemicals were tested at a maximum concentration of 25%, which showed high predictivity versus guinea pig and human data. However, when the OECD guideline was established, testing up to 100% was introduced as a mandatory requirement despite this range never undergoing formal validation. Even accepted solvents and negative standards have yielded false positives under this unvalidated practice. As highlighted in an OECD curation exercise, the specificity of the LLNA versus human data has dropped significantly. The main concern is the assay's tendency for false positives, particularly with irritants. LLNA-positive results at high concentrations may reflect irritation rather than true sensitization. For chemicals positive within this 25-100% range, a Weight-of-Evidence (WoE) approach may be more appropriate for a final conclusion on the sensitization hazard. High-concentration LLNA results may reflect irritant-driven proliferation rather than true sensitization, reinforcing the need for human-relevant, non-animal approaches such as OECD 497. **Methods:** *In vitro*, *in silico*, human, and guinea pig data were compiled for 101 LLNA-positive chemicals. Of these, 69 had at least one LLNA EC3 ≥25%, 19 had EC3 values between 19.4-24.8%, and 13 had mixed positive and negative LLNA data. For each material, corresponding *in vitro*, *in silico*, and Confirmation of no Induction in Humans (CNIH) data were compared, and the Expert Panel for Fragrance Safety chemists classified parent and metabolite reactivity to support the overall WoE evaluation. **Results:** 53 materials had negative CNIH data sufficient to establish a No Expected Sensitization Induction Level (NESIL). 8 were concluded as non-sensitizers through the Research Institute for Fragrance Materials (RIFM) safety assessment process. Using the OECD 497 two-out-of-three (2o3) defined approach, 48 of 101 materials (47.5%) were non-sensitizers, 33 (32.7%) sensitizers, and 20 (19.8%) inconclusive. Overall, 49 were determined to be non-sensitizers based on WoE, 27 as sensitizers, and 25 as inconclusive. Among the non-sensitizers, 67% were LLNA-positive at ≥25%, suggesting many LLNA positives at high concentrations do not translate to human-relevant sensitization. For 53 materials with both LLNA and CNIH potency data, three consistent patterns were observed: (1) close alignment, (2) LLNA overprediction (human NOEL >> mouse EC3), and (3) conservatively low human NOELs indicating high sensitivity. Expert chemists classified 53.4% of parent molecules as non-reactive and 33.7% as reactive, aligning with *in vitro* results for most cases. **Conclusions:** A significant fraction of these chemicals likely yield false-positive results in the LLNA. A comprehensive WoE assessment provides a more granular understanding of sensitization hazard and risk than reliance on LLNA results alone. High-dose LLNA testing may overestimate sensitization hazard, and integrating human and *in vitro* evidence provides a more accurate, biologically relevant foundation for modern risk assessment.

PS 3253 Skin sensitization risk assessment using a machine learning model that considers aggregate exposure to cosmetic products

T. Ashikaga¹, T. Yamada², H. Iwasa³, K. Hatano³, N. Nakamura³, K. Kinoshita⁴, J. Tokunaga⁴, R. Satake⁴, W. Murasaki⁴, and K. Ambe⁵. ¹National Institute of Health Sciences, Kawasaki, Japan; ²National Institute of Health Sciences, Division of Cellular and Molecular Toxicology, Kawasaki, Japan; ³General Research & Development Institute, Hoya Co., Ltd., Nagakute, Japan; ⁴Department of Regulatory Science, Graduate School of Pharmaceutical Sciences, Nagoya City University, Nagoya, Japan; and ⁵Graduate School of Data Science, Nagoya City University, Nagoya, Japan.

Background and Purpose: Chemical-induced contact allergy is a medical issue of considerable concern to consumers, clinicians, industries, and regulatory authorities. Chemicals such as fragrance materials are used in a wide variety of consumer products at varying levels, leading to a wide range of exposure. The previously published quantitative risk assessment (QRA) approach uses both potency prediction and exposure data to assess the risk of skin sensitization to fragrance materials. However, the first version of the QRA method does not incorporate aggregate exposure from multiple product use and requires *in vivo* experimental data, including a murine local lymph node assay. Therefore, in this study, we predicted the potency of target chemicals using *in vitro* test results and a machine learning model. Furthermore, to assess the risk of various commonly used chemicals, aggregate exposure was considered. **Methods:** Salicylic acid and methylisothiazolinone were selected as commonly used skin sensitizers. The no expected sensitization induction levels (NESILs) of these chemicals were calculated using a previously developed *in silico* potency prediction model based on XGBoost, a machine learning algorithm. The acceptable exposure level (AEL) was calculated using both the NESIL and applied safety assessment factor, the latter of which is derived from the product type and inter-individual variability. The consumer exposure level (CEL) was calculated on the basis of intended and foreseeable conditions of use. To predict consumer aggregate exposure, we use the probabilistic Creme RIFM aggregate exposure model. Finally, the maximum acceptable concentration level for each product was calculated as the upper concen-

tration limit (UCL) from the exposure amount at which AEL = CEL. **Results:** For both compounds, lower UCL values were obtained when aggregate exposure was taken into account, suggesting that this is a more appropriate risk assessment approach for these commonly used chemicals. For example, the UCL for salicylic acid in hair sprays was 11.77% when aggregate exposure was not considered and 6.83% (aggregate adjusting) when it was, whereas the respective values for methylisothiazolinone were 0.34% and 0.20% (aggregate adjusting). For both chemicals, the NESIL was calculated using the non-animal testing approach. Furthermore, the UCLs calculated with our machine learning model were similar to the measured values obtained from animal experiments. For example, the aggregate adjusting UCL for salicylic acid in bar soap was 2.54% in conventional animal testing and 8.42% when using the non-animal testing approach, whereas the respective values for methylisothiazolinone were 0.40% and 0.24%. **Conclusions:** In conclusion, this quantitative skin sensitization risk assessment model with aggregate exposure considered is a useful approach for the non-animal safety evaluation of chemicals. To put this method into practical use, verification through accumulated case studies using a large number of chemicals is required.

PS 3254 Investigation of the applicability of a new consensus *in silico* model for predicting skin sensitization using combined alternative approaches methods

R. Murakami¹, M. Imamura², M. Tateshita¹, and Y. Hikida¹. ¹Fujifilm Corporation, Imaging & Informatics Laboratories, Tokyo, Japan; and ²Fujifilm Corporation, Safety Evaluation Center, Kanagawa, Japan. Sponsor: R. Murakami, Japanese Society of Toxicology

Background and Purpose: Skin sensitization is a complex occupational health issue. Historically, it has been assessed with animal tests, which has motivated the development of new approach methodologies and integrated, multi-method assessments due to animal-welfare considerations. To address these limitations, We constructed a consensus model based on three different independent skin sensitization key event (KE)/adverse outcome (AO) s from a rule-based model, a local lymph node assay (LLNA) statistics-based model, and a guinea pig maximization test (GPMT) statistics-based model. Building on this, we developed a rule and statistics-based model of replacement for KE1 (RSRKE1) and performed integrated testing strategy-defined approach (ITS-DA) combining RSRKE1 (KE1), h-CLAT (KE3), and the *in silico* consensus model. Our objective was to build a new ITS-DA for sensitization hazard prediction and benchmark it against the OECD Defined Approaches for Skin Sensitization (DASS) dataset and established *in silico* tools (Derek Nexus and the OECD QSAR Toolbox). **Methods:** We developed a consensus skin sensitization model (Murakami et al., 2025) that integrates a rule-based reactivity component with statistics-based models trained on LLNA and GPMT data and evaluated it within an OECD-aligned ITS-DA spanning KE1 and KE3. Two ITS configurations were assessed: v1 (DPRA + h-CLAT + Derek Nexus) and v2 (DPRA + h-CLAT + QSAR Toolbox). A summed score from KE1 (0-3), KE3 (0-3), and *in silico* (0-1) was used for hazard and Globally Harmonized System (GHS) potency assignments (0-1: not classified; 2-5: Category 1B; 6-7: Category 1A). Across OECD DASS chemicals, we compared KE1 scoring via DPRA versus ADRA and benchmarked *in silico* components using Derek Nexus, QSAR Toolbox, and consensus decision rules—OR, VOTE, and AND. To replace KE1 testing, we introduced RSRKE1, a rule-based surrogate that detects protein reactive structural alerts and assigns 0-3 points via a DPRA/ADRA-calibrated ensemble. We then constructed ITS variants combining RSRKE1, h-CLAT, and the most sensitive the consensus (OR) model and compared their performance with ITS v1/v2 and with versions substituting ADRA for DPRA, using the total battery score for hazard identification and potency subcategorization. **Results:** Replacing Derek Nexus and the QSAR Toolbox with the consensus (OR) model improved performance. On human data, the consensus (OR) model achieved the highest hazard-identification sensitivity (96.4%) and balanced accuracy (70.4%) and delivered the best potency performance for weak sensitizers (GHS Category 1B; 83.9% correct; 71.2% accuracy). When KE1 was scored with RSRKE1 (0-3 points) alongside h-CLAT and the consensus (OR) model, sensitivity increased for both LLNA and human datasets. Balanced accuracy reached 70.4% (exceeding ITS v1: 68.6% and ITS v2: 69.4%), and potency classification correctly identified over 80% of weak sensitizers with accuracy comparable to ITS v1/v2 and superior to DPRA/ADRA for weak substances. **Conclusions:** We developed an *in silico* consensus model that achieved balanced accuracies of 77% (LLNA) and approximately 70% (human), matching or outperforming existing methods. Leveraging its rule-based component, we created RSRKE1 as a higher-accuracy KE1 replacement and showed that an ITS-DA combining RSRKE1 (KE1), h-CLAT (KE3), and the consensus (OR) model delivered sensitivities of about 80% (hazard) and about 70% (potency) for LLNA and about 70% for human data, comparable to current ITS-DAs. These results indicate that the consensus model is suitable for *in silico* ITS-DAs and that RSRKE1, together with a KE3 alternative, can obviate the need for *in vitro* KE1 assays.

PS 3255 Me-Too Validation of the Epi2SensA Method Using EpiDerm™ Model for Skin Sensitization Testing Under OECD TG442D

C. Pellevoisin^{1,2}, H. Kojima^{3,4}, S. Hoffmann⁵, T. Ashikaga⁶, T. Landry¹, C. Romero¹, K. Guntur¹, M. Klausner¹, J. Stadnicki¹, H. Gehrke⁷, R. Mills-Goodlett⁷, N. Panousi⁷, V. J. Johnson⁸, K. Narita⁹, S. Tachibana⁹, K. Kojima⁹, and A. Armento¹. ¹MatTek Corporation, Ashland, MA; ²Urbilateria, Saint Cyr sur Loire, France; ³Sanyo-Onoda City University, Yamaguchi, Japan; ⁴NIHS, Kawasaki, Japan; ⁵Seh Consulting + Services, Paderborn, Germany; ⁶NIHS/JaCVAM, Kawasaki, Japan; ⁷Eurofins, Munich, Germany; ⁸Burleson Research Technologies, Morrisville, NC; and ⁹FDSC, Hadano, Japan.

Background and Purpose: The Adverse Outcome Pathway (AOP) for skin sensitization has driven the development and publication of OECD Test Guidelines 442C, D, and E, enabling animal-free assessment of skin sensitizing potential of chemicals. In 2023, JaCVAM validated the epidermal sensitization assay (EpiSensA), an *in vitro* method addressing the Key event 2 of the AOP by measuring gene expression of four mechanistically-relevant keratinocyte markers in reconstructed human epidermis (RhE) following chemical exposure. The purpose of this study was to validate Epi2SensA, a similar method, using EpiDerm™ (EPI-200) as an alternative RhE model. Like EpiSensA, Epi2SensA will be used in conjunction with other *in chemico* and *in vitro* tests in the OECD TG442 series as part of an IATA in the AOP framework to identify the sensitization potential of substances for the classification and labeling of skin sensitization hazards. Integration of Epi2SensA in the OECD TG442D will provide laboratories with multiple RhE supplier options and ensure worldwide supply chain reliability. **Methods:** The use of EpiDerm in Epi2SensA required the following adaptation of the EpiSensA protocol: a) increased application volume (10 µL vs 5 µL), b) reduced exposure time (1 hour vs 6 hours), c) modified killed controls using basolateral Triton-X application, and d) increased positive control concentration (1.56% vs 0.78% clotrimazole). The me-too validation study was conducted in 2024-2025 across four laboratories, three naïve laboratories (BRT, USA; Eurofins, Germany; FDSC, Japan) and Mattek as the lead laboratory. The validation study was designed according to OECD Guidance 34 principles and to the Epi2SensA performance standards published by the OECD. After a training phase, the laboratories tested the 20 reference substances in a coded manner, 8 in one run and 12 in three independent runs to assess: a) the between laboratory reproducibility (BLR), b) within laboratory reproducibility (WLR) and c) predictivity. Mattek, Eurofins and BRT tested all reference substances while FDSC tested only eight. After selection of the solvent and dose finding to assess cytotoxicity, gene expression of four biomarkers (ATF3, GCLM, DNAJB4, IL-8) was measured by RT-PCR following exposure of EpiDerm™ tissues to four concentrations of the coded substances. At the end of the experimental phase, the identity of the test materials was decoded and statistical analysis of the results was conducted to assess WLR, BLR, and predictive capacity using both original VRM prediction model and modified criteria. **Results:** Using the original VRM criteria, the average WLR was 63.9%, BLR was 70%, with 66.6% specificity, 90.5% sensitivity, and 83.3% accuracy. Modified criteria adapting the cell viability threshold (60% vs 80%) and prediction model (requiring ≥2 positive genes vs 1) significantly improved performance. With the modified criteria, the average WLR reached 83.3% and BLR achieved 85%, both exceeding the minimum performance standard (PS) of 80% for WLR and BLR. The predictive capacity was 88.9% specificity, 88.1% sensitivity, and 88.3% accuracy which exceeded the minimum PS values of 65%, 85%, and 85%, respectively. The independent peer review of the validation concluded that the Epi2SensA method's overall performance meets the VRM performance standards and demonstrates sufficient robustness. **Conclusions:** The Epi2SensA me-too validation successfully demonstrated that EpiDerm™ can serve as an alternative RhE tissue model for skin sensitization testing under OECD TG442D. Method adaptations specific to EpiDerm™ characteristics, including modified assay parameters, acceptance criteria, and the prediction model, resulted in robust performance meeting the performance standard requirements. Independent scientific peer review of the me-too validation concluded that the Epi2SensA assay is sufficiently robust for OECD submission and potential integration into TG 442.

PS 3256 Interpreting *In Vitro* Permeation Testing Layer-Deposition Data Using a Mechanistic Skin Model in MoBi

A. Salminen, J. Willoughby, and J. McKim. LifeNet Health LifeSciences, Virginia Beach, VA.

Background and Purpose: Predicting the bioavailability of a chemical following topical application or exposure is essential for assessing the risk and efficacy of dermatological products. *In vivo* studies using preclinical species are often constrained by cost, complexity, and limited translational relevance. As a result, new approach methodologies (NAMs), including *in vitro* and *in silico* tools, are increasingly relied upon in toxicological evaluations. *In vitro* permeation testing (IVPT) with excised human skin can be combined with mechanistic skin permeation models to extrapolate these data toward *in vivo* predictions. However, refining the implementation and understanding the limitations of such models is necessary before they can be widely adopted for regulatory purposes. In this study, IVPT data were compared with simulated results generated using a skin permeation model implemented in MoBi, part of the Open Systems Pharmacology suite. Additionally, layer-deposition data from both experimental and simulated datasets were analyzed to extrapolate the *in vivo* bioavailability of the test compounds. **Methods:** IVPT was performed on four test articles,

caffeine (CAS No. 58-08-2, MW 194.19 g/mol, LogK_{ow} -0.07), salicylic acid (CAS No. 69-72-7, MW 138.12 g/mol, LogK_{ow} 2.26), testosterone (CAS No. 58-22-0, MW 288.43 g/mol, LogK_{ow} 3.32), and mannitol (CAS No. 69-65-8, MW 182.17 g/mol, LogK_{ow} -3.10). Excised human skin (LifeNet Health; cryopreserved, cadaver, leg or back, 500 µm dermatomed) was mounted on Franz diffusion cells (PermeGear; 0.64 cm² active area) connected to a heated water circulator system. Skin temperature and barrier integrity were measured by infrared thermometer and transepidermal water loss (Delfin VapoMeter), respectively. A finite dose (10 µL/cm²) of test article (1% w/v in buffer) was applied to the apical skin surface, and receptor fluid (DPBS) collections were performed at 0, 0.5, 1, 2, 3, 4, 6, and 24 hours post-dosing. Apical wash, stratum corneum tape strips (three per sample), and tissue were collected following the final (24 hour) receptor fluid sampling. All samples were extracted and analyzed by liquid chromatography tandem mass spectroscopy (LC-MS/MS). *In silico* predictions of chemical dermal absorption were collected in parallel. Test article physicochemical properties and test system parameters were input into the MoBi (version 12.0.434) implementation of the (Dancik et al. Adv Drug Deliv Rev 2013) skin permeation model (<https://github.com/Open-Systems-Pharmacology/Skin-permeation-model>) and simulated cumulative permeation, flux, and layer deposition data were generated. **Results:** The Mean ± SEM 24-hour cumulative absorption observed in the *in vitro* permeation test ranked from lowest to highest as follows: mannitol (no detectable absorption), testosterone (2.53 ± 0.20 µg/cm²), salicylic acid (7.70 ± 3.93 µg/cm²), caffeine (14.84 ± 5.30 µg/cm²). The simulated mean 24-hour cumulative absorption, alternatively, ranked from lowest to highest as follows: mannitol (2.07x10⁻²⁹ µg/cm²), caffeine (0.87 µg/cm²), testosterone (1.75 µg/cm²), salicylic acid (99.92 µg/cm²). For testosterone, the model layer deposition data predicted 96.69% of the applied dose would remain on the apical skin surface versus the experimentally observed 91.62 ± 3.40%. Simulated versus experimental comparisons of apical retention for the remaining test articles were as follows: caffeine = 41.94% vs 70.86% ± 5.32%, salicylic acid = 0.06% vs 3.02% ± 0.18%, mannitol = 57.98% vs 20.85% ± 10.24%. **Conclusions:** The mechanistic skin model was limited in its ability to accurately predict the cumulative absorption of the test compounds. The layer deposition data generated, however, was more accurate at correctly ranking the results observed experimentally. This study underscores the value of mechanistic skin permeation models in refining *in vivo* dermal absorption predictions. Integrating *in vitro* permeation testing data with computational models can strengthen predictive accuracy and increase confidence in risk assessments. Conversely, computational models can contextualize experimental findings, offering deeper insights into observed results. In both scenarios, employing multiple NAMs within a weight-of-evidence framework enhances the robustness and regulatory relevance of the assessment.

PS 3257 Next Generation Risk Assessment Case Study: A Quantitative Machine Learning Approach for Skin Sensitization in Oxidative Hair Dyes

R. Satake¹, J. Tokunaga¹, K. Kinoshita¹, H. Iwasa², K. Hatano², N. Nakamura², H. Arakawa¹, T. Yamada³, T. Ashikaga⁴, and K. Ambe⁵. ¹Department of Regulatory Science, Graduate School of Pharmaceutical Sciences, Nagoya City University, Nagoya, Japan; ²General Research & Development Institute, Hoya Co., Ltd., Nagakute, Japan; ³National Institute of Health Sciences, Division of Cellular and Molecular Toxicology, Kawasaki, Japan; ⁴National Institute of Health Sciences, Division of Genome Safety Science, Kawasaki, Japan; and ⁵Graduate School of Data Science, Nagoya City University, Nagoya, Japan.

Background and Purpose: To establish a skin sensitization risk assessment method, it is important to conduct a case study on the next-generation risk assessment method (NGRA) using *in vitro* and *in silico* new approach methodologies (NAMs). Previously, we have developed an *in silico* model for the quantitative prediction of skin sensitization potency, combining *in vitro* assay data and chemical property information through a machine learning algorithm. In this study, we focused on oxidative dyes used in hair coloring products and aimed to perform a case study of skin sensitization risk assessment using *in silico*-predicted sensitization potency values, following the quantitative risk assessment approach. **Methods:** As oxidative hair dyes, we selected 2-aminophenol, which has strong sensitization potency, and resorcinol, which has moderate sensitization potency. The consumer exposure level (CEL) was calculated based on product usage amount, retention factor, scalp surface area, and formulation concentrations obtained from patent information. The acceptable exposure level (AEL) was calculated by converting the LLNA EC3 values of the oxidative hair dyes to no expected sensitization induction levels (NESIL) and dividing them by a sensitization assessment factor (SAF). In addition, LLNA EC3 values of the selected oxidative hair dyes were predicted using our original machine learning model (XGBoost), which integrates *in vitro* assay data (ADRA, KeratinoSens™, h-CLAT) and chemical structural descriptors. Finally, the margin of safety (MOS) was calculated by dividing the AEL value by the CEL value. **Results:** The LLNA EC3 values predicted by the machine learning model were 0.62 for 2-aminophenol and 9.76 for resorcinol. Meanwhile, the measured LLNA EC3 values were 0.45 for 2-aminophenol and 6.3 for resorcinol. These predicted values closely matched measured LLNA EC3 data, confirming that the model reproduced sensitization potency adequately. The MOS values calculated based on these predictions were 0.03 (2-aminophenol) and 0.38 (resorcinol), while the MOS values calculated based on actual measurements were 0.02 (2-aminophenol) and 0.24 (resorcinol). The assessed exposure scenarios indicated that the risk associated with resorcinol was lower than that of 2-aminophenol. It should be noted that the MOS values calculated in these scenarios represented

conservative estimates. **Conclusions:** In this study, we attempted a quantitative risk assessment case study of oxidative hair dyes with different skin sensitization potencies. Since the risk assessment in this case depends on the prediction accuracy of the LLNA EC3 values, careful interpretation is required. Nevertheless, the results suggest that this approach could contribute to the implementation of NGRA using *in vitro* and *in silico* NAMs.

PS 3258 Skin sensitization assessment of recycled plastics for consumer product based on dermal sensitization threshold and *in vitro* testing methods

S. Suzuki¹, M. Haneoka², K. Saito¹, H. Mizumachi¹, and Y. Ito¹. ¹Kao Corporation, Tochigi, Japan; and ²Kao Corporation, Kawasaki, Japan. Sponsor: S. Suzuki, Japanese Society of Toxicology

Background and Purpose: In recent years, the use of recycled materials is being promoted worldwide. However, unlike virgin materials, recycled plastics can contain non-intentionally added substances. Therefore, when recycled plastics are used in consumer products, it is important to consider the potential migration of hazardous substances from packaging and to conduct careful safety assessments. In 2024, the CosPaTox consortium created guidance on the safety assessment of recycled plastics. In the assessment of skin sensitization, because it is difficult to assess each migration individually, application of exposure-based waiving using a dermal sensitization threshold (DST) has been proposed. Although there are three structure-based DSTs: Non-reactive DST, Reactive DST, and HPC DST (Safford et al., 2015, 2011, Nishijo et al., 2020), it has not been thoroughly examined which DST should be applied. Therefore, in this study we examined what kinds of skin sensitizers could migrate from recycled plastics and how to select appropriate DST value. In addition, because assessment using structure-based DST can be difficult for products with high consumer exposure level, we also conducted case studies assessing skin sensitization using *in vitro* testing. In the case studies, we evaluated the potential of applying *in vitro* data-based DST (Nishijo et al., 2022) and benchmarking assessment. **Methods:** To estimate the potential contamination of HPC substances in recycled plastics, Derek Nexus v2.8.0 predictions were performed for substances in CosPaTox substance list (2024). When "Skin sensitization HPC" alert was fired, the substance was classified as an HPC. For *in vitro* tests, migrations from the virgin container and recycled container of a product package were prepared and concentrated 200-fold before testing. The migrations were prepared at 60°C for 10 days using 95% ethanol as the simulant. Migrations above 10 ppb were then analyzed by GC/MS. KeratinoSens™ and h-CLAT were conducted in accordance with OECD Test Guidelines. The *in vitro* data-based DST was calculated by using KeratinoSens™ and h-CLAT data. **Results:** Based on the Derek predictions on the CosPaTox substance list, several substances whose structures match the HPC rules were identified. Although there were very few HPC substances, if a more precise assessment is required, it was considered preferable to apply Reactive DST after carefully reviewing the available information to confirm that the risk of HPC contamination is low. Therefore, we considered it would be desirable to apply Reactive DST if the following two conditions are satisfied: (i) No HPC substances above the HPC DST are detected by instrumental analysis (e.g. GC/MS), and (ii) There is little concern about impurity contamination from the manufacturing process (equipment qualification and/or Surrogate contaminant testing results). Regarding *in vitro* tests, KeratinoSens™ was negative, whereas h-CLAT showed a positive response in CD54 for the recycled container. Butylated hydroxytoluene was considered to be the cause of the positive response, but it is commonly used as an antioxidant in plastic containers and is of low sensitization concern. As a result, the acceptable exposure level calculated based on *in vitro* data-based DST was higher than the Reactive DST for the recycled container examined in this study, indicating that *in vitro* data-based DST is useful when assessment using structure-based DSTs is difficult. Additionally, equivalent responses were observed in both KeratinoSens™ and h-CLAT with the virgin container. Therefore, from a benchmarking assessment perspective, it was considered that the skin sensitization risk of the recycled container is comparable to or lower than that of the virgin container. **Conclusions:** Because there may be concerns that migrations from recycled containers contain HPC substances, it is necessary, in a more precise assessment, to assess the potential for HPC contamination when applying Reactive DST. The results of instrumental analysis and information on the manufacturing process can be used to assess the potential of HPC contamination. When assessment by exposure-based waiving using the structure-based DSTs is difficult, it was found that using *in vitro* data-based DST or benchmarking assessment can be effective.

PS 3259 Multi-Endpoint Characterization of ArtSkin®-RhE for Detecting Retinoic Acid-Induced Skin Irritation and Barrier Dysfunction

S. Lee¹, S. Moon¹, K. Lim², and T. Kwak¹. ¹NEXT&BIO Inc., Seoul, Korea, Republic of; and ²College of Pharmacology, Ewha Womans University, Seoul, Korea, Republic of.

Background and Purpose: With the global transition toward non-animal alternatives in cosmetic and pharmaceutical safety assessment, it has become increasingly important not only to ensure the reliability and reproducibility of reconstructed human epidermis (RhE) models, but also to diversify the evaluation endpoints. In this

study, we aimed to characterize our newly developed RhE model, ArtSkin®-RhE, and assess its applicability for evaluating retinoic acid (RA)-induced skin irritation and toxicity. Unlike strong irritants such as SDS or SLS described in OECD TG 439, RA induces barrier dysfunction and inflammatory responses while causing only minimal reductions in cell viability. Such characteristics are not easily detected by TG 439, which relies primarily on cell viability as the single endpoint for irritation classification. Therefore, this study sought to validate the stability of the ArtSkin®-RhE model and to develop a multi-endpoint irritation assessment approach capable of detecting more subtle and mechanistic skin responses across a concentration-dependent RA exposure. **Methods:** ArtSkin®-RhE was constructed using an air-liquid interface (ALI)-based keratinocyte differentiation protocol. For quality control (QC), MTT-based viability in negative control (NC) tissues, IC₅₀ values derived from SDS exposure, and histological confirmation of a multi-layered epidermal structure were evaluated. Model suitability for irritation testing was verified by determining accuracy, sensitivity, and specificity using the 20 Performance Standard (PS) reference chemicals described in TG 439. RA was applied at five concentrations (10 µM-10 mM). Irritation and toxicity responses were assessed through: MTT assay for cell viability, ICC for functional and irritation-related protein markers, qRT-PCR for differentiation- and inflammation-related genes, TEER for barrier integrity, ELISA for inflammatory cytokine secretion, H&E staining for histological evaluation. **Results:** ArtSkin®-RhE fulfilled all QC and performance standard requirements of TG 439 and demonstrated reproducible responses comparable to commercial RhE models under both NC and PC conditions. Although RA exposure resulted in minimal reductions in viability even at higher concentrations, multi-endpoint analyses (qRT-PCR, ICC, TEER, ELISA) revealed concentration-dependent alterations in barrier function and irritation/inflammatory markers. Additional analyses are ongoing to further validate the consistency and significance of RA-induced inflammatory responses. These findings suggest that ArtSkin®-RhE, when paired with multi-endpoint evaluation, is capable of detecting mild, functional perturbations that may not be captured by the TG 439 viability-only approach. **Conclusions:** ArtSkin®-RhE exhibited structural and functional performance consistent with TG 439 requirements, and the multi-endpoint assessment strategy enabled sensitive detection of concentration-dependent RA responses. This study highlights the potential of ArtSkin®-RhE as a reliable human-based platform for evaluating skin irritation and toxicity, particularly for substances that induce subtle or chronic barrier-related effects that are not fully identified through traditional TG 439 criteria. The results support the broader applicability of multi-endpoint RhE-based assays in mechanistic research and diverse non-animal skin toxicity evaluations.

PS 3260 Metabolomics analysis of human keratinocyte response to chemical allergens

C. Zimmer¹, K. Hardonnière¹, F. Castell², E. Chu-Van², C. Chollet², M. Pallardy¹, F. Fenaile², and S. Kerdine-Römer¹. ¹Université Paris-Saclay, Inserm, UMR-996, Orsay, France; and ²Université Paris-Saclay, CEA, INRAE, DMTS, MetaboHUB, Gif-sur-Yvette, France.

Background and Purpose: Allergic contact dermatitis (ACD) is a common skin disease caused by drugs and environmental chemicals acting as “chemical allergens”. Keratinocytes (KCs) are the main component of the skin’s epidermal barrier. They play a crucial role in initiating and developing inflammatory responses by releasing pro-inflammatory cytokines into the skin microenvironment. However, the mechanisms by which KCs integrate chemical stress remain incompletely understood. In this study, we investigated the impact of three well-known chemical allergens - hydroxycitronellal (HC), cinnamaldehyde (CINA) and methylisothiazolinone (MIT) - on the metabolome of human primary KCs using a metabolomics approach. **Methods:** Normal human primary epidermal KCs (HPEKp) were exposed to HC, CINA or MIT at low and high concentrations (100 and 500 µM for HC, 25 and 75 µM for CINA, and 10 and 40 µM for MIT). Exposure durations were 1h, 6h, and 24h, with cytotoxicity remaining below 30% in all cases. Intracellular metabolite extraction was performed in culture dishes with a cold H₂O/MeOH mixture (30:70, v/v). The metabolomes of cells treated with chemical allergens or vehicle controls (n = 12 per group) were analyzed using C18- and HILIC-based liquid chromatography coupled with high-resolution Q-Orbitrap mass spectrometry (LC-HRMS). Data processing was achieved using the R package XCMS and Workflow4Metabolomics Galaxy platform tools. Metabolite annotation was performed using an in-house spectral database. In parallel, a panel of pro-inflammatory cytokines (TNFα, IL-1α, IL-1β, IL-18, and CXCL8) was quantified in the extracellular medium using a Meso Scale Discovery (MSD) multiplex chemiluminescent immunoassay (n = 3 per group). **Results:** The metabolomics analysis identified 180 metabolites with high confidence levels (levels 1 or 2 according to the criteria of the Metabolomics Society). To assess differences between allergen-treated cells (HC500, CINA75 and MIT40) and vehicle controls (medium and 0.1% DMSO), multivariate analysis using partial least squares discriminant analysis (PLS-DA) was performed at each time point for the 180 metabolites. On the PLS-DA score plot of the first two components, the HC500-treated cells were clearly separated from the other allergen-treated cells and vehicle controls at all time points. CINA75-treated cells clustered apart from vehicle controls after 6h and 24h of exposure, while MIT40-treated cells showed separation only at 1h. Univariate analysis (Wilcoxon test with Benjamini-Hochberg correction) revealed that 109, 106, and 34 out of the 180 identified metabolites showed significant differences (p-value ≤ 0.05) between the HC500, CINA75- and MIT40-treated cells and their respective vehicle control at one or more time points. A comparison between differential metab-

olites at low and high exposure concentrations of each chemical allergen indicated that more metabolites were altered at higher concentrations, suggesting concentration-dependent effects of the chemical allergens on the KC metabolome. Notably, glutathione (GSH) was the only metabolite affected by all three chemical allergens, regardless of concentration. The significant metabolites in the univariate analysis were subsequently used for pathway analysis, which revealed several pathways commonly altered by HC, CINA and MIT, including glutathione metabolism, amino acid metabolism, glycerophospholipid metabolism, pentose phosphate pathway, and pyrimidine metabolism. Moreover, distinct inflammatory cytokine patterns were observed among the allergen-treated cells. **Conclusions:** This study represents the first comprehensive evaluation of metabolome remodeling and cytokine secretion induced by HC, CINA and MIT in human primary KCs. Significant metabolic changes were observed in allergen-treated cells showing time-, treatment- and concentration-dependent variations. Although the three chemical allergens induced distinct modifications in the abundance of intracellular metabolites in terms of direction and intensity, they also commonly affected several key metabolic pathways. These findings provide a strong foundation for further investigations into the role of metabolic reprogramming in the inflammatory response of KCs to chemical allergens in ACD.

PS 3261 Assessment of skin barrier function: A comparison of transepidermal water loss (TEWL) and skin absorption studies

E. Subeileau, B. Lopez, T. Yon, E. Schaefer, C. Le Saint Quinio, P. El Azzi, and C. Chesné. Wepredic, Rennes, France. Sponsor: M. Pallardy

Background and Purpose: *In vitro* human skin absorption studies are essential for the safety evaluation of chemicals, crop protection products, consumer healthcare items, and cosmetics. According to the OECD 428 guideline, the barrier function integrity of skin samples studies must be verified. Commonly used barrier integrity assays include transepidermal water loss (TEWL), transepithelial electrical resistance, and chemical absorption tests. This study investigates whether TEWL alone is sufficient to detect skin barrier impairment following exposure to irritants or mechanical damage. **Methods:** Human abdominal skin disks from three donors were processed within 24 hours post-surgery and exposed for 24 hours to one of the following two irritants: (i) a finished cosmetic product classified as strongly irritant by MTT assay, and (ii) 10% SDS solution. TEWL was measured using the Aquaflex closed-chamber system (Biox Systems). In parallel, skin absorption of 7 compounds (Methylprednisolone, Umbelliferone, Sulfamethazine, Clopidogrel, PABA, Benzydramine, Carbazeren) was quantified by LC-MS/MS after 2-hour exposure in Franz cells. Mechanical damage was induced using two methods: needle punctures and a derma-roller. Additionally, a retrospective analysis of >1000 TEWL measurements collected over four years was performed to assess variability and influencing factors. **Results:** TEWL was less sensitive than skin absorption measurements in detecting barrier impairment. Irritant cosmetic exposure did not significantly alter TEWL, yet skin absorption increased by 45 (for Methylprednisolone succinate) to 82% (Sulfamethazine and Umbelliferone) across all compounds compared to untreated skin. TEWL rose markedly only after strong irritant exposure (10% SDS) or severe mechanical damage, increasing from 13 to 52 g·m⁻²·h⁻¹ on average. Mild mechanical injuries failed to elevate TEWL despite a 50% increase in skin absorption. Historical TEWL data revealed an average of 10.5 g·m⁻²·h⁻¹ (range: 7-15 g·m⁻²·h⁻¹) with only 3% of samples exceeding the 15 g·m⁻²·h⁻¹ threshold and no significant correlation to age, BMI, or sex. **Conclusions:** Irritant exposure and mild mechanical damage significantly enhance skin permeability, but these changes are not consistently detected by TEWL. While TEWL provides a rapid preliminary screening of skin integrity, it should be complemented by additional methods such as skin absorption assays for reliable assessment of barrier function.

PS 3262 Human skin equivalents reveal multiple cell death modes in mustard agent-induced dermal injury

C. Gaviria, S. Ahmad, C. Anthony, L. Morris, and P. McNutt. Wake Forest University School of Medicine, Winston Salem, NC.

Background and Purpose: Chemical warfare agents represent a major global health concern due to their high morbidity and mortality. Particularly, mustard agents pose a particularly serious public health threat, as they can be easily produced, cause severe injury and lack effective medical countermeasures. While apoptosis and necrosis are known mustard-induced cell death pathways, the involvement of other modes of cell death, such as parthanatos, pyroptosis, necroptosis, and ferroptosis, remains largely unexplored. Understanding these diverse cell death modes could reveal new options for therapeutic intervention; however, progress has been limited by the lack of physiologically relevant human skin models. To address this limitation, we developed a three-dimensional human skin equivalent (HSE) that accurately replicates human skin biology and enables the study of vesicant-induced injury and cell death mechanisms. **Methods:** HSEs consisted of a stratified epidermis of keratinocytes overlying a dermal compartment containing fibroblasts, adipocytes, and endothelial cells. To evaluate their suitability for studying the toxic effects of vesicants, we established a novel method for exposing HSEs to sulfur and nitrogen mustard vapors, reproducing the likely route of exposure during a chemical attack. Histological and genotoxic markers of cellular injury were analyzed as well as the activation of specific cell

death pathways over time. **Results:** HSEs faithfully recapitulated key structural and functional characteristics of human skin, including epidermal stratification, stromal complexity, and spontaneous vasculogenesis. Upon exposure to mustard agents, HSEs exhibited dose-dependent vesication, an effect rarely observed in animal models, as well as DNA damage, as indicated by H2A.X staining. Time-course analyses revealed immunohistochemical evidence for the activation of multiple cell death pathways, including apoptosis, parthanatos, pyroptosis, necroptosis and ferroptosis. These findings were confirmed by immunohistochemistry, TUNEL staining, adenylate kinase release and qPCR analysis. **Conclusions:** Our findings support the use of HSEs as robust and physiologically relevant platform for studying skin pathogenesis of vesicant exposure. HSEs exhibited dose-dependent injury responses consistent with human pathology while revealing the involvement of diverse cell death pathways, offering potential targets for therapeutic development. By incorporating multiple cell types, these models provide a more authentic representation of the complex host responses to vesicant agents. Collectively, our results highlight HSEs as an innovative new approach methodology to reduce the use of animals for studying mechanisms of vesicant injury and screening medical countermeasures. It is anticipated that HSEs will make substantial contributions to the fundamental understanding and treatment of toxicological insults in human skin.

PS 3263 Doxorubicin-induced skin vascular permeability: a potential mechanism for cutaneous toxicities

A. Barnes¹, Y. Li¹, G. Wang¹, H. Gaikwad¹, L. Lofchy¹, R. Kant¹, S. Agrawal¹, N. Mishra¹, R. Agarwal¹, S. Goel², T. Anchordoquy¹, and D. Simberg¹. ¹Department of Pharmaceutical Sciences, Skaggs School of Pharmacy and Pharmaceutical Sciences, University of Colorado, Anschutz Medical Campus, Aurora, CO; and ²Department of Molecular Pharmaceutics, College of Pharmacy, University of Utah, L.S. Skaggs Pharmacy Institute, Salt Lake City, UT.

Background and Purpose: Doxorubicin is an anthracycline chemotherapy drug used in multiple cancers. To avoid cardiotoxicity, its long-circulating liposomal form (PEGylated doxorubicin, Doxil®) was approved in 1997. While Doxil avoids the heart tissue, it causes palmar-plantar erythrodysesthesia (PPE), a cutaneous toxicity characterized by pain, blistering, and erythema in pressure-prone areas (feet, palms, waist, and armpits). High-grade toxicity leads to suffering and drug discontinuation. As the mechanisms of accumulation of Doxil in the skin are not clear, this was the focus of our study. We previously observed that skin vasculature in the pressurized areas, such as feet, demonstrates leakiness and extravasation of liposomes. We hypothesize that initial extravasation of the drug in the skin increases subsequent drug accumulation. Therefore, this study investigates whether the accumulation of Doxil in the skin enhances permeability. **Methods:** We developed a mouse model of systemic or topical skin toxicity, where BALB/c mice were injected with Doxil (8 mg/kg) 3 times per week intravenously or Doxil/doxorubicin was injected intradermally (20 µg). The development of toxicity in mouse skin was characterized by redness, swelling, and nail necrosis in the hindlimb fingers. Following Doxil treatment, mice were injected with fluorescently labeled liposomes (Doxil formula), and their accumulation in the skin was quantified 24 h post liposome injection with fluorescence imaging and optoacoustic tomography. H&E staining was performed for histological assessment of toxicity, which was statistically analyzed using one-way ANOVA (with appropriate post-hoc testing; $p < 0.05$) for comparison among the three groups (control, IV Dox, ID Dox; $n = 3$ per group). **Results:** We found that the accumulation of doxorubicin in the skin increases vascular permeability. Thus, doxorubicin causes up to a 20-fold increase in the accumulation of fluorescent liposomes. Tissue levels of TNF- α , IL-1 β , and IL-6 did not increase after intradermal injection of doxorubicin ($n = 3$ per group), suggesting the absence of any strong inflammation. Histological analysis revealed that doxorubicin caused a modest increase in cell infiltration, with a 3.8-fold increase following intravenous delivery and a 1.57-fold increase following intradermal delivery. Vascular density showed a 1.51-fold increase for intradermal administration and no significant change with intravenous administration. Epidermal thickening was observed, with a 1.95-fold increase in the intravenous group and a 1.33-fold increase in the intradermal group. Stratum corneum integrity was also affected, showing a 2.42-fold increase in degradation and a 4.01-fold increase in detachment following intravenous administration, compared to 1.21-fold and 1.82-fold increases in degradation and detachment, respectively, in the intradermal group. **Conclusions:** We propose that skin damage amplifies Doxil accumulation, initiating a detrimental "vicious" cycle that progressively worsens tissue damage and symptoms in affected patients. This result suggests new nano formulations are needed for the prediction and prevention of cutaneous toxicities. Funding for this work was provided by the National Institutes of Health R01 CA289447, as well as the Skaggs Scholar grant to DS and SG.

PS 3264 Exercises in Applying Chemical Class Skin Sensitization Hazard Determinations

S. R. Larch¹, T. W. Dugan, M.S.¹, R. C. Ticknor, M.S., ERT², I. Hadley, M.S.¹, I. Mohar, Ph.D., DABT², and T. A. Lewandowski, Ph.D., DABT, ERT, ATS². ¹Gradient, Boston, MA; and ²Gradient, Seattle, WA.

Background and Purpose: Direct and prolonged exposure to certain chemicals in consumer products can potentially produce skin sensitization reactions. To minimize the risk of skin sensitization for consumers, hazard assessments can be utilized to classify chemicals that a consumer may come into contact with in products either as non-sensitizers or sensitizers with varying degrees of potency. A typical hazard assessment involves a literature search and evaluation of available toxicological test data. However, in some cases, the chemical of concern has not been tested for skin sensitization potential and read-across to structural analogs may be necessary. This can be true particularly for chemicals that are impurities, breakdown products, or are only tentatively identified in laboratory analysis. Assessing such chemicals can be time intensive, particularly if there is a large dataset of chemicals to evaluate. The objective of our research was to identify and create general hazard determinations for well-defined classes of chemicals with shared structures, which will reduce the effort required to evaluate newly detected chemicals lacking chemical-specific testing data. The results of the first four class evaluations are presented here. **Methods:** We reviewed an in-house database of more than 7,500 skin sensitization chemical assessments for classes of chemicals with similar structures to identify patterns in the conclusions of the assessments. Four groups of chemicals were chosen for investigation based on frequency of detections within consumer product extracts: alkanes, ethylene glycols, silanes and siloxanes, and aldehydes. Available data were tabulated for each previously evaluated member of the class. For the purposes of determining hazard for the chemical class, we relied on qualitative hazard conclusions (i.e., non-sensitizer, weak sensitizer, moderate sensitizer, or strong sensitizer). Based on the review, we developed definitions governing the allowable members of each chemical class. **Results:** Over 40 similarly structured members with hazard determinations were identified within each of these chemical classes. In all but a few cases, chemicals in the class shared the same skin sensitization classification. Skin sensitization hazard was concordant in greater than 97% of members in each class, with the exception of aldehydes. Among the aldehydes identified, saturated aliphatic aldehydes with a carbon chain length greater than 13 carbons were found to be non-sensitizing, while saturated aliphatic aldehydes with a smaller carbon chain length were sensitizing. In addition, unsaturated aliphatic aldehydes were found generally to be sensitizers. In the few instances where the hazard determination of one chemical differed from the rest of the chemical class based on experimental data, the results were not compelling. For example, cyclooctane (CAS 292-64-8) identified among the alkanes as a very weak sensitizer based on a positive mouse local lymph node assay (LLNA) in which an EC3 of 57.1% was derived. Such a high concentration is implausible in the consumer products of interest. The remaining 406 alkanes were all classified as non-sensitizers and this classification was judged suitable for the class. The remaining two chemical classes, ethylene glycols and silanes and siloxanes, were also considered to be non-skin sensitizers, as long as chemicals met the class definition. **Conclusions:** Applying hazard determinations for defined chemical classes to newly detected chemicals that fit within those classes reduces the time and resource burden of assessing large datasets of extracted chemicals. However, we found that, in some cases, a small number of chemicals had hazard determinations that differed from the majority of members in the same chemical class. Given these examples, we suggest that chemical class hazard determinations should only be applied to newly detected chemicals with no experimental skin sensitization data and no distinct features that deviate from the class definition. As illustrated by the aldehydes identified, it is important to carefully define the characteristics of a chemical class. Class-based determinations provide a weight-of-evidence (WoE) approach to the assessment of chemicals that lack experimental data, but should be conducted within a framework that defines and justifies the inclusion of new members.

PS 3265 Reapplication of the Type IV Hypersensitivity Quantitative Risk Assessment to Assess Ingredients Used on Canines

A. T. McDermott¹, G. Lorch², J. Nash¹, and P. Kern³. ¹Procter & Gamble, Mason, OH; ²Department of Dermatology, MedVet Columbus, Worthington, OH; and ³Procter and Gamble Services Company, Strombeek-Bever, Belgium.

Background and Purpose: A quantitative risk assessment (QRA) framework has been effectively developed and applied to evaluate the risk of human skin sensitization from contact allergens. So far, the QRA has not been applied in a canine risk assessment for establishing concentration limits of ingredients with Type IV hypersensitivity potential. Outlining this risk assessment is critical, as shampoos are known to cause allergic contact dermatitis (ACD) in canines, and rates of canine skin allergy insurance claims (both Type I and Type IV summed together) in the US are rising by ~10% each year. While rare, Miniature Schnauzers experiencing ACD can develop a severe and potentially fatal condition known as superficial suppurative necrolytic dermatitis. Additionally, humans have developed ACD after washing their dogs with dog shampoo. These facts underscore the importance of implementing a QRA framework to effectively assess canine personal care products for both human and dog skin sensitization potential. **Methods:** To address this gap, we conducted a

thorough literature review on canine Type IV hypersensitivity and identified potential differences which might demand an adaptation of the QRA. Historic induction of sensitization studies, elicitation patch testing reports, studies with repeated topical application of contact allergens, and skin sensitization reviews regarding dogs were all analyzed for this review article. **Results:** We summarize data from the literature demonstrating that all four key events in the skin sensitization adverse outcome pathway (1. Covalent Interaction with Skin Proteins, 2. Keratinocyte Stress Response, 3. Dendritic Cell Activation, and 4. T-Cell Proliferation) are present in dogs as they are in humans, guinea pigs, and mice. The hazard potential of sensitizers for canines is compared with the established sensitization QRA framework for humans. While there are only 5 chemicals with induction of sensitization data in dogs, only 3 were able to produce positive responses while all 5 have sensitized mice, guinea pigs and humans at equivalent or reduced concentrations as those tested on dogs. For example, cutaneous application of the strong sensitizer para-nitrosodimethylaniline up to 30% was unable to sensitize dogs, but concentrations as low as 2.5% and 0.1% can sensitize mice and guinea pigs respectively. This data further supports why mice and guinea pigs were selected as the model organisms for skin sensitization due to their heightened sensitivity for this endpoint compared to other animals. The topical repeat dose dataset consists of 13 contact allergens applied to dogs. All show equivalent or reduced potency compared to mice, guinea pigs, or humans. The limited collective suggests that dogs are not more susceptible to sensitizers than humans; therefore, safety-defined concentration limits from Type IV hypersensitivity risk assessments for humans can be re-applied to canines so long as their unique exposure considerations are factored in. **Conclusions:** Using the principles in this review, one can evaluate chemical sensitizers to support the safe development of new topical formulations for canines. The result of applying our current best approaches for assessing ACD to canine products should protect both the pet and the owners.

PS 3266 Optimization of the Human Cell Line Activation Test (h-CLAT) for the Identification of Photo-Allergens

J. Phillips¹, A. Islas-Robles¹, G. Ritacco², A. Hilberer¹, C. Deodhar², V. Lough¹, C. Cheng¹, K. Dailey¹, B. Ly¹, D. J. Bolteho², and A. M. Api². ¹Institute for In Vitro Sciences, Gaithersburg, MD; and ²The Research Institute for Fragrance Materials, Mahwah, NJ.

Background and Purpose: Photosensitization refers to light-induced tissue effects upon exposure to photoreactive chemicals and ultraviolet (UV) or visible light. Two primary mechanisms are recognized: phototoxicity, a direct, non-immune reaction leading to cell damage, and photoallergy, an immune-mediated delayed hypersensitivity response that occurs when light converts a chemical into a sensitizing agent capable of inducing allergic contact dermatitis. Photoreactivity is an emerging area of interest in the field of *in vitro* toxicology and increasingly seeks to differentiate between photoirritants and photoallergens using new approach methodologies (NAMs). One strategy is to adapt existing skin sensitization assays, such as those described in OECD Test Guidelines 442C-E, by incorporating a light-exposure step. However, published information on the photo-modified human cell line activation test (h-CLAT) procedures is scarce. Herein describes the adaptation, optimization, and transfer of the photo-h-CLAT assay for identifying photo-induced allergens that activate dendritic cells. Following optimization, the assay's performance was evaluated using a set of ten reference chemicals with compelling evidence of photoallergic potential. **Methods:** The photo-h-CLAT was established based on previously reported protocols (Hino, 2008; Hoya, 2009) and further refined using procedures developed by a partnering laboratory. The assay combined the standard h-CLAT method (OECD TG 442E) with UVA irradiation at an intensity of 5 J/cm² to compare cellular responses in the presence or absence of light. Following exposure to a test chemical, THP-1 cells were harvested and stained with antibodies against cell surface markers, CD54 and CD86, and expression was quantified by flow cytometry. Photoallergic potential was determined by comparing the relative fluorescence intensity (RFI) under light versus dark conditions. Compounds were classified as positive if the light-to-dark RFI ratio was ≥ 2.0 for CD54 or ≥ 1.5 for CD86. Optimization steps included evaluating extended antibody incubation times, the use of phenol red-free medium instead of DPBS, and adjusted test chemical exposure times to improve assay consistency. The reference chemical set was selected based on well-characterized literature containing clinical data for photoallergic responses. **Results:** During assay transfer and optimization, three chemicals, chlorpromazine, (CPZ), 6-methylcoumarin, and ketoprofen, were initially tested to evaluate reproducibility and performance thresholds. CPZ was tested 25 times and consistently exceeded the 2.0 CD54 threshold at 1.4 $\mu\text{g/mL}$ under UVA exposure but did not reach the 1.5 CD86 threshold. These results confirmed CPZ as a reliable positive control for photoallergic activation of dendritic cells. 6-Methylcoumarin exceeded the CD54 threshold (6.1 $\mu\text{g/mL}$) but not the CD86 threshold. Ketoprofen showed variable outcomes across four trials, some exceeding the CD54 threshold, others the CD86 threshold, and some negative for both. Following optimization, the full set of ten reference chemicals was evaluated. The adapted photo-h-CLAT correctly identified nine of ten compounds as photoallergens: 3,3',4',5-Tetrachlorosalicylanilide, CPZ, 6-Methylcoumarin, Bithionol, 4-Methyl-7-ethoxycoumarin, Musk Ambrette, Sulfanilamide, Lomefloxacin Hydrochloride, and Fencitol. One material, 7-Methoxycoumarin, tested negative despite literature evidence of photoallergenicity. The overall predictive accuracy was 90%, and optimization modifications did not affect the assay's classification outcomes. **Conclusions:** The optimized photo-h-CLAT successfully identified known photo-allergens through the incorporation of UVA exposure into the standard h-CLAT framework, demon-

strating its potential as an *in vitro* assay for assessing photo-allergic haptens. While a single false negative was predicted among ten reference chemicals, the overall results support the feasibility of the photo-h-CLAT for identifying chemicals that activate dendritic cells following light exposure. Continued evaluation using broader chemical sets will help further validate this method and strengthen its role among NAMs for photoallergy assessment.

PS 3267 Hyposkin as a human-based NAMs platform for local toxicity and formulation safety assessment

J. Magerman¹, K. Polak², O. Binazon¹, A. Ochando², and J. Baumeister¹. ¹Argenx bvba, Zwijnaarde, Belgium; and ²Genoskin, Toulouse, France. Sponsor: A. Ochando Descargues, EUROTOX

Background and Purpose: In drug development, the appropriate design of the drug formulation is essential to ensure the successful commercialisation of a safe, stable, and effective product. Despite scientific advances, preclinical evaluation of local tolerance still relies largely on animal testing due to the lack of human-relevant *in vitro* alternatives accepted by regulatory agencies. Developing and validating translational, human-based New Approach Methodologies (NAMs) is therefore essential to improve predictive accuracy and reduce reliance on animal models. HypoSkin®, a biostabilized *ex vivo* human skin model developed by Genoskin, preserves the epidermis, dermis, and hypodermis, offering a physiologically relevant immunocompetent and injectable platform for assessing formulation-induced toxicity. **Methods:** Subcutaneous injections of various formulations of a test item were administered into HypoSkin® explants. The explants were derived from the skin of 3 human donors. To validate the *in vitro/in vivo* correlation of the model, control compounds were added including apomorphine, a known cytotoxic agent and a reference formulation previously associated with local toxicity in minipigs. Multiple complementary readouts were applied: macroscopic imaging, histopathological evaluation, TUNEL assay for apoptosis, LDH release assay for cytotoxicity, and an integrated control-based scoring system for comparative analysis across donors and replicates. **Results:** The HypoSkin® platform successfully identified toxic reference formulations, demonstrating sensitivity and validating an *in vitro-in vivo* correlation. Macroscopic imaging and histopathology consistently detected compound-induced alterations, confirming their robustness and reproducibility across donors. However, high variability in TUNEL results limited the interpretability, likely reflecting interindividual differences inherent to human skin. Similarly, LDH assays exhibited limited sensitivity to controls, highlighting the need for additional quantitative endpoints. Both assays were excluded from the final scoring system. These findings underscore both the advantages and practical challenges of human skin-based systems in early safety screening. **Conclusions:** This study validates HypoSkin® as a translational alternative to animal-based local tolerance assessment. Its ability to detect formulation-induced tissue alterations in a human model supports its potential use in preclinical safety evaluation. Continued optimization of assay design and endpoint selection will further enhance reproducibility, positioning the *ex vivo* skin model as a valuable NAMs candidate to support future regulatory acceptance in local toxicity assessment.

PS 3268 Microfluidic co-culture of iPSC-derived sensory neurons and human melanocytes demonstrates neuron-melanocyte interactions relevant to melanogenic pathways and neurocutaneous toxicology

V. Chakravarty¹, S. Dhepe¹, N. Salman², R. Chandratike¹, N. Ftaich², K. Rajendran¹, T. Honegger², P. Bhanushali¹, and A. Khanna¹. ¹Yashraj Biotechnology Ltd, Navi Mumbai, India; and ²NETRI, Lyon, France.

Background and Purpose: Melanocytes and peripheral sensory neurons both arise from neural crest cells during embryonic development, reflecting their shared lineage. As development progresses, Schwann cell precursors migrate along sensory axons and can differentiate into melanocytes within the skin. This process results in the formation of a specialized neurocutaneous interface—a site where neurons and melanocytes directly interact—which continues to function into adulthood. Investigating this physiological crosstalk is essential for understanding how neurons influence pigmentary processes and how the skin responds to neurotoxic insults. However, studying these interactions *in vitro* has been limited by the distinct media requirements of human induced pluripotent stem cell (iPSC)-derived sensory neurons and melanocytes, making their co-culture technically challenging. To address this limitation, this study used a compartmentalized microfluidic culture system. This model enables the controlled co-culture of iPSC-derived sensory neurons and melanocytes, facilitating the investigation of their reciprocal molecular influences—particularly on melanogenic signaling pathways. **Methods:** iPSC-derived neural crest cells were differentiated into sensory neurons within one microchannel compartment of DUALINK chips. Upon neuronal maturation and establishment of neuritic extensions through microchannels, primary human epidermal melanocytes were seeded in an adjacent compartment. Cultures were maintained under fluidically isolated conditions for 72 hours before termination. Melanocyte maturation and pigment-related markers were evaluated using RT-qPCR and immunocytochemistry. **Results:** Melanocytes exposed to extended sensory neurites exhibited pronounced morpho-

logical maturation and melanin accumulation compared to controls. RT-qPCR analysis revealed significant upregulation of TYR, MITF, PMEL, Rab27A, MYO5A, and MLPH expression, indicating enhanced melanosome biogenesis and trafficking. Immunostaining corroborated increased tyrosinase and MITF accumulation in neurite-associated melanocytes, suggesting that neuronal factors or physical contact modulate melanocyte activity *in vitro*. **Conclusions:** This microfluidic co-culture platform successfully reconstructed neurocutaneous interactions using human iPSC-derived cells. The observed neurite-dependent melanogenic activation highlights a mechanism by which neurotoxicants or skin-targeted drugs could alter pigmentation via neuronal influence. By enabling physiologically meaningful hetero-cellular interaction, the DUALINK system serves as an advanced platform to develop *in vitro* model for evaluating neurocutaneous toxic effects, screening for drug-induced pigment loss, and studying factors that promote melanocyte over activity.

PS 3269 Advanced Human-Based *In Vitro* Models for assessing Cardiac Toxicity and Arrhythmia Mechanisms

R. J. Knox. Nanion Technologies Inc, Livingston, NJ. Sponsor: E. Dragicevic, Safety Pharmacology Society

Background and Purpose: Background/Purpose Cardiac toxicity and arrhythmias, particularly atrial fibrillation (AF), represent major contributors to morbidity and mortality worldwide. Preclinical evaluation of cardiac safety often depends on animal models that inadequately reflect human-specific electrophysiological mechanisms, thereby limiting translational predictivity. To overcome these limitations, we established an atrial fibrillation assay using human induced pluripotent stem cell (hiPSC)-derived atrial cardiomyocytes and a real-time impedance-based toxicity monitoring system, to enable quantitative assessment of electrophysiological function and cardiotoxic responses in a high-throughput, human-relevant context. **Methods:** hiPSC-derived atrial cardiomyocytes (Axol Biosciences Ltd.) were pre-cultured for 6 days in 96-well plates and subjected to electrical tachypacing at 2.5 Hz for 23 h using the CardioExcyte 96 system to induce an AF-like phenotype. Electrophysiological parameters, including extracellular field potential duration (FPD) and beat duration, were recorded before and after pharmacological intervention. In parallel, impedance-based assays using the AtlaZ system (6 × 96-well plates) employed Electric Cell-substrate Impedance Sensing (ECIS) across 0.1-100 kHz frequencies to monitor cell adhesion, proliferation, and cytotoxicity in real time. Human cardiomyocyte-like cells (H9C2) were exposed to a panel of cardiotoxic compounds, such as Vincristine, BMS-986094, and Doxorubicin, over acute (24-48 h) and chronic (up to 7 days) durations to quantify dose-dependent structural and functional effects. **Results:** In the hiPSC-AF model, hERG channel blocker dofetilide (1-10 nM) produced a clear, concentration-dependent prolongation of FPD by up to 48 ± 4% at 10 nM compared to baseline, along with a 37 ± 5% increase in beat duration, reflecting delayed repolarization and restored rhythmicity consistent with clinical QT-prolongation data. These findings validated the model's sensitivity to hERG-mediated pharmacodynamics. Impedance-based toxicity profiling revealed distinct compound-specific signatures. Vincristine induced a 25% reduction in Cell Signal after 48 h at ≥100 nM, indicating disrupted cell adhesion and viability. BMS-986094 caused a progressive 60% linear decay in impedance over 72 h at 10 μM, suggesting cumulative structural degradation and metabolic impairment. Doxorubicin triggered a concentration- and time-dependent decline in impedance (IC₅₀ ≈ 1.2 μM after 48 h), consistent with oxidative stress-induced cardiomyocyte damage. In contrast, ET-1, Nilotinib, and Erlotinib exhibited no significant changes (<5%) across all concentrations tested, confirming assay specificity. Multi-frequency impedance spectra provided additional insights: low-frequency data (≤2 kHz) reflected loss of barrier integrity and adhesion, while high-frequency signals (>40 kHz) captured changes in cell volume and proliferation dynamics. Long-term monitoring revealed early morphological alterations up to 24 h before cell death became evident microscopically, underscoring the method's predictive capacity for early-stage cardiotoxicity detection. **Conclusions:** Combining hiPSC-derived atrial electrophysiology with impedance-based cytotoxicity assays offers a comprehensive human-relevant approach to cardiac safety assessment. These systems provide quantitative, label-free, real-time data on functional and structural cardiomyocyte responses, capturing both acute and chronic toxicity mechanisms. The dofetilide response validates the electrophysiological platform for screening rhythm-modulating compounds, while impedance analyses accurately detect early toxic signatures of diverse agents. Together, these technologies represent a powerful framework for predictive cardiotoxicity testing, improving translational fidelity, reducing animal model dependence, and accelerating the development of safer therapeutics targeting cardiac function.

PS 3270 Human iPSC-Derived Mammary Gland Organoids for Non-Genotoxic Carcinogen Hazard Assessment

R. R. Nair¹, P. Bouwman¹, B. van de Water¹, M. Ganne², and C. Scheele². ¹Leiden Academic Centre for Drug Research, Leiden University, Leiden, Netherlands; and ²VIB-KU Leuven, Center for Cancer Biology, Leuven, Belgium.

Background and Purpose: Non-genotoxic carcinogens (NGTxCs), including endocrine-disrupting chemicals (EDCs) and oxidative stress-inducing agents, have been increasingly implicated in breast cancer initiation, particularly in individuals with

genetic susceptibility. Conventional breast cancer cell lines used for hazard assessment already carry oncogenic mutations, limiting their relevance for studying early carcinogenic events. To overcome these limitations, we established a physiologically and genetically adaptable human induced pluripotent stem cell (hiPSC)-derived mammary gland organoid model. This platform aims to provide a human-relevant, mechanistically informed New Approach Methodology (NAM) for studying early molecular and phenotypic events during mammary carcinogenesis. **Methods:** hiPSC-derived mammary organoids were generated through stepwise differentiation and characterized for structural and functional fidelity by immunostaining for lineage markers (KRT8, KRT14, SMA, TBX3, ESR1), hormone-responsive milk protein production, and mammary fat pad repopulation *in vivo*. To evaluate chemical responses, organoids were exposed for 24 hours to compounds with distinct modes of action (MOAs), including Aflatoxin B1, Bisphenol A (BPA), Phorbol 12,13-dibutyrate (PDBu), and Sulforaphane. Exposure responses were assessed using organoids expressing an endogenous Fucci cell cycle reporter and SRXN1 oxidative stress reporter, combined with transcriptomic profiling to capture molecular pathway activation. To model genetic susceptibility, TP53-knockout (p53KO) organoids were generated using CRISPR-Cas9. Dextran diffusion assays were performed to assess lumen filling, epithelial polarity, and barrier integrity. **Results:** HiPSC-derived mammary organoids exhibited distinct luminal and basal cell organization, Robust differentiation was achieved for wild-type, SRXN1-GFP, Fucci, and p53KO hiPSCs into mammary organoids, maintaining transcriptomic stability throughout differentiation and across exposures. Confocal imaging revealed concentration- and time-dependent cytotoxicity and reporter activity across several compounds. Transcriptomic analyses demonstrated compound- and concentration-specific responses, reflecting their distinct MOAs, and provided mechanistic insights into oxidative stress, and ERK pathway. p53KO organoids exhibited disorganized architecture and enhanced transcriptional sensitivity to chemical exposures, particularly in cell cycle-related pathways. Dextran diffusion assays showed measurable differences in lumen filling and epithelial polarity, supporting the use of these organoids for phenotypic carcinogenic endpoint assessment. **Conclusions:** This hiPSC-derived mammary organoid system provides a human-relevant, mechanistically rich platform for evaluating non-genotoxic carcinogenic hazards. Integration of live-cell reporters, confocal imaging, and transcriptomics enables quantitative, pathway-level assessment of chemical mode of action and genetic susceptibility. Ongoing work includes expanding the chemical library, introducing additional cancer driver mutations (BRCA1, PTEN, TP53). Together, these advances establish a New Approach Methodology (NAM) for mechanistic, human-based carcinogen hazard assessment. This project is financially supported by European Partnership for the Assessment of Risks from Chemicals (PARC) (This partnership has received funding from the European Union's Horizon Europe research and innovation programme under Grant Agreement No 101057014)

PS 3271 IPS-KOM : Immunocompetent Kidney Organoids as an Advanced *in vitro* Model for Immune-related Kidney Injury.

L. Wijaya¹, S. van Veen¹, V. Orlova², and B. van de Water¹. ¹Leiden University, Leiden, Netherlands; and ²Leiden University Medical Center, Leiden, Netherlands.

Background and Purpose: Immune-mediated kidney injury is a major contributor to drug-induced nephrotoxicity. Although this mechanism has been extensively studied, modelling this adversity *in vitro* remains challenging due to the structural complexity of the kidney and the absence of immune components in most models. Recently, kidney organoids have emerged as a promising *in vitro* platform for studying kidney injury because they recapitulate key features of nephron architecture and function. However, their lack of immune cells limits their ability to relevantly reflect mechanisms of this injury. To address this limitation, we established a co-culture system of the immunocompetent kidney organoid model called IPS-KOM by incorporating kidney organoids with polarized macrophages, as the main immune cells orchestrating the progression of immune-mediated kidney injury. **Methods:** To generate the IPSKOM we incorporated kidney organoids differentiated from RFP-H2B hiPSC using the Takasato protocol and hiPSC-derived monocytes from the Orlova protocol. Upon the kidney organoid maturation, the organoids were sensitized with various cytokines known to be secreted during the course of kidney injury. Following, hiPSC-derived macrophages (M0, M1 and M2) are introduced to the sensitized organoids. This co-culture kidney organoids model was imaged live for 24 hours to investigate the invasion (temporal) dynamics. Furthermore, we applied a high-content image analysis pipeline to quantify the number of invading macrophages. In addition, we also investigate the mechanism of the immunogenic interaction between the kidney organoids and macrophages by performing immunostaining on the organoids as well as profiling the gene expression and secretome of the co-culture system. **Results:** Our findings showed an increase of macrophage invasion to the inflammatory sensitized kidney organoids including TNFalpha treatment which was associated with the upregulation of the NFkB target gene ICAM1. Interestingly, based on our quantification, different macrophage subtypes exhibit distinct activity upon different cytokines. Overall, our data suggests that the immunocompetent kidney organoids exhibit expected specific functionality reflecting immune-mediated kidney injury. Further investigations on the gene expression and secretome profiles confirmed the mechanisms of this immunogenic interaction. **Conclusions:** Our studies demonstrate a promising novel co-culture model for immunocompetent kidney organoid models. IPS-KOM represents a potential *in vitro* platform to study immune-mediated kidney

injury in a more physiologically relevant context. Ultimately, this model could serve as a holistic and high-throughput approach for disease modeling, chemical testing and safety assessment related to kidney injury.

PS 3272 p,p'-DDE Induces an Epidermal Phenotype and Perturbs Cell State and Stem Cell Markers in Mammospheres

J. L. Miller¹, A. Tapaswi¹, J. W. Wotring², K. M. Polemi¹, L. K. Svoboda¹, J. Z. Sexton², and J. A. Colacino¹. ¹University of Michigan School of Public Health, Ann Arbor, MI; and ²University of Michigan, Department of Medicinal Chemistry, Ann Arbor, MI.

Background and Purpose: Breast cancer is the second leading cause of cancer deaths in U.S. women. Endocrine disruptors, such as the DDT metabolite DDE, are environmental factors linked to breast cancer risk. Emerging evidence shows that during carcinogenesis, cells can reacquire stem cell-like traits, losing their identity and exhibiting phenotypic plasticity. In this state, breast cells can transition from epithelial to mesenchymal (EMT) phenotypes or exist in a hybrid luminal/basal state, identified by their co-expression of keratin 8 and 14, a luminal and basal marker, respectively. Furthermore, breast cell populations that are CD44+/CD24- yield undifferentiated basal/mesenchymal cell properties and may indicate more favorable tumor initiation conditions. Discovering how environmental factors alter cell phenotype may be a critical step in preventing and treating breast cancer. Our objective was to use a mammosphere assay which provides a three-dimensional readout of breast cancer stem cell proliferation and self-renewal along with immunostaining for cell identity and stemness markers to test for alterations in stemness and phenotypic plasticity after introducing DDE. We performed RNA-seq analysis on the mammospheres to identify differentially expressed genes attributed to DDE exposure and then to assess mechanisms behind differential expression of identified genes, hypothesizing that DDE induces cellular plasticity via Wnt signaling. **Methods:** MCF10A cells were cultured in DDE-dosed mammosphere-forming media (0 μ M, 0.025 μ M, 0.25 μ M, 2.5 μ M, and 25 μ M) for seven days. The mammospheres were stained with the nuclear stain Hoechst 33342, immunostained with keratin 8, keratin 14, CD24, and CD44, and imaged. CellProfiler was used to quantify the count, area, and stain intensity of the mammospheres. This experiment was performed in triplicate and generalized linear regressions were used to measure effects of DDE on size, area, and intensity. A subset of mammospheres were collected and lysed for RNA sequencing. In the second round of RNA sequencing, primary mammospheres were formed in the following dosed media: 0 μ M, 25 μ M DDE, 2.5 μ M DDE, 3.75 μ M cardamonin, a known Wnt inhibitor, 0.9375 μ M cardamonin, and four mixtures of DDE and cardamonin at the same concentrations. We identified dose-dependent expression changes with BMDEExpress3. Benchmark concentration analyses were performed using the ToxicR Model Averaging analysis and the REACTOME pathway database was used for pathway enrichment analysis. **Results:** Keratin 8 and keratin 14 mean intensity significantly decreased in 25 μ M-treated DDE mammospheres compared to control ($p = 0.0001$ & $p = 0.008$). CD44 mean intensity significantly increased in mammospheres treated with DDE at concentrations of 2.5 μ M ($p = 0.012$) and 25 μ M ($p = 0.010$). In the first round of RNA-seq, mammospheres exposed to 25 μ M DDE had 578 genes upregulated and 628 genes downregulated out of 15,536 total genes compared to control. Keratinization and formation of the cornified envelope were biological pathways upregulated with a maximum fold change of 360.47 ($p = 2.44e-15$ & $3.09e-21$). In the second round of RNA sequencing, genes related to epidermal differentiation were upregulated in DDE as seen in the first round, confirming the reproducibility of this process. In the mixtures of DDE and cardamonin, many of the same genes related to keratinization were differentially expressed but at a modestly lower fold change. **Conclusions:** At 25 μ M DDE, keratin 8 and keratin 14 expression decreased, CD44 expression increased, and CD24 intensity did not change. This indicates a shift from an epithelial to mesenchymal phenotype. The RNA-seq data support these findings, where 25 μ M DDE treatment upregulated genes linked to keratinization and cornification, possibly linked to a squamous cell metaplastic phenotype. This phenotypic change was not fully rescued by cardamonin, a Wnt inhibitor, indicating that the effects of DDE on squamous metaplasia is likely through biological mechanisms besides altered Wnt signalling. This is currently being investigated. This study highlights the association between alterations in breast stem cell populations and exposure to environmental contaminants, showing that DDE can impact phenotypic plasticity, a Hallmark of Cancer, *in vitro*.

PS 3273 Flame Retardant Triphenyl Phosphate Induces Genetically Variable Exposure Responses in Mouse Pluripotent Stem Cells

M. Armstrong^{1,2}, K. Janeczko¹, H. Dewey^{1,2}, A. Czechanski¹, Q. Chen¹, E. Swanzey¹, C. O'Connor^{1,2}, S. Munger^{1,2}, and L. Reinholdt^{1,2}. ¹The Jackson Laboratory, Bar Harbor, ME; and ²Tufts University, Boston, MA.

Background and Purpose: Despite advances in genomic technologies, the effects of genetic variation on responses to environmental toxicants remain largely uninvestigated, and this is one reason for the use of an uncertainty factor in chemical risk assessment. Genetic variation impacts the biological response to chemical and environmental exposures, contributing to differences in resistance or susceptibility. Forward genetic screens of genetically diverse cell populations can be used to identify the precise genetic variants that drive response variation, but such screens

are limited by the lack of available genetically diverse human derived cell panels. Cell lines from laboratory mouse genetic reference populations like the Diversity Outbred (DO) population are genetically diverse and powered for genetic mapping but also offer the significant advantage of *in vitro* / *in vivo* trait correlation and *in vivo* validation using genetically matched individuals. These diverse cell panels are especially beneficial for studying early developmental effects of chemical exposures. Triphenyl phosphate (TPHP) is an organophosphate flame retardant that has recently been linked to adverse developmental effects, including altered cell cycle and increased cell death in stem cell populations. Self-renewal and pluripotency are defining properties of stem cells during development; therefore, it is important to understand how chemicals like TPHP may alter these critical characteristics within a genetically diverse population. **Methods:** We created a panel of induced pluripotent stem cells (iPSCs) from more than 300 DO mice, as well as the 8 founder inbred strains that were used to create the DO population. Next, we exposed a subset of these lines to triphenyl phosphate (TPHP), an organophosphate flame retardant that has been linked to numerous adverse developmental effects, to identify cellular responses associated with developmental exposure risk. Beginning with the 8 DO founder strain iPSCs, we utilized high content imaging and flow cytometry after TPHP exposure to observe genetically variable changes to iPSC colony volume and cell cycle. We then expanded our analysis to characterize interline variation in gene expression in response to TPHP in 200 DO iPSC lines by RNA-seq and applied expression quantitative trait loci (eQTL) mapping to identify genomic loci that contribute to variation in gene expression following TPHP exposure. **Results:** Cell imaging and flow cytometry showed TPHP exposure increased cell death and reduced the G2 cell cycle population with significant interstrain variation in cell lines derived from NOD/ShiLtJ and A/J strain backgrounds. We mapped a genomic locus on chromosome 15 that is linked to expression variation in many genes and co-localized with a region of known importance for cell cycling. In addition, we observed that TPHP exposure reduces expression of important pluripotency genes like *Klf4* in mouse iPSCs. **Conclusions:** Using these data, we propose a potential cellular mechanism of TPHP-induced effects on pluripotent stem cells, where TPHP causes altered cell cycle and proliferation, in addition to increased cell death. Moving forward, we will continue to investigate the effects of TPHP on cell cycle and proliferation, which are crucial characteristics for the normal function of pluripotent stem cells. This information will further our understanding of the molecular and biological pathways that modulate triphenyl phosphate exposure response within developing tissues.

PS 3274 Isolation and Culture of Human Bone Marrow MSC Under Unbroken Physioxia for Better Cell Growth and Translatability of Studies

A. D. Henn, S. L. Darou, C. E. Gbegbeawu, and S. A. Mustafa. BioSpherix, Parish, NY. Sponsor: A. Henn, American Association for Cancer Research

Background and Purpose: Human bone marrow mesenchymal stromal/stem cells (MSC) are used for *in vitro* toxicologic assays, both in traditional 2D and in 3D organoid cultures for microphysiological systems. Publications by others showing that supraphysioxia room air adds artifact to *in vitro* assays have led to calls to protect cells from room air. We previously showed that commercially available MSC cultures proliferate faster and grow for more passages under physioxia (5% O₂) than under traditional conditions (18% O₂). We also showed that HIF-1 α , a key signaling molecule upstream of cell growth pathways, is modulated by room air exposure in MSC. Here we extend earlier findings by isolating the cells from cadaver bones and expanding them under constant physioxia, so that the cells are never exposed to supraphysioxia room air oxygen. The null hypothesis for this study is that there will be no difference in doubling times between cells exposed to, and those protected from, room air. **Methods:** Except for commercially sourced MSC cell lines, all cell isolation and culture operations were performed under closed and controlled conditions in Xvivo Systems (BioSpherix). Centrifuges, microscopes, and other laboratory equipment were housed inside the closed modules. Commercial human bone marrow MSC (Lonza) were cultured at constant 5% or 18% O₂ (room air incubator O₂ control) plus 5% CO₂ in T-flasks. Media were pre-equilibrated to the proper oxygen level. Commercially available MSC specialty media were tested for cell growth kinetics under constant physioxia. Cell counts were obtained with the Denovix CellDrop and manual trypan blue count. Cells were isolated from human cadaver pelvic bones, sourced from a licensed organ procurement organization, inside the Xvivo System for unbroken control of the cell environment. The primary bone marrow cell isolate was subjected to discontinuous centrifugal gradient separation and mononuclear cells were selected for adherence to plastic. To confirm MSC identity, flow cytometric analysis was done with a Cytek Aurora and the following anti-human antibody panel (Dead cell-Zombie Aqua, CD38-PACBLUE, HLA-DR-BV785, CD45-FITC, CD14-PerCP-Cy5.5, CD73-PE-Cy7, CD105-APC, CD90-APC-Cy7 (Biolegend), CD11b-BUV395 (BD), CD34-PE (Thermo)). The cells were cultured for 2-4 weeks in specialized media (Thermo) to differentiate them into adipocytes, chondrocytes, and osteocytes. The cultures were stained with Oil Red O, Alcian Blue, and Alizarin Red S, respectively, and assessed visually (qualitatively) for cell staining. **Results:** Flow cytometric analysis showed that the bulk of the cells isolated under full-time physioxia were negative for CD45, HLA-DR, CD14, CD11b, and CD38, and positive for CD73, CD90, and CD105. The cells cultured with adipocyte differentiation media stained positive with Oil Red O, the cells cultured with chondrocyte differentiation medium stained positive with Alcian Blue, and the cells cultured with osteocyte differentiation medium stained positive with Alizarin Red S. Together these findings suggest that the plastic-ad-

herent cells cultured from human bone marrow under fully controlled physiologic oxygen can be classified as MSC. At passage number 8, MSC isolated and cultured under traditional culture conditions averaged 128 $\pm$ 15.2 hrs doubling time (n=2 separate cultures). Isolated and cultured under unbroken physioxia (5% O₂), MSC at the same passage averaged 43.2 $\pm$ 1.2 hrs doubling time (n=3 separate cultures), less than half that of the cells grown under traditional conditions, disproving the null hypothesis. Under constant physioxia, different commercially available MSC culture media also affected cell doubling time and number of passages before cell senescence, with basic DMEM + 10% FBS performing well to passage 9. **Conclusions:** We concluded that human bone marrow MSC isolated and grown under traditional laboratory conditions exhibit slower growth at Passage 8 than those isolated and grown under constant physioxia. The artifact that is introduced by room air oxygen into MSC-based assays cultured under traditional conditions may be avoided by protecting MSC from room air. Protecting MSC from supraphysiologic oxygen even during cell isolation can help produce a more robust cell line that can help improve the reproducibility and translatability of MSC-based *in vitro* assays for toxicology.

PS 3275 Cannabidiol and Δ^9 -Tetrahydrocannabinol alters *in vitro* human hematopoiesis

D. M. Khan, R. B. Crawford, and N. E. Kaminski. Michigan State University, East Lansing, MI.

Background and Purpose: Cannabidiol (CBD) and Δ^9 -Tetrahydrocannabinol (THC), the primary active compounds in *Cannabis sativa*, are recognized for their therapeutic potential and immune-modulating effects. CBD is a non-euphoric compound widely used in over-the-counter products for purported benefits whereas THC is mostly used recreationally for its psychoactive properties. With increased legalization of cannabis and related products across many US states, CBD and high-THC containing cannabis products are commonly used by diverse population groups including pregnant women. The effects of CBD and THC on many aspects of human health are not well known and there is a critical need to understand their effects on different developing physiological systems. We studied the effects of CBD and THC on the early stages of human immune cell development from hematopoietic stem and progenitor cells (HSPCs) over 28 days. **Methods:** In a 96-well plate, 10,000 human umbilical cord-blood derived CD34⁺ HSPCs per well were plated in RPMI media supplemented with 5% human AB serum, cytokines (IL-6, IL-7) and growth factors (SCF, Flt3L), and cultured over a 28-day period. SCF, Flt3L, and IL-6 (each at 25 ng/mL) were added on day 0. CBD or THC were added at different concentrations on day 0 only. Concentrations used were 1, 3, 5, and 10 μ M. DMSO (0.02%) was used as the solvent. On day 7, half of the culture media was replaced with fresh media and SCF (25 ng/mL), Flt3L (25 ng/mL), and IL-7 (20 ng/mL) were added. Half of the culture media was then replaced every 7 days with cytokine-free fresh media. Cells were collected every 7 days for phenotypic analysis using flow cytometry. **Results:** We observed that both CBD and THC induced loss of CD34 expression on HSPCs in a concentration-dependent manner, suggesting faster differentiation of HSPCs to downstream progenitors. At multiple time-points, there was a trend towards increased proportions of monocyte populations with increasing concentrations of CBD and THC. On days 7 and 14, CBD induced a decrease in percentage of CD1c⁺ cells whereas THC had the opposite effect. Percentage of CD10⁺ lymphoid populations was also lower in CBD-treated cells at early timepoints when compared to vehicle-treated cells. However, THC did not elicit any appreciable differences in lymphoid cells. Megakaryocyte progenitors were unaffected by CBD and THC at all time-points. **Conclusions:** This study demonstrated, for the first time, in an *in vitro* model of human hematopoiesis, that CBD and THC deregulate hematopoietic differentiation towards specific cell populations, and identified the differential effect each compound has on hematopoietic lineage development. These results support the need for more investigation to determine the safety of cannabis and cannabinoid product use during pregnancy.

PS 3276 Electronic Cigarette Flavor Chemicals and Synthetic Coolants Disrupt Critical Processes in Human Embryonic Stem Cells Through TRP-Mediated Calcium Dysregulation

S. Etemadi, and P. Talbot. University of California Riverside, Riverside, CA.

Background and Purpose: Electronic cigarette (EC) use among reproductive-age individuals continues to increase, yet the developmental risks posed by flavor chemicals and synthetic coolants remain poorly defined. Menthol, vanillin, and WS-23 are frequently used at high concentrations in EC refill fluids and are known activators of transient receptor potential (TRP) channels involved in regulating intracellular calcium. Early embryogenesis and gastrulation occur when pregnancy is commonly unrecognized, disruption of calcium homeostasis or pluripotency during these stages may compromise normal development. This study used human embryonic stem cells (hESCs), which model the human epiblast, to determine how exposure-relevant concentrations of menthol, vanillin, and WS-23 affect cellular processes essential for early development, including viability, proliferation, colony growth, maintenance of pluripotency, and lineage specification. **Methods:** hESCs were exposed to menthol, vanillin, or WS-23 and evaluated across multiple endpoints. Calcium influx was quantified using Fluo-8 dye to assess activation of TRP channels known to be expressed in hESCs, as confirmed by immunocytochemistry. Time-lapse imaging over 72 hours

was analyzed using StemCellQC software to extract quantitative features describing colony size and morphology. Cell death was measured via activated caspase-3 immunostaining, and mitotic index was calculated to determine effects on cell division. To assess impacts on pluripotency and lineage bias, OCT4 expression and germ layer markers were evaluated after 72 hours. Preincubation with selective antagonists for TRPA1, TRPM8, and TRPV4 was used to determine whether observed effects were TRP-mediated. **Results:** All three EC chemicals activated distinct TRP channels and triggered sustained calcium influx. Menthol at nanomolar concentrations selectively activated TRPA1, leading to increased cell death and significant inhibition of colony expansion. Vanillin activated TRPV4 and caused significant cytotoxicity, characterized by reduced colony size and complete disintegration at exposure-relevant concentrations. Nanomolar WS-23 activated TRPM8, suppressing proliferation, impairing cell viability, and reducing colony integrity. Beyond growth and survival effects, vanillin and WS-23 downregulated OCT4 and induced premature SOX17 expression indicative of endodermal differentiation. These data demonstrated loss of pluripotency and altered lineage commitment. Across all endpoints, chemical-induced effects were prevented when cells were preincubated with the corresponding TRP antagonists, confirming that TRP-mediated calcium dysregulation was a primary mechanism underlying toxicity. **Conclusions:** Menthol, vanillin, and WS-23 each initiated TRP channel-dependent calcium influx and disrupted key processes required for maintaining the epiblast-like state of hESCs, including survival, proliferation, pluripotency, and proper lineage allocation. These findings identify a mechanistic basis by which flavor chemicals and coolants used in EC products may pose developmental risks during early pregnancy. Given the high concentrations of these chemicals in EC formulations and the potential for systemic exposure, these results underscore the need to consider flavor chemicals and coolants when evaluating the developmental toxicity of EC products.

PS 3277 New Approach Methodologies (NAMs): Assessing cardiotoxicity and neurotoxicity *in vitro* using human iPSC-derived cells

J. R. Bhagwan¹, F. Régent², J. Tilman¹, K. Gillois³, B. Lickiss³, J. Hunker³, M. Gossmann³, D. Wallbank¹, and B. Onteniente². ¹Axol Bioscience, Cambridge, United Kingdom; ²Axol Bioscience, Grasse, France; and ³Innovitro GmbH, Jülich, Germany.

Background and Purpose: New approach methodologies (NAMs) are gaining traction for drug toxicity screening. In recent years, human induced pluripotent stem cell derived cardiomyocytes (hiPSC-CMs) and hiPSC-derived neurons have found greater utility for *in vitro* toxicity screens. They are a scalable, physiologically relevant model system, providing an ethical alternative to animal testing. The current study aims to investigate the toxicity profiles of two novel, unknown compounds using commercially available hiPSC-derived excitatory cortical neurons and hiPSC-derived ventricular cardiomyocytes, validating the combined use of these NAM models for integrated safety screening. **Methods:** Toxicity assessment was performed using axoCells™ Human iPSC-derived Cortical Excitatory Neurons and axoCells™ Human iPSC-derived Ventricular Cardiomyocytes. Neural stem cells were differentiated and matured to cortical neurons over 21 days. The two test compounds were applied on day 15 at concentrations of 0.1 μ M, 1 μ M, and 10 μ M. Neurite outgrowth and branching were monitored using the IncuCyte S3 Live-Cell Analysis System over the course of 7 days, and cell viability was quantified at the experimental endpoint using the CellTiter-Glo® assay. hiPSC-CMs were cultured and matured for 7 days prior to compound exposure. Acute cardiotoxicity was evaluated using the CardioExcyte 96 platform to assess changes in field potential duration (FPD), with dofetilide serving as a positive control. Chronic cardiotoxicity was evaluated over a 48-hour period using impedance-based measurements on the same platform, with doxorubicin as a positive control. Both test compounds were evaluated at identical concentrations (0.1 μ M, 1 μ M, and 10 μ M). **Results:** Initial control experiments demonstrated that dofetilide produced a significant increase in field potential duration (FPD), confirming hiPSC-derived cardiomyocyte sensitivity to acute hERG block. Doxorubicin exposure resulted in a time-dependent loss of impedance, consistent with chronic cardiotoxicity and cell death. Glutamate demonstrated neurotoxicity at the highest concentrations by inhibiting cortical neurite outgrowth. The risk profile of the unknown compounds will be compared against these reference compounds. **Conclusions:** These findings support the application of hiPSC-derived neuronal and cardiac models as complementary NAMs for *in vitro* toxicity assessment. The ability to perform both toxicity assessments in a 96-well plate format allows for concurrent evaluation of neurotoxicity and cardiotoxicity. This approach provides a scalable, human-relevant platform for early safety de-risking of novel compounds and may facilitate more predictive, mechanism-based toxicological screening in drug discovery and development.

PS 3278 Potential Impact of Anion Channels on the Interpretation of NIS Assay Results in the Fisher Rat Thyroid Cells (FRTL-5)

M. Battalora¹, P. Paramasivan², R. S. Sharma², V. S. Gawali³, J. S. Bhalli³, I. Wohlman¹, and H. McCarren¹. ¹FMC Agricultural Solutions, Newark, DE; ²Concept Life Sciences, Dundee, United Kingdom; and ³Frontage Laboratories, Concord, OH.

Background and Purpose: The Sodium/Iodide Symporter (NIS) assay is used as an *in vitro* screen to investigate a potential role for the inhibition of iodide uptake into thyroid cells on thyroid hormone synthesis. It is known that some compounds can

impact the assay by interfering with ATP synthesis or the electrochemical sodium gradient needed to drive the symporter. Other mechanisms can potentially confound the interpretation of the assay. Here we present data implicating changes in intracellular calcium with iodide excretion. Fischer Rat Thyroid Low Serum 5% (FRTL-5) cells have been shown to express a calcium activated anion channel called anoctamin 1 (ANO1), also known as transmembrane protein TMEM16A. The present work investigated a possible role for ANO1 to influence intracellular anion levels in FRTL-5 cells. **Methods:** FRTL-5 cells were treated with ionomycin to mobilize intracellular calcium, and internal iodide levels were monitored using the Sandell-Kolthoff method. An anoctamin-1 inhibitor (T16Ainh-A01) was used to inhibit the efflux of iodide from the cells treated with ionomycin. Perchlorate was used as a classical NIS inhibitor to demonstrate the sensitivity of the assay. Cell viability was monitored by measuring ATP levels in the cells. In separate experiments, endogenous calcium activated anion currents were measured in FRTL-5 cells using whole cell patch-clamp electrophysiology. Cells were held at -80 mV and stimulated with a voltage step pulse protocol from -100 to +120 mV at 0.2 Hz frequency. Data were recorded using a Molecular Devices pClamp 11 bundle. Ionomycin was perfused as positive control in the presence and absence of calcium into the cells. The impact of T16Ainh-A01 on anion currents through ANO1 channels in cells treated with ionomycin was also investigated. **Results:** In the NIS assay, the release of calcium from intracellular stores in FRTL-5 cells treated with ionomycin caused an apparent increase in iodide efflux. Treatment of the FRTL-5 cells with ionomycin plus T16Ainh-A01 weakly decreased the level of efflux of iodide from the cells compared to cells treated with ionomycin alone. In the patch-clamp assay, ionomycin was perfused into cells in the presence and absence of calcium in the internal solution, showing an enhancement of anion efflux for both chloride and iodide. Perfusion of cells with T16Ainh-A01 decreased the ionomycin-induced anion currents. **Conclusions:** The experiments described herein suggest that increases in internal calcium ion through ionomycin treatment decreased the level of iodide in FRTL-5 cells. Patch-clamp data shows that ionomycin-induced calcium release increases the efflux of anion (both iodide and chloride). T16Ainh-A01 decreased the ionomycin mediated anion efflux, however, it was not a strong inhibitor. This could suggest that T16Ainh-A01 is a weak anoctamin 1 inhibitor in FRTL-5 cells or multiple channels mediate calcium induced iodide efflux. Follow-up on these observations is important, as these findings suggest that a decrease in activity in the NIS assay can in some cases be due to other mechanisms, and be misinterpreted as NIS inhibition.

PS 3279 Monitoring Thyroid Hormone Action in Human Hepatocytes and Evaluating Chemical Exposure Effects to Support Thyroid Disruption Safety Assessment

C. Wang, S. Caron, M. Adams, K. Gardner, and B. Johnson. Michigan State University, East Lansing, MI.

Background and Purpose: The EPA has emphasized the development of human-relevant new approach methodologies (NAMs) to identify chemicals that may disrupt thyroid hormone regulation and to reduce dependence on animal testing. This project aims to develop a human thyrocyte/hepatocyte screening model to elucidate the mechanism by which chemical exposures disrupt human thyroid kinetics and action with the goal of supporting population-level chemical risk assessment. Thyroid hormones play a key role in regulating energy balance by controlling cellular energy expenditure. TH levels are tightly regulated through multiple mechanisms; systemic levels are maintained by the hypothalamic-pituitary-thyroid (HPT) axis, the liver influences TH kinetics, and local intracellular deiodination modulates TH action at the tissue level. Intracellular deiodination of T4 to T3 separates liver TH levels from serum level. In the liver and other tissues, thyroid action controls cellular energy balance through T3 binding to thyroid receptors, which regulates the transcription of key regulatory proteins. Therefore, systemic TH levels may not accurately reflect tissue-specific TH activity. Chemicals including polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs) and per- and polyfluoroalkyl substances (PFAS) can disrupt TH action in humans and animals. **Methods:** We tested hepatic metabolic endpoints using high-content confocal imaging to evaluate thyroid hormone action in response to chemical disruption. HepG2 cells were treated with chemicals, and imaging was used to assess fatty acid uptake (FAU), mitochondrial content, and mitochondrial membrane potential (MMP) using specific fluorescent stains. CYP1A1 luminescent assay was performed to evaluate the effect of chemical exposure on hepatic enzyme activity. **Results:** Treatment of HepG2 cells with 1,2,7,8-TCDD showed fatty acid uptake (FAU), mitochondria, and mitochondrial membrane potential (MMP) exhibited dose-response decreases with IC50s at 0.71, 0.46, and 0.09 nanomolar. PCDD/F congeners, 1,2,3,7,8-PCDF, and 1,2,3,4,6,7,8-HCDF, showed approximately 10-fold and 100fold lower IC50s compared to 1,2,7,8-TCDD. CYP1A1 luminescent assay also demonstrated dose-response relationships with 1,2,7,8-TCDD, 1,2,3,7,8-PCDF, and 1,2,3,4,6,7,8-HCDF with IC50s at 0.44, 3.00 and 8.4 nanomolar. PFOS significantly induced both MMP and FAU. However, as to the TH responsiveness, HepG2 monolayers did not respond to TH treatment, whereas HepG2 spheroids showed responsiveness to both TCDD and T4. We further investigated chemical disruption of hepatic metabolic endpoints using 3D hepatocyte spheroids. TCDD was found to reduce MMP, with an IC50 of 0.12 nanomolar, comparable to the effect observed in 2D cultures. In contrast, PFOS no longer induced MMP, and no combined effects were observed in PFOS and TCDD mixture experiments. **Conclusions:** Based on our current findings, MMP emerged as the most sensitive metabolic endpoint

for reflecting TH action in the liver. It is capable of detecting disruptions induced by low nanomolar concentrations of chemicals, including those naturally present in the environment.

PS 3280 Multimodal preclinical screening of glucocorticoid-induced disruption of bone remodeling in rat

A. Tuladhar, C. Carter, E. Vaughan, M. Voorbach, S. Biswas, T. Brayman, P. Kumar, A. Marinopoulos, X. Huang, S. Finnema, R. Christmann, T. vanVleet, B. Enright, M. Guffroy, and S. Fossey. AbbVie, North Chicago, IL.

Background and Purpose: Bone toxicity is a critical consideration during drug development and may result from both intended pharmacologic mechanisms and off-target effects. While standard histopathological evaluation is routinely used in nonclinical toxicity studies, it often lacks the sensitivity to detect early or subtle skeletal alterations, particularly in short-term or exploratory dosing regimens. Early detection of bone changes is essential for mitigating downstream risk, especially in compounds with the potential to interfere with skeletal remodeling, growth, or maintenance. **Methods:** All animal procedures complied with institutional and national guidelines and were IACUC-approved. Sprague-Dawley rat serum (9-10/sex) was collected monthly for 8 months (starting ~1 month old) to assess age sensitivity of bone turnover biomarkers. In a separate study, male rats received subcutaneous DMSO/CMC (n=10) or prednisolone 7.5 mg/kg (n=10) for 14 or 28 days. Serum was collected at baseline, and days 2, 7, 15, 21, and 29 for bone biomarker analysis. Animals were euthanized at study endpoints; femur and tibia were collected, cleaned, fixed in 10% formalin, decalcified, sectioned, stained (H&E), and evaluated by a veterinary pathologist. Tibial growth plate thickness (2- or 8-month-old rats) was analyzed with Qu Path software; seven 1-mm measurements were averaged per sample. Group differences were tested with Tukey-Kramer. In the prednisolone study, proximal tibial physal thickness was analyzed with Visiopharm; Student's t-test compared groups. JMP® 14 was used for statistics. Hindlimbs were also collected for bone imaging. Rat mesenchymal stem cells were differentiated into osteoblasts ± prednisolone (12.5, 25, 50 µM), followed by Alizarin Red staining for matrix mineralization and quantification at 405 nm using ClarioStar. Cell viability (ATP) was measured with CellTiter-Glo and SpectraMax Plus 384. *Ex vivo* femur bone mineral density was assessed with InAlyzer2 DXA scanner. Micro-CT (Rigaku CT Lab GX130; 300 µA, 130 kV, 20 µm voxel, 14 min) evaluated distal femur trabeculae, analyzed in Dragonfly 2024. Serum P1NP, osteocalcin (formation), and CTX-1 (resorption) were quantified using IDS EIA kits and SpectraMax Plus384 according to the manufacturer. **Results:** To better characterize bone-related effects, we first compiled data from naïve Sprague-Dawley rats of ages typically used in early exploratory and later chronic toxicity studies. Then we applied these endpoints to assess changes in a rat model of glucocorticoid-induced bone loss. Two-month-old naïve male Sprague-Dawley rats were treated with prednisolone (7.5 mg/kg/day) for 14 or 28 days, with vehicle-treated animals serving as controls. Bone mineral density (BMD) was assessed *ex vivo* using dual-energy X-ray absorptiometry (DXA), which revealed a significant reduction in femoral BMD in the 28-day treatment group and a decreasing trend in the 14-day group. Micro-computed tomography (microCT) analysis of the distal femur demonstrated compromised trabecular microarchitecture in prednisolone-treated animals, with decreased trabecular thickness and increased separation consistent with decreased bone mass. Histological evaluation also revealed thinning of the physis, indicative of impaired longitudinal bone growth. Systemic effects of prednisolone were further evidenced by changes in serum bone turnover biomarkers, including N-terminal propeptide of type I procollagen (P1NP), osteocalcin, and C-terminal telopeptide of type I collagen (CTX-1), suggesting suppression of both bone formation and resorption. **Conclusions:** A multimodal approach improved the ability to detect and characterize early skeletal toxicity, providing a more comprehensive assessment than using standard histopathology alone. DXA imaging enabled the quantification of changes in bone density and Micro-CT enabled quantification of subtle bone architectural findings in a rat toxicity study with a bone toxicant. Incorporation of bone-specific endpoints (serum biomarkers and imaging assays) will aid in identifying compounds with potential impact on skeletal health guiding drug development.

PS 3281 Impact of climate change on the estrogenic activities of paraquat

I. M. Omoruyi^{1,2}, U. E. Osemwowa², O. Uyi³, and R. Pohjanvirta⁴. ¹Benson Idahosa University, Benin City, Nigeria; ²University of Helsinki, Finland, Helsinki, Finland; ³University of Georgia, Athens, GA; and ⁴University of Helsinki, Finland, Finland, Finland. Sponsor: J. Flaws

Background and Purpose: Rising global temperatures and altered aquatic physico-chemical regimes are likely to modify the environmental fate and biological activity of agrochemicals, yet few studies have quantified how climate-change influences the endocrine activity of commonly used herbicides. **Methods:** Here, we investigated how simulated climate-change stressors (elevated temperature, reduced pH and increased UV exposure) modulate the estrogenicity of paraquat using a yeast estrogen bioreporter assay (YES) with *in vivo* endocrine end-point assays in the African catfish *Clarias gariepinus*. Paraquat was preconditioned under control and climate-simulated treatments for 14 days to produce environmentally relevant transformation mixtures. Estrogenic activity of parent and transformed mixtures was quan-

tified using a recombinant *S. cerevisiae* YES (ER α and Luc) reporter, while sub-chronic exposure (28 day) of juvenile *C. gariepinus* to paraquat was used to assess biological responses such as plasma vitellogenin induction, 17 β -estradiol/testosterone ratios, gonadosomatic index (GSI), and gonadal histopathology. **Results:** When compared to control conditions, climate-simulated treatments produced transformation mixtures that elicited significantly higher reporter activation in the YES assay (over 1.8-4.0-fold; $p < 0.05$) and induced measurable vitellogenin synthesis and feminizing shifts in sex-steroid profiles in exposed fish ($p < 0.05$). Histopathological analyses revealed dose-dependent intersex features and reduced GSI consistent with endocrine disruption. **Conclusions:** These results suggest that climate-driven alteration can increase the estrogenic potential of paraquat and the integration of climate-change parameters and its transformation products into ecological risk assessments is crucial for more protective regulatory decision-making.

PS 3283 Quercetin enhances steroidogenesis in mouse Leydig cells MLTC-1 and I-10 exposed to atrazine

H. Elkady, S. Fierro, and P. Bu. St. John's University College of Pharmacy and Health Sciences, Queens, NY.

Background and Purpose: Testosterone is the principal male sex hormone necessary for male fertility and overall well-being. Approximately 95% of total testosterone in the male body is produced by Leydig cells within the testes in a process called testicular steroidogenesis. Exposure to pesticides, diseases, medication, and the aging process can result in reduced testosterone levels in men. With a functional hypothalamic-pituitary-gonadal axis, testosterone deficiency can be attributed to: (1) decreased Leydig cell numbers and/or (2) their reduced steroidogenic capacity. The present study focuses on the Leydig cell level and investigates the effect of the herbal medicine quercetin (Quer) on the viability and steroidogenic capacity of mouse Leydig cells exposed to the pesticide atrazine (ATZ). **Methods:** Two mouse Leydig cell lines MLTC-1 and I-10 were treated with either DMSO (control), ATZ (3, 10, 30, and 100 μ M), Quer (1, 3.3, 10, and 30 μ M), or co-treatment of Quer + ATZ (Quer 3.3 μ M + ATZ 33 μ M or Quer 3.3 μ M + ATZ 100 μ M) for 2, 4, and 6 days, with medium/chemical change every two days. At each time point, cell viability was assessed, culture medium was collected for progesterone (P4) and testosterone (T) quantification with ELISA, and total RNA was extracted for RT-qPCR analysis of gene expression of key steroidogenic genes, StAR, Cyp11a1, Hsd3B6, and Hsd17B3. **Results:** When treated with ATZ alone, the viability of both MLTC-1 and I-10 cells decreased throughout the 6-day treatment concentration-dependently. For I-10 cells, this decrease was seen as early as Day 2 with the lowest concentration of ATZ (3 μ M). Interestingly, this decrease in cell viability was also accompanied by a concentration-dependent stimulation of T production in both cell lines. However, such stimulation was not evident for P4 production. On the other hand, Quer alone treatment at lower concentrations did not cause significant changes in cell viability at earlier time points, but rather decreased viability at the last time point, Day 6, with the highest concentration (30 μ M). In MLTC-1 cells, T production increased with higher Quer concentrations, most notably at 30 μ M across the treatment, with a 4.7-fold increase compared to control on Day 4. Similarly, P4 production also increased with higher Quer concentrations at later time points. For I-10, T production was stimulated on Day 2 and on Day 6 at 3.3 and 10 μ M. Like MLTC-1 cells, the increase in T production was most notable at 30 μ M on Day 2 (2.4-fold compared to control). P4 production was also increased on Days 2 and 6 at all concentrations. The two co-treatments (Quer 3.3 μ M + ATZ 33 and Quer 3.3 μ M + 100 μ M) had different effects on each cell line. For MLTC-1, Quer + ATZ 33 μ M caused a significant increase in cell viability compared to control and the individual treatments (Quer alone and ATZ 33 μ M) on Day 4. However, this protective effect did not sustain on Day 6. For I-10 cells, the co-treatment with the higher ATZ concentration (i.e., Quer + ATZ 100 μ M) on Day 4 significantly increased cell viability compared to ATZ 100 μ M. The protective effect of Quer persisted on Day 6, resulting in significantly increased cell viability compared to both control and ATZ 100 μ M. For both MLTC-1 and I-10 cell lines, addition of Quer augmented T production. For MLTC-1, this stimulation was observed in both co-treatments on Day 2 (Quer + ATZ 33 μ M: 2.4-fold; Quer + ATZ 100 μ M: 3.6-fold, compared to control) and for Quer + ATZ 100 μ M on Day 4 (2.9-fold compared to control). A similar stimulation was also observed for P4 production in MLTC-1 cells in Quer + ATZ 100 μ M co-treatment at all time points. For I-10, T production in both co-treatment groups was significantly increased on Days 2 and 4 compared to control and Quer alone. Similar to MLTC-1 cells, T production was stimulated the most in Quer + ATZ 100 μ M co-treatment on Day 2. Additionally, P4 production was also elevated in both co-treatments compared to ATZ alone (33 μ M and 100 μ M) treatments. **Conclusions:** In both MLTC-1 and I-10 mouse Leydig cells, Quer enhanced steroid production in the presence of atrazine. These results indicate that there may be crosstalk between Quer and ATZ, which influences testicular steroidogenesis, leading to enhanced steroid production in mouse Leydig cells.

PS 3284 Long-term exposure to a phthalate mixture reprograms white and brown adipose tissue phenotypes through estrogen signaling pathways in female mice

F. Farias dos Santos^{1,2}, K. R. Eskridge³, M. J. Laws¹, J. A. Flaws¹, and J. B. Graceli^{3,2}. ¹University of Illinois, Urbana, IL; ²Federal University of Espirito Santo, Vitoria, Brazil; and ³Southern Illinois University, Carbondale, IL.

Background and Purpose: Phthalates are synthetic chemical compounds commonly used in consumer products that act as endocrine disrupting chemicals. Phthalates are frequently prevalent as mixtures, and women are more likely to be exposed to phthalates than men. Although phthalates are obesogens and affect metabolic function, limited information was available on whether chronic exposure for 12 months to an environmentally relevant phthalate mixture alters the adipose tissue phenotype in female mice. For this reason, we tested the hypothesis that chronic exposure to a mixture of phthalates changes white and brown adipose tissue (WAT and BAT) morphology and adipose gene expression in female mice. **Methods:** Female CD-1 mice (6 weeks of age) were fed vehicle control (corn oil) or a mixture of phthalates (0.15 ppm, 1.5 ppm, and 1500 ppm) through the chow for 12 months. The mixture was composed of DEP (35.2%), DEHP (21.0%), DBP (14.9%), DIBP (8.6%), DiNP (15.1%), and BzBP (5.1%). White adipose tissue and brown adipose tissue (WAT and BAT) were analyzed for morphological characteristics and expression of adipogenesis, proliferation, angiogenesis, inflammation, collagen deposition, and steroidogenic factors, and estrogen receptor (ER) markers. **Results:** The results indicate that the phthalate mixture increased estradiol levels compared to control. In WAT, the mixture decreased adipocyte size and increased adipose number compared to controls. The mixture significantly increased inflammatory infiltrates and mast cell number compared to controls. In addition, the mixture-exposed groups contained adipocytes surrounded by macrophages. The mixture exposure reduced the expression of the adipogenic marker leptin (*Lep*) and peroxisome proliferator-activated receptor gamma coactivator 1 alpha (*Ppargc1a*) compared to controls. Further, the mixture increased an angiogenesis and inflammatory marker vascular endothelial growth factor a (*Vegfa*) and chemokine ligand 5 (*Ccl5*) compared to controls. Interestingly, mixture exposure changed several markers of steroidogenesis. Specifically, the mixture increased cytochrome P450 side-chain cleavage (*Cyp11a1*) and androgen receptor (*Ar*), but decreased cytochrome P450 aromatase (*Cyp19a1*) exposure compared to controls. In BAT, the mixture increased adipocyte and cell droplet number and decreased cell size compared to controls. Further, mixture exposure increased whitening area, blood vessel number, inflammatory infiltrates, BAT collagen deposition, ER α and ER β protein expression, and expression of the inflammatory marker chemokine (C-C motif) ligand 2 (*Ccl2*) and decrease the brown adipogenesis markers uncoupling protein 1 (*Ucp1*) and *Ppargc1a* and beta-3 adrenergic receptor (*Adrb3*) compared to controls. Further, the mixture decreased lipid droplet marker perilipin 1 (*Plin1*) and growth factor marker fibroblast growth factor 2 (*Fgf2*). **Conclusions:** These data suggest that exposure to a mixture of phthalates promotes abnormal WAT and BAT morphology and adipose gene expression in female mice, which may be related to a change in steroidogenesis and estrogen signaling on female adipose tissue. Supported by Brasillinois and NIH R01ES03112.

PS 3285 In life low-volume sampling and bioanalysis of thyroid hormones on a short-term mode of action study in Han Wistar rats: 6-PTU case study.

H. Myles¹, S. Renaut¹, E. Moore¹, S. Totti², L. Youngs², C. C. Lord³, P. Whalley², and D. Cowie². ¹Labcorp Early Development Laboratories Ltd., Huntingdon, United Kingdom; ²Syngenta Jealott's Hill International Research Centre, Bracknell, United Kingdom; and ³Syngenta Crop Protection, LLC, Greensboro, NC.

Background and Purpose: Vital to homeostasis, altered thyroid function can impact thermoregulation, metabolism, behaviour and neurodevelopment. Consequently, thyroid hormones are now routinely measured on a number of OECD test guidelines that evaluate systemic and reproductive toxicity (e.g. OECD 408, 414 and 443). However, there are currently no internationally validated short-term screening studies to evaluate mechanisms of thyroid disruption *in vivo*. Historically, thyroid hormone analysis has been conducted on terminal fasted or unfasted blood samples (~2 mL) collected from the orbital sinus, sublingual vein, cardiac puncture or via decapitation under isoflurane anaesthesia. Considered a potential 3R's benefit, the purpose of the current study was to elucidate temporal effects on thyroid hormones in-life, via low volume blood sampling (0.3 mL) on Days 4, 8 and 14 without overnight fasting. **Methods:** As part of a multi-test item mode of action study, a known thyroid peroxidase inhibitor, 6-propyl-2-thiouracil (6-PTU) was administered to male and female Han Wistar (RccHan®/WIST) rats via gavage for 14 days (n=10/sex/group). A comparable control group received the 0.5% w/v carboxymethyl cellulose vehicle only. In-life blood samples were collected from the main study animals for thyroid hormone (T4, T3 and TSH) analysis on Days 4, 8 and 14 and for toxicokinetic assessment on Days 1 and 14. Blood samples for the thyroid hormone analysis were allowed to clot and centrifuged at 2000 g for 10 minutes, in order to obtain two aliquots of serum for LC-MS/MS quantification of Thyroxine (T4) and triiodothyronine (T3) or Luminex Milliplex assay analysis of Thyroid Stimulating Hormone (TSH). All bioanalysis was conducted using GLP validated analytical methods, which are presented in a separate publication (Brewin S, 2025). Additional endpoints assessed in the study included body weights, food consumption, terminal organ

weights and histopathology of liver and thyroid. **Results:** Repeat dose administration of 6-PTU in male and female Han Wistar (RccHan®:WIST) rats elicited the expected dose-dependent effects in thyroid parameters, which was supported by toxicokinetic analysis. Dose dependent increases in thyroid weights were observed in both sexes, which correlated with thyroid follicular cell hypertrophy and decreased follicular cell vacuolation. Dose and time-dependent effects on thyroid hormones were successfully identified in life, using lower serum volumes which increased data quality and reduced the number of animals required per group. Time-course effects on thyroid hormone levels in response to 6-PTU administration are presented. **Conclusions:** The study demonstrated advancements in sampling practices and analytical capabilities that refine and reduce animal use in thyroid mode of action studies. The validation of an analytical method to measure T3 and T4 from 35 µL of serum (Brewin S, 2025) facilitated the in-life blood sampling on Days 4, 8 and 14 from rats using lower blood volumes, which offered clear advantages over terminal sampling. The study design significantly reduced the number of animals required to meet the study objectives, representing a refinement and reduction in animal use consistent with the Principles of the 3R's. Furthermore, the in-life sampling enabled time-course evaluation of thyroid hormones within individual rats, allowing a direct correlation to other study endpoints.

PS 3286 Thyroxine (T4) and Triiodothyronine (T3): Validation of Methodology for the Determination of Concentrations in Surrogate Matrix and Serum Using Low Sample Volumes

S. Brewin¹, and E. Moore². ¹Labcorp Early Development Laboratories Limited, Occold, United Kingdom; and ²Labcorp Early Development Laboratories Limited, Huntingdon, United Kingdom.

Background and Purpose: The monitoring of T3 and T4 levels in blood is used as a measure of potential disruption of the endocrine system, following exposure to certain chemical types. Concentrations of these thyroid hormones are often assessed as endpoints in toxicology studies to identify potential effects on thyroid function. The analysis of T3 and T4 is routinely required to support toxicological studies in the relevant animal species. One of the main challenges for rodent studies is the limited blood volumes, making it difficult to conduct multiple tests requiring separate analytical methods from the same sample or animal. Using a micro-sampling technique and low blood volume method enables a reduction in animal numbers whilst obtaining in-life real time thyroid data. An LC-MS/MS method was developed and validated for quantitation of T3 and T4 levels in rat serum, based on a 10 µL serum sample volume, in accordance with the SANTE/2020/12830 guidance. The method was developed to cover a range of concentrations, based on the endogenous levels and the ranges observed in previous studies. **Methods:** The developed method of analysis for T3 and T4 in low sample volume involved extraction/precipitation with acetonitrile/water, followed by dilution with water (T3) or water/acetonitrile (T4). Sample extraction was performed using both surrogate matrix (containing PBS, BSA and tween20) and rat serum. Surrogate matrix confirmed method specificity at the LOQ, which serum cannot demonstrate due to endogenous analyte levels. Quantitation was performed by reverse phase LC-MS/MS with the use of isotope labelled internal standards, using solvent-based calibration solutions. Other tests included final extract and fortification solution stability. Instrument matrix effects were addressed by the use of the internal standards. **Results:** The method was successfully validated within a GLP study for T3 and T4 in surrogate matrix and rat serum, covering the required concentration ranges and achieving the required LOQ of 0.2 ng/mL and 10 ng/mL in surrogate matrix for T3 and T4, respectively. For serum, the lowest validated concentrations were 0.5 ng/mL and 50 ng/mL for T3 and T4, approximately equivalent to the endogenous levels. The upper validated concentrations were 2 ng/mL and 200 ng/mL for T3 and T4 respectively. **Conclusions:** The analytical method was shown to be reliable and robust for the quantitation of T3 and T4 over the range of concentrations tested, meeting the SANTE validation acceptance criteria. Repeatability in T3/T4 concentrations was demonstrated within a number of replicate samples (n=15) using 10 µL of rat serum, confirming acceptable method performance when using the low sample volume. The use of solvent-based calibrations allows for accuracy in quantitation of the endogenous concentrations in serum. The use of surrogate matrix confirmed acceptable method performance for detecting potential treatment-related changes in both directions in serum T3/T4 levels of a study sample. This GLP-validated method has been used for routine study sample analysis supporting a range of toxicology studies.

PS 3287 Nonylphenol and Cetyl Alcohol Polyethoxylates Disrupt Thyroid Hormone Receptor Signaling to Promote Adipogenic and Obesogenic Effects

D. R. McGrail, R. Berube, B. Murray, M. LeFauve, S. Heldman, T. A. Kocarek, and C. D. Kassotis. Wayne State University, Detroit, MI.

Background and Purpose: Chronic health conditions, including obesity, are rising globally, with over 42% of U.S. adults affected and over \$300 million spent annually on related illnesses. Traditional explanations—diet, activity, and genetics—fail to fully account for this trend. Emerging evidence points to endocrine disrupting chemicals (EDCs), specifically obesogens, as contributing factors. This study investigates

two classes of widely used nonionic surfactants—nonylphenol ethoxylates (NPEOs) and cetyl alcohol ethoxylates (CetAEOs)—found in common household products and environmental samples. **Methods:** For adipogenesis assays, exposed cells included: murine pre-adipocytes, zebrafish mesenchymal stem cells (MSCs), and human MSCs. These cells were exposed to various concentrations and NPEO chain lengths. For *in vivo* work, Zebrafish were exposed to varying concentrations and chain lengths of NPEOs and CetAEOs. Nuclear receptor assays were conducted in zebrafish and human MSCs, along with co-exposure experiments. Osteogenesis assays were conducted solely on human MSCs. Most adipogenic data was obtained through Nile Red Staining. **Results:** hMSCs exposed to NPEOs and AEOs showed a heightened increase in triglycerides per cell. Zebrafish exposed to medium-chain NPEOs showed increased body mass and visceral fat, while CetAEOs promoted subcutaneous fat with slightly reduced weight. Both chemicals cause hyperactivity and decreased energy expenditure in larvae. Mechanistic studies revealed these ethoxylates interact with nuclear receptors. NPEOs acted as estrogen receptor agonists, while CetAEOs showed antagonistic activity. Both chemical groups indirectly antagonized thyroid receptor beta (TRβ). Co-treatment with thyroid hormone (T3) reversed ethoxylate-induced fat accumulation in stem cells, implicating thyroid disruption as a key pathway. **Conclusions:** Overall, our findings suggest that common consumer surfactants can disrupt metabolism and promote adiposity by interfering with hormone signaling, particularly thyroid pathways, across multiple biological models.

PS 3288 Multi-model predictions of potential endocrine disruptors in cosmetic ingredients: Comparing *in vivo* and *in vitro* data to *in silico* predictions

G. O. Corrêa¹, N. A. Abreu¹, A. Falcão², C. Bavoux³, A. D. Canavez¹, and D. C. Schuck¹. ¹Grupo Boticário, Paraná, Brazil; ²Aima Toxicology, São Paulo, Brazil; and ³Cethra, Saint Ouen, France.

Background and Purpose: Endocrine-disrupting chemicals (EDCs) are considered a serious health threat, contributing to major diseases. Classical targets of EDCs include nuclear receptors such as estrogen (ER), androgen (AR), and thyroid (TR), among others. These receptors are part of the so-called EATS, which includes several bioassays to detect activation/inhibition of estrogen, androgen, and thyroid receptor signaling as well as steroidogenesis ("E-A-T-S"). Considering the current regulatory scenario for cosmetics, safety assessment is constrained, requiring reliance only on available data and New Approach Methodologies (NAMs), specifically *in vitro* and *in silico* testing. This study aimed to assess the performance of *in silico* models in predicting endocrine activity of cosmetics ingredients, comparing them with *in vitro* and *in vivo* data available in the literature for the substances evaluated. **Methods:** Sixty substances with a warning for endocrine disruption were selected as potentially positive (PP), according to the definition of OECD GD 150, for substances that might be expected to lead to endocrine disruption, and twenty without the warning were selected as potentially negative (PN). These eighty substances were assessed by computational predictions for three hormonal receptors (ER, AR, and TR) using three software platforms (Danish QSAR, Vega QSAR, and Endocrine Disruptome), which included quantitative structure-activity relationship (QSAR) and molecular docking models. Model performance was evaluated based on coverage and concordance with *in vitro* and *in vivo* data. Finally, a majority consensus approach was applied to the *in silico* predictions to classify substances as having endocrine activity potential (>0.5) or non-endocrine activity potential (<0.5), by assigning scores of 0 and 1 for negative and positive results, respectively. **Results:** The Endocrine Disruptome was the most comprehensive tool, providing predictions for 95% of all substances. Danish QSAR exhibited good coverage for the ER and AR receptors, reaching 96.7% for the PP substances and 95% for the PN substances, but poor coverage for TR (59.3%). Vega QSAR covered 90% of the PN substances. For the PP substances, performance was better for ER (85%) and TR (98.3%), while coverage for AR was 68.3%. The concordance between predictions and *in vivo/in vitro* data was low for PP substances across all platforms. Endocrine Disruptome predicted the most positive results among the PP substances, with rates of 18.3% for ER, 23.3% for AR, and 45% for TR. Danish QSAR predicted positive results for 30% of the substances for ER, 15% for AR, and 6.7% for TR. Vega QSAR presented the lowest rates of positive prediction, being 23.3% for ER, 1.7% for AR, and no positive prediction for TR. In contrast, for the PN substances, the concordance with the *in vivo/in vitro* data was high, as only the Endocrine Disruptome predicted two positive results for AR. Finally, upon applying the majority consensus approach (considering only the *in silico* results), the analysis indicated that, within the PP substance group, approximately 35% are considered potentially active for ER, 23.3% for AR, and 30% for TR. For the PN substance group, the consensus demonstrated high agreement with the absence of activity, no substance showed potential activity for the ER and TR, and only one substance (5%) was classified as potentially active for the AR receptor. **Conclusions:** Given the increasing demand for NAMs in hazard identification, *in silico* methods serve as valuable tools, particularly for addressing data gaps. While the models showed high reliability in identifying PN substances, the low concordance observed between the positive predictions for the PP group and *in vivo/in vitro* data highlights the need for caution when interpreting isolated data. This suggests that the tools used in this study can be useful for hazard identification purposes, with a good performance especially in predicting the negatives. Conversely, any positive outcome should be considered with precaution. In those cases complementary predictions or *in vitro* results might be required.

A. Karmaus¹, C. Koenig², B. Riffle³, A. Charlton¹, and S. Marty⁴. ¹Syngenta Crop Protection, LLC, Greensboro, NC; ²Corteva Agriscience, Indianapolis, IN; ³BASF Agricultural Solutions US, LLC, RTP, NC; and ⁴Dow Chemical, Midland, MI.

Background and Purpose: Prioritization of chemicals that may disrupt androgen signaling is central to the United States Environmental Protection Agency (US EPA) Endocrine Disruption Screening Program (EDSP). The program recently leveraged scores from the ToxCast androgen receptor (AR) Pathway Model, which integrates data from 11 *in vitro* assays, to prioritize chemicals for Tier 1 ED testing (i.e. Group 1 Chemicals). A high percentage of Group 1 chemicals exceeded the AR Pathway Score cutoff of 0.1, with most predicted to have AR antagonism - specifically, 28 out of 30 Group 1 chemicals were predicted to be AR antagonists. This retrospective analysis uses previously reviewed List 1 chemical data to assess whether AR antagonism scores correlate with *in vivo* anti-androgenic effects and proposes a tiered follow-up strategy for currently prioritized Group 1 chemistries. **Methods:** AR Pathway Model data (scores, flags, and cytotoxicity) for EDSP List 1 chemicals, previously reviewed by the Agency, were obtained from Kleinstreuer *et al.* (2017). US EPA risk assessment documents for List 1 chemicals were then reviewed for Tier 1 and 2-generation study results, where available. Additionally, assay-level data were examined to identify those most influencing antagonism predictions. **Results:** Our analysis, consistent with Kleinstreuer *et al.* (2017), found that integration of cytotoxicity and antagonism confirmation flags improved prediction accuracy. Across all compounds tested in ToxCast, the Odyssey Thera AR dimerization assays (OT_AR_ARSRC1 at 48 and 96 hour time points), showed the highest hit rate (15-21%), followed by Tox21 AR antagonist assays (TOX21_AR_BLA_Antagonist_ratio and TOX21_AR_LUC_MDAKB2_Antagonist) (~18%). Of the 49 List 1 chemicals, 8 had AR Pathway Model scores >0.1; 5 of these had antagonism confirmation flags or low confidence scores (<3), and 3 were negative in Tier 1 testing. In contrast, chemicals with high-confidence antagonism confirmation flags having AR Model Pathway scores suggesting predicted antagonism, showed concordant effects in the Hershberger assay supporting the suitability of this assay for targeted follow-up. **Conclusions:** Evaluation of EDSP List 1 chemicals supports refining interpretation of AR Pathway Model results by integrating antagonism confirmation flags, confidence scores, and cytotoxicity evaluation. For chemicals with high-confidence AR Pathway Model antagonism predictions, a tiered strategy prioritizing *in vitro* assays and the Hershberger assay is recommended over full Tier 1 testing.

PS 3290 **L-type voltage gated calcium channel blocker nifedipine blocks MIN6 cell depolarization with or without diphenhydramine; a live-cell fura-2 fluorescence imaging study.**

E. Herr, P. Lamar, and J. Edwards. Midwestern University, Downers Grove, IL.

Background and Purpose: Several antipsychotic medications have reported diabetogenic effects with patients taking them having a 2 fold higher risk of becoming type II diabetic (T2DM). Furthermore, specific antipsychotic drugs most often associated with T2DM also inhibit histamine 1 receptors (H1R). Diphenhydramine (DPH), is one of the most commonly used H1R inhibitors used over the counter for treatment of seasonal allergies (brand Benadryl®) and as a sleep aid (brand ZzzQuil®). It is unknown if DPH alters pancreatic beta cell function which could contribute to the onset of T2DM. This study was performed to examine if there are DPH effects on the excitability of MIN6 cells, an *in vitro* model of the pancreatic β -cell. **Methods:** Live fura-2 fluorescence of MIN6 cells was performed in the presence and absence of L-type calcium channel blocker (nifedipine 5 μ M) and agonist (BayK 8644 5 μ M) to examine the role of these channels in MIN6 cell response to DPH. MIN6 cells were incubated in 5 μ M fura-2 AM then all cells were depolarized by perfusing 40 mM KCl HEPES buffered saline for 2 min. After returning to baseline fluorescence, treated cells were perfused in buffer containing DPH (10 μ M) with and without 5 μ M nifedipine and 5 μ M BayK 8644 for 2 min then depolarized a second time in a 40 mM KCl solution that contained the same concentration of DPH 5 μ M with and without nifedipine and 5 μ M BayK 8644. Saline-control cells were perfused a second time with 40 mM KCl buffer only. **Results:** There were statistically significant ($p \leq 0.05$) decreases in both the slope and peak fluorescence of fura-2 in nifedipine-treated cells with or without 10 μ M DPH. No changes in time to onset and time to peak of fura-2 fluorescence were detected. These results indicate that the L-type calcium channel blocker, nifedipine at 5 μ M, inhibited 40 mM KCl-induced depolarization and importantly, that 10 μ M DPH did not alter this response. No significant differences were detected in BayK 8644-treated MIN6 cells for the quantitative endpoints examined. **Conclusions:** In contrast to our previous studies showing that 10 and 50 μ M DPH caused changes in time to onset and peak fura-2 fluorescence; 10 μ M DPH, in this study, did not alter these endpoints. Furthermore that DPH did not change MIN6 cell response to nifedipine or BayK 8644 would suggest that any actions that DPH has on MIN6 cells is not mediated via L-type calcium channels. Further research is needed to determine the dose-dependent effects of DPH on MIN6 cell fura-2 fluorescence, insulin release and *in vivo* effects on blood glucose.

C. Koenig¹, J. Lagonell², and J. Olson². ¹Corteva Agriscience, Indianapolis, IN; and ²Corteva Agriscience, Newark, DE.

Background and Purpose: Apical toxicological effects observed in rats at high dietary levels of fenbuconazole have been consistently associated with hepatic toxicity. To further elucidate the mechanistic basis for these findings, integrated *in vivo* and *in vitro* studies were conducted to evaluate hepatic enzyme induction, aromatase inhibition, and steroid hormone synthesis. **Methods:** In two *in vivo* mechanistic studies, nine-week-old female rats received diets containing 0, 8, 80, or 800 ppm fenbuconazole (~0.6, 6, or 60 mg/kg bw/day). In the proestrus study, animals were treated for ~7 weeks and euthanized on proestrus; in the pregnancy study, treatment began 3 weeks prior to mating and continued through gestation (GD19-21). Serum hormone levels and hepatic CYP enzyme activities were assessed. Complementary *in vitro* assays were conducted including a human recombinant microsome assay to assess aromatase inhibition, and an H295R Steroidogenesis Assay to evaluate effects on testosterone (T) and 17 β -estradiol (E2) production. **Results:** At ≤ 80 ppm *in vivo*, no treatment-related effects were observed. At 800 ppm, systemic and hepatic toxicity was evident, with CYP2B1 and CYP3A2 induction up to 31-fold and CYP1A1 suppression. In pregnant rats, estradiol and corticosterone were significantly reduced, while progesterone was slightly elevated. *In vitro*, fenbuconazole inhibited human aromatase activity with an average LogIC₅₀ of -5.89 M (IC₅₀ = 1.29×10^{-6} M), achieving 1.4% residual activity. In the H295R assay, fenbuconazole produced a statistically significant 1.5-fold decrease in E2 at 1.78×10^{-5} M without affecting T modulation. **Conclusions:** Collectively, these data demonstrate that apical toxicological effects of fenbuconazole occur only at doses associated with overt hepatic toxicity, identifying the liver as the most sensitive target organ. Other systemic effects are considered secondary to hepatic perturbations. Mechanistically, induction of hepatic enzymes and weak inhibition of aromatase and steroidogenic pathways contribute to altered steroid hormone profiles, further supporting the liver as the central driver of systemic toxicity.

PS 3292 **LC-MS/MS-Based Deiodinase (DIO1, DIO2, DIO3) Inhibition Assays: Validation and Application to Human DIO1 Proficiency Testing for Endocrine Disruption Assessment**

R. S. Sharma, M. Gibson, D. Lee, A. Augello, and J. McManus. Concept Life Sciences, Dundee, United Kingdom. Sponsor: R. Sharma, EUROTOX

Background and Purpose: Deiodinase (DIO) enzymes are key regulators of thyroid hormone (TH) activation and inactivation, and inhibition of these enzymes is recognised as a molecular initiating event (MIE) contributing to TH disruption. Reliable *in vitro* assays are therefore essential to support the mechanistic evaluation of potential endocrine-disrupting (ED) chemicals. Building on our previously developed LC-MS/MS-based deiodinase inhibition assays for rat and human DIO1, DIO2 and DIO3, which have been validated in compliance with Good Laboratory Practice (GLP) principles, this study aimed to demonstrate assay robustness and to extend its application to the testing of proficiency items for human DIO1. The objective was to evaluate the method's suitability for proficiency testing and for future use in regulatory and research contexts focused on thyroid hormone disruption. **Methods:** Recombinant rat and human DIO enzymes are ectopically expressed in HEK293 cells. Cell lysates prepared from HEK293 cells expressing recombinant rat and human DIO1, DIO2, and DIO3 were used as enzyme sources. The LC-MS/MS-based bioanalytical (BioA) method quantitatively measures reaction products specific to each isoform: 3,3'-diiodothyronine (T2) for DIO1, 3,5,3'-triiodothyronine (T3) for DIO2, and 3,3',5-triiodothyronine (rT3) for DIO3 to determine enzyme activity and inhibition. For the current study, approximately 20 proficiency items were tested for their inhibitory potential toward recombinant human DIO1. Enzymatic conversion of rT3 to T2 was monitored by LC-MS/MS, and inhibition data were compared to published literature values. 6-Propyl-2-thiouracil (PTU) served as the positive control inhibitor. **Results:** The deiodinase inhibition assays demonstrated high sensitivity and precision, consistent with previous GLP validation data. The use of LC-MS/MS to monitor the production of the reaction products T2, T3 and rT3- for DIO1, DIO2 and DIO3 respectively, enables a higher degree of selectivity towards each analyte, consistent across all three isoforms, coupled with increased sensitivity over alternative detection techniques. The human DIO1 proficiency testing demonstrated excellent reproducibility and strong concordance with literature trends confirming the assay's analytical robustness and biological relevance. The LC-MS/MS readout provided high specificity for each analyte and enabled accurate quantification even at low enzyme activity levels thus ensuring reliable determination of inhibition potency. Application to approximately 20 human DIO1 proficiency items showed reproducible enzymatic activity inhibition measurements, which were in strong concordance with published literature values thus confirming both the analytical robustness and biological relevance of the assay. Compared with traditional Sandell-Kolthoff (SK) reaction-based methods, the LC-MS/MS BioA approach provided superior sensitivity and selectivity allowing reliable quantification of low-level enzyme activity- efficient discrimination of high, medium and low-level enzyme activity inhibitors, and accurate determination of inhibition potency for each analyte. **Conclusions:** GLP-validated LC-MS/MS-based deiodinase inhibition assays for rat and human DIO1,2 & 3 demonstrate robust, sensitive and selective measurement of enzymatic activity analytical plat-

form for investigating TH pathway interference. Application of the human DIO1 assay to proficiency testing demonstrates its suitability for use in inter-laboratory comparisons and regulatory screening frameworks and highlights their reproducibility and alignment with literature data. The LC-MS/MS BioA methodology offers improved sensitivity and specificity over traditional SK-based methods thus making it a reliable tool for assessing the ED potential of chemical compounds. Collectively, these assays strengthen the available toolkit for identifying and characterising chemicals with potential TH-disrupting activity and contribute to the broader implementation of mechanistic *in vitro* approaches in endocrine disruption testing strategies.

PS 3293 Robustness and Predictive Utility of the TruVivo® T4 Glucuronidation Assay in Primary Hepatocytes for Regulatory Safety Evaluation

A. Raza¹, A. Salminen², S. Kellum¹, J. Dong¹, J. Brown¹, A. Negusse¹, J. Willoughby², E. LeCluyse², J. LaRocca³, L. Kent⁴, M. Corvaro⁵, R. Settivari¹, and S. M. Catalano¹. ¹Conteva AgriScience, Newark, DE; ²LifeNet Health LifeSciences, Kalamazoo, MI; ³Conteva AgriScience, Indianapolis, IN; ⁴Conteva AgriScience, Oxford, United Kingdom; and ⁵Conteva AgriScience, Cremona, Italy.

Background and Purpose: No *in vitro* or *in vivo* methodologies exist with international validated guidelines that can quantitatively assess liver-mediated thyroid hormone disruption across species to inform the human relevance of chemically induced thyroid toxicity. This highlights a critical need for NAMs that incorporate both relevant test species and human models for chemical safety evaluation. Previous study from our laboratory established 1. assay positive control (PC; PCB153) 2. historical control database (HCD) for vehicle and PC to define T4G assay variability and set acceptance criteria. The present study evaluated 26 compounds for their potential to alter thyroxine (T4) glucuronidation using primary rat and human hepatocytes within the TruVivo® system (co-culture model of feeder cells and primary hepatocytes). Expanding the compound set is essential to refine interpretation criteria for regulatory application. **Methods:** 26 compounds were selected based on literature evidence of nuclear receptor activation (CAR, PXR, AhR and PPAR) and preclinical or clinical data indicating alterations in circulating T4 levels. An initial screen of 26 compounds was conducted to determine solubility limits (macroscopic) and cytotoxicity (MTT assay). Subsequently, the compounds were pre-screened for T4 glucuronidation using a TruVivo® test system. Hepatocytes from one human male donors and one pooled male rat lot were exposed daily for 7 days to test compounds (3 dilution each), a positive control (PCB153; 30 µM) and reference compounds (PCN; 10 µM, PB; 500 µM, RIF; 10 µM) at non-cytotoxic concentrations (<20%). Physiological level of ¹³C₆T4 (0.05, 0.1µM rat and human) was added with the 7th exposure. T4 glucuronide (T4G) was quantified in the medium 24 hours post-T4 addition using a validated LC-MS/MS. The ΔT4G (T4G relative to DMSO) was calculated to assess compounds response. Post-exposure cytotoxicity was measured using ATP Glo® assay. From this, 12 compounds (PCB126, pentachlorophenol, carbamazepine, phenytoin, lansoprazole, and oxiconazole nitrate, levetiracetam, lamotrigine, flumazenil, ketoconazole, diclofenac sodium, and loratadine) were selected for further evaluation in TruVivo® test system (4 donor/lot). These evaluations were conducted under GLP conditions and established assay acceptance criteria across two laboratories. **Results:** The mean±SD T4G rates for vehicle control samples were 2.3±0.4 and 19±1.2 pmol/10⁶ cells/24 hours for human and rat hepatocyte respectively and fall within the HCD range. The PC showed mean±SD ΔT4G induction of 4.5±1.9 and 79.4±12.2 pmol/10⁶ cells/24 hours for human (in one instance didn't not fall within the HCD range) and rat (within the HCD range) hepatocyte respectively. Screening of test compound revealed that, in rat hepatocytes, 10 compounds induced a mean ΔT4G response ranging from 5 to 52.4 pmol/10⁶ cells/24 hours, while the remaining 16 compounds showed responses of <0 pmol/10⁶ cells/24 hours. In human hepatocytes, 6 compounds demonstrated ΔT4G responses of > 5 to 36.4 pmol/10⁶ cells/24 hours, 3 compounds showed responses of <0 pmol/10⁶ cells/24 hours, and remaining fell within the mid-range of 0 - 4.9 pmol/10⁶ cells/24 hours. These findings illustrate a quantitative species-specific modulation between human and rat hepatocytes. The post-exposure toxicity criteria were met, as neither the PC nor the two reference compounds (RIF & PCN) exhibited any cytotoxicity. Based on these results, 12 compounds were selected to represent a broad spectrum of chemical classes with varied ΔT4G in both species. These compounds are currently being evaluated to assess the dose-dependent responses, definition of positive and negative thresholds and further characterize quantitative species-specific modulation. **Conclusions:** TruVivo® T4G assay showed reproducibility with repeated data falling within HCD ranges, confirming robustness of the assay acceptability criteria. The ongoing evaluation is a step toward refinement of interpretation criteria, contributing to the establishment of a NAM for regulatory safety assessment of thyroid-disrupting chemicals.

PS 3294 Assessing different *in vitro* hepatocyte models using *in vitro* to *in vivo* extrapolation to predict liver-mediated thyroid hormone clearance in rats

B. Bhattacharya¹, H. Tinwell², C. Lopez Zazueta², A. Raza¹, R. Ghaffari¹, J. McKenna¹, Z. Sutake¹, E. Bianchi¹, and J. LaRocca¹. ¹Corteva Agriscience, Indianapolis, IN; and ²Bayer SAS, Lyon, France.

Background and Purpose: The development of plant protection products involves extensive *in vivo* testing, ranging from subchronic to chronic cancer bioassays using thousands of animals with thyroid being a common target organ. A key mode of action for chemically induced thyroid toxicity in rodents involves liver-mediated enhancement of thyroxine (T4) metabolism and clearance. Although rats remain the preferred test species, there are known quantitative differences in liver-mediated thyroid toxicity where rats are established to be more sensitive than humans. To accurately interpret biological responses, it is essential to quantitatively map the key event relationships underlying the liver-thyroid adverse outcome pathway (AOP) in rats. With the advancement of new *in vitro* models and growing regulatory support for reducing animal use in toxicity testing, new approach methodologies (NAMs) offer the possibility to assess key events associated with rodent thyroid toxicity and address human relevance without additional animal use. This study explores two *in vitro* hepatocyte models for characterizing liver-induced thyroid disruption in rats, using quantitative *in vitro* to *in vivo* extrapolation (QIVIVE) to assess hepatic UGT induction and T4 metabolism. **Methods:** Two separate rat hepatocyte coculture models, a Wistar sandwich culture and a Sprague Dawley triculture (TruVivo), were exposed for seven consecutive days to known reference inducers of hepatic cytochrome P450 and UDPGT enzymes in rats. T4 was added to the final dose and supernatants analyzed by HPLC-MS/MS for T4 glucuronidation. CYP and UGT gene expressions in the liver were investigated using RNAseq in the TruVivo model. In the Wistar model, on Day 7 mRNA was extracted for RT-qPCR (Phase I and II genes) and P450 enzyme and UGT-T4 activity were measured. Supernatants were also analyzed for T4 clearance, glucuronidation and T3/rT3 formation. The *in vitro* CYP/UGT expression and activity and T4 clearance were utilized to extrapolate the 5% benchmark concentration (BMC) and its lower confidence bound (BMCL) to derive the *in vivo* administered equivalent dose (AED) using reverse dosimetry. These were then compared to the *in vivo* benchmark dose (BMD) and its lower confidence bound (BMDL). **Results:** Both *in vitro* hepatocyte models showed significant increases in the rates of T4 glucuronidation when exposed to known positive controls. In the TruVivo model, PB and PCN increased glucuronidation compared to vehicle controls, with PCB153 inducing the highest rate of glucuronidation and UGT-T4 activity, making it the reference positive control. All three compounds also upregulated liver phase I and II enzyme biomarkers. In the Wistar culture, T4 glucuronidation was markedly increased in hepatocytes treated with PCN and PB, with PCN showing a marked increase in UDPGT-T4 activity whereas only marginal increases were observed with PB. QIVIVE using *in vitro* data produced the most accurate oral AED estimates when based on plasma AUC (0-24 h). Extrapolation of BMCL from mRNA and hepatic enzyme activity showed better accuracy than extrapolation from T4 clearance *in vitro*, when compared to the *in vivo* data obtained from male adult rats. Furthermore, the predicted AED was significantly lower than the BMD(L) values for T4 levels obtained from *in vivo* studies. **Conclusions:** Regulatory assessment of thyroid toxicity is shifting from animal studies towards alternative methods, emphasizing the need for robust *in vitro* approaches to characterize liver-mediated thyroid AOPs. We examined the effects of thyroid-disrupting compounds on T4 clearance and metabolism using two rat hepatocyte models and compared findings with short-term *in vivo* studies in Wistar and Sprague Dawley rats. Points of departure (PODs) were derived from *in vivo* studies and evaluated against predicted *in vitro* PODs using QIVIVE. Our study confirmed species differences supporting rat liver-mediated thyroid clearance is not biologically relevant for human risk assessment due to higher hepatic activity in rats. These results support the use of optimized *in vitro* systems as predictive tools for thyroid disruption, reducing animal use and enabling early de-risking of agrochemicals to improve next-generation risk assessment (NGRA).

PS 3295 Predictive *in silico* assessment of endocrine-disrupting activity in bioactive peptides

J. Marquez-Lazaro, A. M. Marrugo-Padilla, A. Barbosa-Torres, A. Bru-Reason, and R. Ramos-Bastidas. Corporación Universitaria Rafael Núñez, Cartagena, Colombia.

Background and Purpose: Bioactive peptides (BPs) are short chains of amino acids with a wide range of biological activities, making them valuable in medicine and the food industry. However, their resemblance to natural hormones allows certain BPs to bind to nuclear receptors and alter cell signaling, raising concerns about possible endocrine interference. Thus, understanding these molecular interactions is essential to anticipate and prevent possible toxic effects related to peptide-based products. Therefore, this study aimed to examine the endocrine disruption potential of the most representative BPs using a combined *in silico* and machine learning framework, aimed at mapping receptor binding patterns and identifying structural features related to hormonal modulation. **Methods:** The work began with the extraction of the main BPs reported in the scientific literature between 2019 and 2024 through a systematic approach; Antihypertensive, antioxidant, anticancer and multifunctional effects with experimentally validated bioactivity were taken into account. The molecular structures of the selected BPs were drawn in ACD/ChemSketch and converted

to SMILES format using the NIH Translator tool. The potential for endocrine disruption was then assessed using the Endocrine Disruptome web platform, which simulates molecular docking in 14 human nuclear receptors, including AR, ER α / β , GR, LXR α / β , PPAR α / β / γ , RXR α , and TR α / β . Peptide-receptor binding energies ≤ -7.0 kcal/mol were considered physiologically significant. Interaction matrices were standardized and analyzed by principal component analysis (PCA) and K-means clustering to reveal receptor binding trends. Finally, a supervised machine learning model was integrated to validate and refine the predictive clustering, estimating variable importance scores and confirming the discriminative power of peptides previously classified as highly promiscuous. **Results:** Initially, 132 BPs were extracted from the articles consulted; among these, 97 showed significant affinity for at least one nuclear receptor, yielding 277 peptide-receptor interactions. Most peptides interacted primarily with the glucocorticoid receptor (27.1%), followed by the thyroid receptors TR β (11.6%) and TR α (9.8%) and the androgen receptor (9.8%). While 76.3% of BPs showed low promiscuity (binding to ≤ 3 receptors), only 2.1% were classified as highly promiscuous, interacting with seven or more receptors. The PCA explained 43.6% of the variance, revealing distinct groups consistent with receptor selectivity profiles. Dipeptide H3-01 (WF) and anticancer peptide C5 (RWQWRWQWR) showed the strongest multireceptor affinities (-9.8 to -11.9 kcal/mol) toward LXR β , LXR α , GR, and PPAR γ , suggesting potential for pan-receptor modulation. Machine learning validation strengthened the PCA-based classification, confirming that these peptides are predictive outliers with high endocrine binding probabilities and unique physicochemical signatures (aromatic density, charge distribution, and hydrophobicity index). **Conclusions:** This integrative analysis suggests that certain bioactive peptides behave as endocrine-active compounds able to influence several nuclear receptors. Combining computational modeling with a machine learning validation step increased confidence in the receptor-binding patterns observed and strengthened the identification of peptides showing high binding promiscuity. Altogether, the results point to a small subset of molecules with potential endocrine activity that deserves closer toxicological scrutiny. Early application of predictive toxicology frameworks could help refine safety assessments and ensure that peptide-based nutraceuticals and therapeutics advance with stronger evidence of biological selectivity and reduced endocrine risk.

PS 3296 Luteolin promotes steroidogenesis in I-10 mouse Leydig cells exposed to atrazine

M. Dawod, A. Siddiqi, and P. Bu. St. John's University College of Pharmacy and Health Sciences, Queens, NY.

Background and Purpose: Testosterone, the primary male sex hormone, is essential for male fertility and overall health. About 95% of total testosterone is synthesized by testicular Leydig cells via steroidogenesis. Disruption of this process by factors like pesticide exposure can lead to testosterone deficiency. Atrazine (ATZ), a widely used herbicide, can impair steroidogenic function, while luteolin (Lut), a flavonoid, exhibits antioxidant properties. This study examines luteolin's effects on ATZ-induced dysfunction in I-10 Leydig cells by assessing viability, steroidogenesis, and gene expression. **Methods:** Mouse Leydig I-10 cells were treated with DMSO (control), ATZ (3.3, 10, 33, and 100 μ M), Lut (1, 3.3, 10, and 33 μ M), and a co-treatment of ATZ + Lut (ATZ 33 μ M + Lut 3.3 μ M or ATZ 100 μ M + Lut 3.3 μ M) for 2, 4, and 6 days, with medium/chemical change every two days. Cell viability was measured at each time point, with testosterone (T) and progesterone (P4) levels quantified by ELISA, and the expression of key steroidogenic genes (StAR, Cyp11a1, Hsd3 β 6, and Hsd17 β 3) analyzed by RT-qPCR. **Results:** ATZ alone reduced cell viability in a concentration-dependent manner but temporarily increased T levels. Lut alone enhanced both P4 and T production at higher concentrations (10 and 30 μ M). In the co-treatment, Lut protected I-10 cells from ATZ-induced cytotoxicity and transiently stimulated both P4 and T production. Specifically, the ATZ 100 μ M + Lut 3.3 μ M co-treatment showed the strongest effects, with P4 and T rising 2.6-fold and 1.9-fold, respectively, on Day 2, before returning to baseline by Day 6. These findings suggest co-exposure of Lut and ATZ may confer modest stimulation on steroidogenesis in I-10 cells. **Conclusions:** In I-10 mouse Leydig cells, luteolin promoted survival and steroidogenesis in the presence of atrazine, suggesting a modulatory interaction that benefits I-10 cell vitality and enhances its steroid production.

PS 3297 Endocrine disrupting effects of jet fuel: Changes in rodent estrous cycle and ovary size after 6-month oral exposure

L. Olsen, N. Gargas, V. Ethridge, K. Mumy, W. Howard, and J. Rohan. Naval Medical Research Unit Dayton, Wright-Patterson AFB, OH.

Background and Purpose: Recent incidents involving contaminated water, such as the Red Hill water crisis, have shown that we need a better understanding of the effects of oral exposure (i.e., ingestion) of jet fuel. Ingestion has not historically been widely studied as a standard route of jet fuel exposure for health assessments given that ingestion does not present as a typical occupational exposure risk. Endocrine-disrupting chemicals (EDCs) are garnering greater attention and wider concern for their previously unknown effects mimicking, blocking, or interfering with the body's hormones. We have previously demonstrated that the military aviation fuel Jet Propellant (JP)-5 is capable of modulating nuclear human estrogen receptor

(ER) activity in an *in vitro* HEK293 cell line stably expressing an ER-luciferase gene reporter, suggesting that JP-5 can act as an EDC. Here, we assess the endocrine effects of *in vivo* 6-month occupational exposures to JP-5 in female rats. **Methods:** Animal activities were IACUC protocol approved. To evaluate JP-5's effects on the endocrine system, female Sprague Dawley rats were exposed to 1 (LOW), 10 (MID), or 100 (HIGH) mg JP-5 per kg body weight (BW) diluted in corn oil via gavage five days/week for six months. Control rats were exposed to the vehicle only (corn oil). These rats underwent ~ 14 continuous days of vaginal lavage pre-exposure, ~ 16 wk into exposure, and the last two weeks of exposure. Samples were fixed and stained using 0.1% methyl blue to determine estrous cycle. Plasma samples were collected during humane euthanasia ~ 6 -7 wk post-last dose of JP-5 to assess delayed hormonal effects via enzyme linked immunosorbent assay. A separate subset of rats also underwent 6-month oral JP-5 exposure, with plasma samples collected 24 h post-last dose to assess immediate hormonal effects. Ovaries were collected from both cohorts to measure changes in Ovary:BW ratio. Group differences were analyzed using a one-way analysis of variance and Dunnett's post-hoc test. **Results:** There were no group differences in estrous cycle at baseline pre-exposure. After ~ 16 wk of oral JP-5 exposure the LOW, MID, and HIGH groups experienced increased number of days in diestrus ($p < 0.05$). However, by the end of the exposure period only the MID and HIGH group had increased number of days in diestrus ($p < 0.05$). Immediately after 6-month JP-5 exposure there was a dose-dependent decrease in plasma estradiol (E2, $p < 0.01$), and a reduction in progesterone (PROG) in the HIGH group ($p < 0.01$). Although ~ 6 -7 wk post exposure found no group differences in hormone levels, a lesser but significant relationship between JP-5 exposure level and E2 ($r = -0.35$, $p < 0.001$) existed. Ovary:BW ratio did not differ between groups 24 h post-last dose of JP-5, but ~ 6 -7 wk post exposure found LOW JP-5 to have greater Ovary:BW ratio. This larger Ovary:BW ratio negatively correlated to plasma corticosterone levels ($r = -0.786$, $p < 0.01$), while E2 correlated to parathyroid hormone (PTH) levels ($r = 0.915$, $p < 0.001$). Multiple linear regression analyses found PTH to be a significant predictor of Ovary:BW ratio immediately following JP-5 exposure and ~ 6 -7 wk following exposure. **Conclusions:** Our study suggests long-term ingestion of JP-5 leads to changes in estrous cycle, hormone levels, and ovary size. Reduction in E2 and PROG levels coincide with increased time spent in diestrus. Although hormonal group differences were not present, correlational analyses indicate that there are sustained effects over a month after JP-5 exposure ends. Sustained low levels of JP-5 may contribute to increases in ovary size, albeit PTH may mediate these effects. Further research is needed to investigate the potential EDC effects of JP-5 on ovaries, including hormone related disorders such as polycystic ovarian syndrome and endometriosis. No DoD endorsement implied. This work was funded by Defense Health Program, Military Operational Medicine Research Program 330, Joint Program Committee 5.

PS 3298 Associations Between Co-Exposure to Environmental Toxins and Type 2 Diabetes in U.S. Adults: Insights from NHANES on Perchlorate, Nitrate, and Thiocyanate

N. Keddari¹, and Z. Qiao². ¹Zhengzhou University, Zhengzhou, Henan, China; and ²Zhengzhou University, Zhengzhou, Henan, China. Sponsor: N. Keddari, American College of Toxicology

Background and Purpose: Perchlorate, nitrate, and thiocyanate are environmental anions known to disrupt thyroid function by competitively inhibiting iodide uptake via the sodium-iodide symporter (NIS), potentially reducing thyroid hormone synthesis. Although thyroid dysfunction is linked to metabolic disorders, the relationship between these anions and type 2 diabetes mellitus (T2DM) has not been fully elucidated in human populations. **Methods:** A total of 5,196 adults aged ≥ 20 years from the National Health and Nutrition Examination Survey (NHANES 2011-2020) were included. Nine Survey-weighted multivariable logistic regression models were used to evaluate the associations between urinary perchlorate, nitrate, and thiocyanate and T2DM. Weighted quantile sum (WQS) regression was applied to assess the combined effects of co-exposure to these anions. **Results:** Higher urinary perchlorate concentrations were significantly associated with increased odds of T2DM (OR = 1.92; 95% CI: 1.10-3.37; $p < 0.05$) in fully adjusted models. WQS regression showed that co-exposure to perchlorate, nitrate, and thiocyanate was positively associated with T2DM; each unit increase in the WQS index corresponded to a 33% higher risk of T2DM (OR = 1.33; 95% CI: 1.07-4.65; $p < 0.001$). After adjusting for age, gender, race/ethnicity, and urinary creatinine (Model 2), the association remained significant, indicating a 45% higher risk of T2DM per unit increase in the WQS index (OR = 1.45; 95% CI: 1.045-7.00; $p = 0.02$). Perchlorate and thiocyanate contributed the greatest weights within the mixture. **Conclusions:** Higher urinary perchlorate levels and co-exposure to perchlorate, nitrate, and thiocyanate were significantly associated with T2DM. Perchlorate and thiocyanate were the primary contributors to the observed mixture effect. These findings highlight the metabolic relevance of environmental anion exposure and underscore the need for further mechanistic and mixture-based investigations.

E. Bianchi, K. Johnson, Z. Satake, J. McKenna, W. Chen, J. LaRocca, and S. Gehen. Corteva Agriscience™, Indianapolis, IN.

Background and Purpose: Rodents are the standard model for regulatory toxicity testing; however, they are particularly sensitive to thyroid disruption. Thyroid-related findings in rodent studies are common and generally arise from hepatic mechanisms that lack human relevance. A well-characterized pathway involves liver enzyme induction—particularly UDP-glucuronosyltransferases (UGTs)—which accelerates the clearance of thyroid hormones like thyroxine (T4). This can lead to compensatory thyroid follicular cell hypertrophy and, in some cases, tumor formation. However, these liver-mediated thyroid effects are not considered human-relevant, as the underlying mechanisms and thresholds differ significantly between species. Historically, *in vivo* animal studies have been the foundation of thyroid safety evaluations for agrochemicals. However, there is growing momentum within the scientific and regulatory communities to adopt New Approach Methodologies (NAMs) that reduce reliance on animal testing and improve human relevance. This study aims to validate an *in vitro* liver-thyroid organ-on-chip model capable of investigating mechanisms of thyroid toxicity. **Methods:** Cryopreserved human primary hepatocytes from mixed donors were co-cultured with hepatic stellate cells at a 24:1 ratio directly in the small compartment of the HUMIMIC Chip2 system (TissUse, Berlin, Germany) utilizing a polycarbonate Dynarray microcavity membrane. Thyroid microtissues underwent a five-day pre-incubation in Matrigel-coated 96-well plates, following protocols established by Dr. Deisenroth, prior to hydrogel overlay and subsequent transfer into the large compartment of HUMIMIC Chip2 chips. The liver/thyroid co-cultures were maintained on-chip with thyroid stimulating hormone (TSH) stimulation preceding exposure to two reference chemicals: liver-mediated thyroid disruptor (PCB153) and direct thyroid disruptor (methimazole). Quantification of albumin, T4, and T4 metabolites (T4-glucuronide and/or T4-sulfate) was performed using liquid chromatography-mass spectrometry. Additionally, immunostaining was employed to confirm the functional integrity of both liver and thyroid tissues. **Results:** Primary thyrocytes cultured on Matrigel-coated plates self-assembled into rounded, hemispherical 3D microtissues and exhibited pronounced responsiveness to TSH stimulation, with an average production of T4 at 7.5ng/mL. As anticipated, methimazole treatment produced a concentration-dependent decrease in thyroid hormone secretion, whereas PCB153 exposure did not induce any measurable changes in the thyroid microtissue model. Liver spheroids remained viable and functional for over 14 days, forming bile canaliculi with MRP2 expression and producing albumin as well as thyroid hormone metabolites (T4-glucuronide and/or T4-sulfate) following T4 supplementation. Methimazole treatment did not affect T4 metabolite concentrations, whereas PCB153 exposure significantly increased T4G levels, indicating a pronounced liver-mediated effect. The integrated liver/thyroid co-culture system secreted measurable thyroid hormones, which declined following methimazole administration, while albumin production remained stable throughout the two-week study. **Conclusions:** These findings confirmed that both the liver and thyroid models were fully characterized and functioned as intended. It underscores the value of an integrated liver/thyroid co-culture system for the early investigation of mechanisms of thyroid disruption. Furthermore, the model offers a mechanistic framework to support demonstrations of non-human relevance for liver-mediated thyroid disruption pathways. A follow-up study is currently underway to optimize the co-culture system and enhance its predictive performance.

PS 3300 *In Vitro* assessment of AhR/CAR/PXR activators within the thyroid endocrine disruption (T-) modality framework: Implications for human relevance

A. Baze¹, B. Ory¹, L. Wiss¹, A. Schäfer¹, C. Chaneil¹, C. Guicheney¹, K. Biemel², and L. Asselin¹. ¹KaLy-Cell, Plobsheim, France; and ²Pharmacelsus, Saarbrücken, Germany. Sponsor: C. Guicheney, EUROTOX

Background and Purpose: Thyroid hormones (THs) regulate metabolism, growth, and neurodevelopment. Xenobiotics can disrupt TH homeostasis by interfering with the thyroid axis through distinct molecular initiating events (MIEs), which may lead to altered, often decreased, circulating TH levels. EU regulation 2018/605 and ECHA-EFSA guidance require evaluation of endocrine-disrupting potential, including thyroid (T-) modality. Key MIEs include inhibition of the sodium/iodide symporter (NIS), thyroid peroxidase (TPO), and deiodinases (DIO1, DIO2, DIO3), which respectively impair iodide uptake, TH synthesis, and peripheral conversion of thyroxine (T4) to triiodothyronine (T3) or reverse T3 (rT3). In parallel, activation of hepatic nuclear receptors such as the Aryl hydrocarbon receptor (AhR), constitutive androstane receptor (CAR) and pregnane X receptor (PXR) can induce phase I (CYP) and phase II (UGT) enzymes, enhancing hepatic clearance of conjugated THs, mainly via glucuronidation. However, the human relevance of liver enzyme-mediated thyroid effects remains a regulatory challenge in the EU. This study integrates multiple new approach methodologies (NAMs) covering both thyroid MIEs and hepatic metabolism pathways to investigate the mechanisms underlying TH disruption. A set of test substances, including AhR, CAR and/or PXR activators, with or without reported effects on serum TH levels in humans, was tested for inhibition of NIS, TPO and DIO1-3 and for indirect liver enzyme-mediated thyroid effects. **Methods:** NIS-mediated iodide uptake was assessed in HEK293 cells stably expressing human

NIS using the Sandell-Kolthoff reaction. TPO activity was measured in human thyroid microsomes using the Amplex UltraRed method. DIO (1, 2 and 3) activities were assessed in HEK293 cell pellets expressing each human DIO isoform, with T3 and rT3 quantified by LC-MS following T4 incubation. Test substances were assessed across different assays, with respective positive and negative controls included to ensure assay specificity and reproducibility. Liver-mediated effects were investigated in cryopreserved rat and human primary hepatocytes cultured in a 2D-sandwich configuration (2 male and 2 female batches per species). Cells were exposed for 7 days to test substances or to reference CYP inducer compounds β -naphthoflavone (BNF), Phenobarbital (PB), Rifampicin (RIF) or 5-pregnen-3 β -ol-20-one 16a-carbonitrile (PCN). CYP1A, CYP2B and CYP3A mRNA expression and related enzymatic activities were measured as markers of AhR, CAR and PXR activation, respectively, along with UGT mRNA expression and T4-glucuronidation (T4-UGT) activity. T4 disappearance and T4 metabolite formation were quantified in both species to assess interspecies differences in TH metabolism and clearance. **Results:** In line with previous results (Asselin et al., 2024; Friedman et al., 2016) with CAR/PXR activators RIF and PB showing mild (PB) or strong TPO inhibition and mild DIO1 inhibition (PB), our present data show that 5/9 AhR, CAR and/or PXR test substances for which effects on serum THs have been reported in humans exhibit multiple mode of actions (MoAs). These findings suggest that liver enzyme induction alone is unlikely to explain the observed alterations in serum TH levels. Ongoing work using the same set of test substance aims to address liver-mediated mechanisms, focusing on CYP and UGT increase and T4 metabolism in human and rat hepatocytes to clarify the contribution of hepatic pathways to TH homeostasis disruption. **Conclusions:** These findings illustrate that AhR/CAR/PXR activators can influence TH homeostasis through multiple mechanisms, including direct effects on TH synthesis. By combining these complementary assays, the work contributes to the refinement of thyroid (T-) modality testing strategies and to improving human relevance assessments within the EU endocrine disruptor regulatory framework.

PS 3301 Differentiating Thyroid Modes of Action in Short-Term Rodent Toxicity Studies Using Toxicogenomics

C. C. Lord¹, S. Totti², L. Youngs², J. P. Rooney¹, L. B. Doonan², A. Kende², L. Swindale², and D. E. Cowie². ¹Syngenta Crop Protection, LLC, Greensboro, NC; and ²Syngenta Ltd., Jealott's Hill International Research Centre, Bracknell, United Kingdom.

Background and Purpose: Alterations in thyroid parameters in rat toxicity studies can arise from direct thyroid disruption or via indirect mechanisms such as liver enzyme induction and systemic toxicity. Distinguishing between these thyroid modes of action (MOAs) is key to understanding human relevance but is rarely possible through traditional toxicology endpoints. Through rapidly evolving omics technologies such as transcriptomics and metabolomics, it is now possible to generate vast amounts of molecular information from tissue samples collected in toxicity studies, potentially refining and reducing the overall use of animals. This study investigated whether toxicogenomic analysis of liver, thyroid, and plasma in short-term rat studies would allow mechanistic differentiation between established direct thyroid MOAs, including inhibition of Thyroid Peroxidase (TPO), Sodium Iodide Symporter (NIS), or Deiodinase (DIO), and thyroid effects secondary to liver enzyme induction or systemic toxicity. **Methods:** Male and female Han Wistar rats (n=10/group) were treated for 14 days with reference chemicals representing direct thyroid MOAs (methimazole, 6-propyl-2-thiouracil, sodium perchlorate) or liver enzyme induction (phenobarbital) at 3 dose levels per chemical, alongside respective concurrent vehicle control groups. Two levels of food restriction were also included in the study to emulate the physiological stress typically observed with systemic toxicity (reduced food consumption and lower bodyweight gain). Study endpoints included toxicokinetic analysis of each reference chemical at 2 timepoints, in-life thyroid hormone analysis (T4, T3, TSH) at 3 timepoints, body weights, and terminal organ weights and histopathology on all animals. Transcriptomics data (liver, thyroid) and metabolomics data (liver, plasma) were generated on all groups to investigate the molecular profiles associated with each MOA. **Results:** Toxicokinetic analysis for each reference chemical confirmed appropriate separation of systemic exposure levels across groups, corresponding with observed dose-related changes in apical thyroid endpoints. Toxicogenomic analyses revealed distinct, dose-related profiles for each reference MOA, achieving mechanistic differentiation between direct and indirect thyroid MOAs at the molecular level. **Conclusions:** Toxicogenomic analysis enabled detection of molecular effects following short-term dosing that allowed successful differentiation between direct and indirect thyroid MOAs in rats. This work demonstrates the potential for omics-based MOA categorization of test chemicals with thyroid effects, based on similarity with reference profiles of known thyroid MOAs. Ultimately, this approach could be used to inform regulatory decision-making and reduce uncertainty in human health risk assessments for test chemicals with rodent thyroid effects.

G. H. Casciano. Oak Ridge Institute for Science and Education, Duluth, MN.

Background and Purpose: Adverse Outcome Pathways (AOPs) are a conceptual framework that describe the mechanistic links between biological processes and events at the molecular level to adverse effects at the individual and population levels. The thyroid hormone signaling pathway, which involves the thyroid hormones T3 and T4, is one such molecular-level process critical for the development and viability of vertebrates, including fish. **Methods:** In this study, CRISPR/CAS technology was used to better understand the role of key thyroid hormone signaling pathway enzymes, deiodinase 3a and 3b (Dio3a, Dio3b), which regulate thyroid hormone concentration in tissues through inactivating T3 and T4, to assist in AOP development. Zebrafish Dio3a^{-/-} and Dio3b^{-/-} mutant lines with a 31-base pair (bp) deletion and 11-bp insertion, respectively, were produced using CRISPR/CAS-12a and three generations of genotyping and selective breeding. Equal numbers of either mutant Dio3a or Dio3b embryos and wildtype (WT) embryos (n=120-144) were incubated in 24-well plates for six days (6-144 hours post-fertilization, hpf) and observed daily, taking note of phenotypic abnormalities including edema, reduced pigmentation, altered swim bladder inflation, and deformed body shape. At 144 hpf, larval fish were pooled into 20-23 groups per genotype (3-6 fish per group), and RNA was sequenced. **Results:** Phenotypic data observed between Dio3a^{-/-} and Dio3b^{-/-} versus WT groups displayed similar trends. Rates of survival were lower for Dio3a^{-/-} compared to WT (77% vs. 85% for WT), while abnormalities remained similar amongst groups (5% vs. 6%). Swim bladder inflation at 144 hpf was higher amongst the WT group (73% vs. 65% for Dio3a). Meanwhile, amongst the Dio3b mutant group, there was a significant difference in survival (70% vs. 93% for WT; p<0.0001), with the frequency of abnormalities in the surviving groups averaging 10% (Dio3b^{-/-}) and 16% (WT). Swim bladder inflation at 144 hpf exhibited no difference between WT and Dio3b^{-/-} groups. RNA sequencing revealed large differences in global gene-expression patterns between WT in both mutant groups, with 1638 differentially expressed genes (DEGs) in the Dio3a^{-/-} fish and 1506 DEGs in Dio3b^{-/-} fish. **Conclusions:** Overall, stable lines of zebrafish with Dio3a/b mutations were generated with CRISPR/CAS-12a that will serve as a valuable system to identify causal relationships between key events for future studies focused on thyroid-related AOPs. The contents of this abstract neither constitute nor necessarily reflect US EPA policy.

PS 3303 Developing A Curated Resource of Rodent Pubertal Studies in Support of the US EPA Endocrine Disruptor Screening Program (EDSP)

J. Abedini. US EPA, Durham, NC.

Background and Purpose: Endocrine disrupting chemicals may interfere with the endocrine system functions such as normal reproduction and developmental processes in humans and wildlife. The United States Environmental Protection Agency (US EPA) Endocrine Disruptor Screening Program (EDSP) seeks to screen for and protect against possible endocrine effects associated with chemicals using a tiered testing approach. The male and female rodent pubertal studies (890 Series Health Effects Test Guidelines OCSPP 890.1450 and 890.1500) are EDSP Tier 1 assays that assess a chemical's potential to disrupt endocrine-mediated development by examining changes during sexual maturation. These studies help determine if chemicals can interfere with the estrogen, androgen, and thyroid hormone pathways in the developing endocrine system by assessing endpoints specific to pubertal development in both male and female rats. **Methods:** An effort was initiated to comprehensively identify documents from 1990 to present that describe studies with data similar to the pubertal test guidelines. Using study evaluation criteria, studies were designated as "guideline"-adherent, "guideline-like" or "useful" and prioritized for curation. Statistically significant and treatment-related findings were extracted via an application-based curation workflow using EPA's Health Assessment Workspace Collaborative (HAWC) program. Study metadata included rat strain, sex (male or female), animal source and husbandry, exposure lifestage, diet, route of exposure, and exposure duration. Curation is ongoing. **Results:** Preliminary assessment of the data includes 136 pubertal curations (59 male, 57 female) covering 86 chemicals, the majority of which are biocides. Out of the 147 unique endpoints curated, 94 endocrine endpoints relevant for both male and female rats were identified in relation to the reproductive and endocrine systems, affecting organs such as the testis, uterus, thyroid, and pituitary gland. Potential estrogenic effects evaluated include age and body weight at vaginal opening, organ weights and histology of uterus and ovary, and estrus cyclicity endpoints. Potential androgenic effects evaluated include age and body weight at preputial separation, and organ weights and histology of the epididymis and testis. Potential thyroidogenic effects assessed may include hormone measurements (e.g. T4), organ weights and histology of the thyroid. **Conclusions:** The rodent pubertal assays are part of the larger EDSP Tier 1 battery designed to provide a comprehensive screen of a chemical's potential endocrine activity. Developing a curated resource facilitates the discovery of reference compounds and produces a database of results from an established guideline study that could be used to build scientific confidence in New Approach Methods. This abstract does not necessarily reflect U.S. EPA policy.

PS 3304 Application of a NOAEL and LOAEL Boundary Approach to Identify a Point of Departure for Derivation of Minimal Risk Levels for Hazardous Substances

K. Zaccaria¹, J. Klotzbach¹, R. Benedict², C. Muianga², B. Alman², F. Atif², F. Scinicariello², B. Szafran², and G. Diamond¹. ¹SRCL, Liverpool, NY; and ²The Agency for Toxic Substances and Disease Registry (ATSDR), Office of Innovation and Analytics (OIA), Atlanta, GA.

Background and Purpose: For ATSDR to develop minimal risk levels (MRLs) for hazardous substances, selection of the most appropriate point of departure (POD) is paramount. When available and adequate, ATSDR preferentially selects PODs from epidemiological data; otherwise, appropriate experimental animal laboratory data are used. When adequate dose-response data are available, benchmark dose modeling (BMD) is used. In the absence of such data, the NOAEL/LOAEL (N/L) approach is used, in which ATSDR sets the POD at either the highest NOAEL below the lowest LOAEL or the lowest free-standing LOAEL (if there is no accompanying NOAEL). Often, when MRLs are based on human data, POD selection defaults to the N/L approach since human data often lack multiple exposure levels required for robust dose-response analysis within a single study. However, reliance on the N/L approach often leads to uncertainties in POD selection from epidemiological studies due to substantial overlap in reported NOAELs and LOAELs for the critical effect. Here, we present an alternative approach that utilizes data from multiple studies to identify an exposure that is most likely to be the N/L boundary, a threshold exposure level at which adverse effects may or may not occur. **Methods:** For this presentation, illustrative cases utilizing the N/L boundary methodology to identify a POD are reported for the chronic-duration inhalation MRLs from the Toxicological Profiles for Mercury (Hg) and Carbon Disulfide (C2S). For this approach, we made the following assumptions: 1) A N/L boundary exists and is located somewhere within the range of overlapping NOAELs and LOAELs; 2) Each NOAEL and LOAEL in this range represents an independent estimate of the N/L boundary; 3) The best estimate of the N/L boundary is the weighted median of the set of overlapping NOAELs and LOAELs (weighted for study size); and 4) The best value for the POD is the lower 95% confidence limit on the median (to account for uncertainty in the estimate). To calculate the N/L boundary, overlapping NOAELs and LOAELs included all LOAELs ≤ the highest NOAEL for the critical effect, plus all NOAELs ≥ the lowest LOAEL for the critical effect. **Results:** For Hg vapor, the most sensitive effect following chronic inhalation exposure was tremors. The highest identified NOAEL was an estimated air concentration of 8.74 µg Hg/m³ by Boogaard et al. (1996) and the lowest identified LOAEL was an estimated air concentration of 4.90 µg Hg/m³ by Wastensson et al. (2006, 2008); air concentrations were estimated from urinary Hg levels using a pharmacokinetics model. A total of seven epidemiological studies identifying a NOAEL or a LOAEL in the approximated "overlap range" of estimated air concentrations of 4-9 µg Hg/m³ were included in the N/L boundary calculation. Based on these studies, a weighted median N/L boundary (95% Confidence Interval [CI]) of 4.92 (2.84, 7.00) µg Hg/m³ was calculated, resulting in a selected POD of 2.84 µg Hg/m³. For C2S, the most sensitive effect following chronic inhalation exposure was impaired nerve conduction velocity. The highest identified NOAEL was 5.64 ppm by Yoshioka et al. (2017) and the lowest identified LOAEL was 2.9 ppm by Godderis et al. (2006). A total of seven epidemiological studies identifying a NOAEL or a LOAEL in the identified "overlap range" of measured air concentrations of 2.9-5.64 ppm were included in the N/L boundary calculation. Based on these studies, a weighted median N/L boundary (95% CI) of 4.76 (4.02, 5.64) ppm was calculated, resulting in a selected POD of 4.02 ppm. **Conclusions:** Use of a weighted median N/L approach allows for multiple human studies to contribute to the POD determination for MRL calculations. This approach can result in reduced uncertainty associated with basing a POD on a single human study, especially when there is an overlap in reported NOAELs and LOAELs for the critical effect. Where appropriate, this approach should be considered and applied for future POD determinations based on epidemiological data. **Disclaimer:** The findings and conclusions in this presentation have not been formally disseminated by the Centers for Disease Control and Prevention/ATSDR and should not be construed to represent any agency determination or policy.

PS 3305 Framework for Intracochlear Accepted Daily Intake Determination for Human Health Risk Assessment

C. Callis¹, R. Jolly¹, L. Cooper¹, E. Andres-Mateos¹, M. Willming², A. Maier³, and E. S. Fung⁴. ¹Eli Lilly & Company, Indianapolis, IN; ²Integral Consulting, Boise, ID; ³Integral Consulting, Cincinnati, OH; and ⁴Integral Consulting, Los Angeles, CA.

Background and Purpose: The cochlea is separated from systemic circulation by the blood-labyrinth barrier (BLB) limiting the passage of molecules in or out. Direct delivery of therapeutics into the cochlea chambers (i.e. intracochlear administration) allows for efficient drug delivery, bypasses the barriers of the middle ear, and allows for more targeted and controlled dosing. Intracochlear administration involves directly injecting into the peri-lymphatic chambers through the round window membrane. Due to the unique nature of intracochlear administration, an accepted daily intake (ADI) specific to this route of administration is necessary. The goal of this study is to establish a framework for determining intracochlear ADIs from parental ADIs and provide examples to illustrate the utility of the framework. **Methods:** Both systemic and local effects must be considered when establishing an intracochlear ADI from a parental ADI. A framework for human health risk assessment

was developed considering: *Toxicokinetic considerations*: 1) bioavailability assumed to be 100% since substances are delivered directly into the cochlea; 2) substance assumed to be equally distributed throughout the cochlea; 3) metabolic pathways assumed to be similar to systemic pathways; elimination is assumed to be *de minimis* due to BLB. *Toxicodynamic considerations*: 1) the inner ear expected to be sensitive to neurotoxic substances; 2) receptor density assumed to be similar to systemic receptor density. *Irritation and Sensitization Effects*: 1) cochlear cells demonstrate immune responses after exposure to ototoxic substances; 2) if a substance is a known irritant or sensitizer, the local concentration following intracochlear administration should be evaluated to determine irritation or sensitization potential; 3) acute ICM administration of a known eye irritant at ppm levels did not result in any treatment-related local irritation. *Clinical Experience*: 1) substances administered into the cochlear rapidly dilute and diffuse within the intracochlear space; 2) diffusion along the entire cochlea is achieved with a volume of 90 μ L; 3) the cisterna magna may be connected to the intracochlear space by CSF flow. **Results**: A framework for determining intracochlear ADIs from parental ADIs was developed using information considered from the intracochlear route of administration. Firstly, the parenteral ADI is adjusted by applying a 10x factor for intracisternal magna (ICM) administration to account for additional uncertainty. Secondly, based on the volume difference between the cisterna magna and intracochlear space (approximately 3 vs 0.2 mL), an additional 10x factor is applied. Therefore, a total factor of 100 is applied to the parenteral ADI to determine an intracochlear ADI. If a substance is neurotoxic, an additional 10x factor is recommended unless substance-specific neurotoxicity information is available. Lots The first case study is for Triton X-100 with a parenteral ADI of 750 μ g/day. Triton X-100 is not neurotoxic but was reported to be irritating to the eye at 0.3% (3 μ g/ μ L). Therefore, a factor of 100 was applied to the parenteral ADI yielding an intracochlear ADI of 7.5 μ g/day. Assuming that 7.5 μ g is injected into the intracochlear space with a volume of 190 μ L, the worst-case local concentration is estimated to be 0.04 μ g/ μ L, which is 75 times lower than the concentration reported to be irritating to the eye. The second case study is for Poloxamer-188 with a parenteral ADI of 460 μ g/kg/day. Poloxamer-188 is not neurotoxic or irritating. Therefore, a factor of 100 was applied to the parenteral ADI yielding an intracochlear ADI of 4.6 μ g/kg/day. The intracochlear ADIs illustrated in these case studies are not expected to cause adverse systemic effects. Further, the local concentrations inside the intracochlear space are not expected to cause adverse local effects. Consultation with a clinical neurologist indicated that the safety risk is considered low at these concentrations. **Conclusions**: The utility of this proposed framework is illustrated by the two case studies in this study. While this framework provides a qualitative approach to determining intracochlear ADIs, it is a preliminary approach. Further refinement with quantitative data would further refine this approach and increase its applicability.

PS 3306 Using a Framework Approach to Determine Parenteral Accepted Daily Intake for Benzonase

R. Jolly¹, C. Callis¹, L. Cooper¹, P. Cornwell¹, M. Willming², A. Maier³, and E. S. Fung⁴.
¹Eli Lilly & Company, Indianapolis, IN; ²Integral Consulting, Boise, ID; ³Integral Consulting, Cincinnati, OH; and ⁴Integral Consulting, Los Angeles, CA.

Background and Purpose: Enzymes are a diverse group of proteins that have a variety of functions. The use of enzymes in pharmaceutical manufacturing and therapeutics has increased over the years. Due to the diverse nature of enzymes, their safety profiles may vary considerably. Unfortunately, there is no consensus on how to determine health-based exposure limits (HBELs) for enzymes. Many industries default to the exposure limit of a highly sensitizing enzyme, subtilisin, and few enzyme-specific HBELs are available. A preliminary framework for HBEL determination for enzymes was previously presented by Fung et al. The goal of this study was to apply the preliminary framework and determine an accepted daily intake (ADI) for benzonase. **Methods**: In the preliminary framework presented by Fung et al., the recommendation is to first determine whether enzyme-specific data is available when determining a HBEL. If enzyme-specific data is not available, a default approach is taken based on enzyme characteristics including whether the enzyme is biocatalytic, endogenous, and/or sensitizing. If enzyme-specific data is available, a data driven approach should be taken. **Results**: Benzonase is a genetically engineered endonuclease used to remove residual nucleic acids in the purification process of pharmaceutical manufacturing. Benzonase-specific toxicological data is limited but data is available for similar endonucleases including DNase I (endogenous human enzyme that catalyzes the hydrolysis of extracellular DNA); therefore, a data driven approach was taken to determine the parenteral ADI for benzonase. The point of departure (POD) was determined from DNase I data. The amount of DNase I that can be added to the serum while remaining below the threshold of activity (concentration where DNA hydrolysis is observed) was calculated by subtracting the 95th percentile concentration of serum DNase I of 6 ng/mL from the threshold of activity required for catalysis of 50 ng/mL, yielding a value of 44 ng/mL. Benzonase was reported to have 34-fold greater activity compared to DNase I; therefore, the amount of benzonase that can be added to serum while staying below the threshold of activity is 1.3 ng/mL. Assuming that benzonase is distributed throughout the blood and a total blood volume of 4,700 mL, the amount of benzonase that can be added while staying below the threshold of activity is 6,000 ng/day. The value of 6,000 ng/day or 6 μ g/day was selected as the POD. The POD is derived from a minimum active serum concentration in humans and accounts for difference in activity of DNase I compared to benzonase; therefore, further adjustment factors are not warranted. Together, a parenteral ADI of 6 μ g/day

is recommended for benzonase. **Conclusions**: This study demonstrates the utility of preliminary framework presented by Fung et al. where enzyme-specific data is available. Additional case studies using this framework may help refine the framework to determine HBELs for enzymes without data.

PS 3307 Risk Assessment and Pharmacokinetic Modeling of Incidental Ingestion of Ethanol from Mouthwash

D. G. Kougias¹, M. Kovochich¹, S. Ejaz², A. Najjar³, S. Nair², B. Michelin⁴, C. Chu², and M. D. Southall². ¹K2 Toxicology and Integrated Risk Assessment, LLC, Las Vegas, NV; ²Kenvue Medical Clinical and Safety Sciences, Summit, NJ; ³Beiersdorf AG, Hamburg, Germany; and ⁴Kenvue Regulatory Affairs, Val-de-Reuil, France.

Background and Purpose: Mouthwashes containing ethanol for antiseptic properties have a long history of use and well-established oral hygiene benefits by significantly enhancing the control of dental biofilm and reducing gingival inflammation. Despite the substantial health benefits from ethanol-containing mouthwashes, there has been ongoing scrutiny by regulatory and health authorities of products containing ethanol resulting from the classification of consumption of alcohol-containing beverages as a potential carcinogen. Unlike alcohol-containing beverages, mouthwash products are not intended to be ingested, and the potential ethanol exposure is substantially lower for mouthwash products. Therefore, we conducted a risk assessment that benchmarked estimated and modeled incidental exposure to ethanol in mouthwash products against endogenous blood levels, dietary exposure, and health-based guidance values (HBGVs) for ethanol. **Methods**: Several approaches were used to estimate and benchmark exposure to ethanol from mouthwash use for risk characterization purposes. First, an internal dose, or systemic exposure dose (SED), was calculated from three use scenarios, including average use, 90th-percentile use, and maximum-label use. Data for average use and 90th-percentile use were based on previously reported exposure data in representative European countries. The estimated exposure to ethanol from various mouthwash-use scenarios was compared to typical dietary intake levels to contextualize the relative magnitude of exposure. Second, a physiologically based pharmacokinetic (PBPK) model was used to estimate ethanol blood levels associated with the three use scenarios, which were then compared to typical endogenous ethanol blood levels to further understand the relative magnitude of exposure. Finally, the SEDs from the three use scenarios were benchmarked against different HBGVs to determine whether these exposures are consistent with levels considered to be without safety concern. **Results**: The estimated potential exposure to ethanol from average use, 90th-percentile use, and maximum-label use of a 26.9% ethanol-containing mouthwash in a 60-kg person was 4.46 mg/kg/day, 7.65 mg/kg/day, and 14.15 mg/kg/day, respectively. All use scenarios, including maximum-label use which is nearly two-fold above 90th-percentile use, were within the range of dietary intake levels (excluding alcoholic beverages). Using PBPK modeling for twice daily 20-mL (maximum-label) mouthwash use, the predicted C_{max} of 1.16 mg/L and a 24-h constant blood alcohol concentration of 0.16 mg/L derived from the predicted AUC of 3.84 (mg/L)·hr are within range of average endogenous blood ethanol concentrations. All mouthwash-use scenarios—including average, 90th-percentile, and maximum-label use—resulted in relatively low estimated ethanol exposures that were below various reference and HBGVs, including the HBGV of 1 g/day for ethanol (16.7 mg/kg/day in a 60-kg human), a conservative value that is considered to be protective against chronic health endpoints. The findings suggest that ethanol from mouthwash use does not significantly contribute to systemic levels of ethanol, falls within dietary intake levels, and remains below HBGVs. **Conclusions**: Taken together, this assessment concludes that incidental oral exposure of ethanol-containing mouthwashes represents a *de minimis* health risk.

PS 3308 Quantitative Risk Assessment for t-Butyl Alcohol in Drinking Water

A. Sleiman, B. Lampe, P. Jewell, and T. D. Vincent-Hall. NSF, Ann Arbor, MI.

Background and Purpose: Tert-butyl alcohol (TBA, CAS #75-65-0) is a branched-chain tertiary alcohol used in fuel blending, industrial solvents, and chemical synthesis. It is also a primary metabolite of methyl tert-butyl ether (MTBE) and ethyl tert-butyl ether (ETBE), both of which have been widely used as gasoline oxygenates. TBA has been detected in groundwater and drinking water systems, yet it remains unregulated by the U.S. EPA and Health Canada. This assessment was conducted under NSF/ANSI/CAN 600 standard to establish an oral reference dose (RfD) and corresponding drinking water criteria for TBA, supporting product certification and public health protection. **Methods**: A comprehensive toxicological review was conducted, including chronic and subchronic toxicity, carcinogenicity, genotoxicity, developmental and reproductive toxicity, and ADME data. The key study selected was an NTP chronic drinking water bioassay in F344/N rats and B6C3F1 mice. The critical effect was increased absolute kidney weight in female rats. Benchmark dose modeling yielded a BMDL₁₀ of 91 mg/kg-day, which was allometrically scaled to a human equivalent dose (HED) of 22 mg/kg-day. A composite uncertainty factor of 30 was applied to account for inter- and intra-species differences, resulting in an oral RfD of 0.7 mg/kg-day. Drinking water criteria were calculated using U.S. EPA 90th percentile intake rates. **Results**: The derived RfD supports a total allowable concentration (TAC) of 4 mg/L and a single product allowable concentration (SPAC) of 0.4 mg/L. Cancer

endpoints were evaluated based on thyroid follicular cell hyperplasia and adenomas observed in mice. Although U.S. EPA previously applied linear low-dose extrapolation, recent mechanistic studies (Borghoff et al., 2025) support a threshold-based mode of action involving CAR/PXR activation, hepatic enzyme induction, and disruption of thyroid hormone homeostasis. This anti-thyroid MOA is consistent with a non-mutagenic, receptor-mediated mechanism. Benchmark dose modeling of thyroid hyperplasia yielded a BMDL10_{HED} consistent with the kidney endpoint. Recent TBA studies including bacterial mutation, *in vivo* micronucleus and comet assays, and transgenic rodent mutation studies with MTBE and ETBE showed no DNA damage or increased mutation rates and strongly support that TBA does not act through a genotoxic mechanism. Developmental toxicity studies showed fetal effects only at high doses (≥ 1000 mg/kg-day), typically accompanied by maternal toxicity. In a key oral study, decreased fetal body weight and increased skeletal variations were observed at 1000 mg/kg-day. The NOAEL for developmental effects was 500 mg/kg-day, corresponding to a NOAEL_{HED} of 126 mg/kg-day. A short-term exposure level (STEL) of 100 mg/L was derived using maternal and fetal endpoints, adjusted for a 30x uncertainty factor and a 0.033 L/kg intake rate for pregnant women. **Conclusions:** This assessment provides a comprehensive, threshold-based risk characterization of TBA in drinking water. The derived RfD, TAC, SPAC, and STEL are protective of both cancer and non-cancer endpoints. The updated genotoxicity data and mechanistic evidence support a non-genotoxic, receptor-mediated MOA for thyroid effects. The recent IARC classification of TBA as Group 3 further supports the conclusion that TBA is not classifiable as to its carcinogenicity to humans. The proposed drinking water criteria ensures public health protection under NSF/ANSI/CAN 600.

PS 3309 Derivation of an oral reference dose and drinking water criteria for lithium

B. J. Lampe, S. Sriram, and T. J. Vincent-Hall. NSF, Ann Arbor, MI.

Background and Purpose: NSF is an independent non-governmental organization that provides health-based risk assessments for drinking water contact chemicals in accordance with the published Health Effects Standard, NSF/ANSI/CAN 600. Although lithium is not intentionally added to drinking water, low levels have been observed to extract from cement and concrete drinking water system components undergoing certification. Accordingly, the purpose of this research was to derive an oral reference dose (RfD) and corresponding drinking water criteria for lithium. **Methods:** A comprehensive literature search for toxicological data on lithium compounds was conducted. *In vivo* and *in vitro* studies were critically evaluated against guidelines and for data quality. Clinical and cohort studies involving human participants that included clear information on dosing and adverse event reporting were also reviewed. Since lithium doses in the clinical studies were typically reported as blood plasma levels, conversion to oral doses was facilitated by a dosimetric adjustment that considered pharmacokinetic data identifying typical human clearance values for lithium compounds. The RfD was subsequently derived by dividing the selected oral POD by appropriate uncertainty factors. To calculate drinking water criteria, 90th percentile drinking water intake rates identified in the U.S. EPA Exposure Factors Handbook were incorporated. **Results:** The therapeutic use of lithium salts in the treatment of psychiatric disorders dates back to at least the mid-20th century; thus, the dataset relevant to human toxicity consists primarily of clinical trials and hospital-based cohort studies, with relatively few guideline-compliant studies in laboratory animals. However, taken collectively, the human data revealed several consistent lithium-induced effects to the kidney (polyurea), thyroid (increased TSH and hypothyroidism), and nervous system (reduced nerve conduction velocity and reduced performance in tests of memory). As the human studies were largely designed to evaluate effects after long-term therapeutic doses, it was not possible to determine a NOAEL or critical effect. Therefore, the above “constellation of effects” associated with serum concentrations of approximately 0.6 mmol/L (that increased in severity at higher doses) were considered co-critical effects. The selected POD of 0.6 mmol/L was extrapolated to an oral dose of approximately 2.0 mg/kg-day based on the median of the clearance values identified from a range of pharmacokinetic studies in humans (0.02 L/kg-hr) and assuming an oral bioavailability of 100%. To derive the oral RfD for lithium, a total uncertainty factor of 300 was applied to the POD of 2 mg/kg-day, which included a factor of 10 to account for the lack of a clear NOAEL, a factor of 10 to account for intraspecies differences in sensitivity, and a factor of 3 to address the lack of a chronic study. Therefore, the oral RfD was 2 mg/kg-day divided by 300, or 6.67 mg/kg-day. From the oral RfD, a total allowable concentration (TAC) of 40 µg/L (rounded) was derived based on the 90th percentile intake rate of 0.034 L/kg-day for adults and application of a 20% relative source contribution to account for potential exposure to lithium from sources other than drinking water. To address the possibility of multiple sources of lithium in drinking water, a single product allowable concentration (SPAC) of 4 µg/L was identified, assuming 10 sources of contamination. Lastly, a short-term exposure level (STEL) of 100 µg/L was derived from the same POD that was used to derive the TAC, using the drinking water intake for a child 0-12 months of age (0.15 L/kg-day) and an uncertainty factor of 100. **Conclusions:** Based on the selected POD and the application of appropriate uncertainty factors that consider interspecies and intraspecies differences in sensitivity, the TAC, SPAC, and STEL drinking water action levels derived in this assessment are considered protective of public health. Despite the lack of suitable guideline-compliant studies in animals, confidence in the overall assessment is high due to the extensive human clinical data available for lithium compounds.

PS 3310 Identification of Proposition 65 MADLs for Methyl Chloride

J. Lee, J. Ator, and M. H. Whittaker. ToxServices LLC, Ann Arbor, MI.

Background and Purpose: Methyl chloride is a naturally-occurring component of environmental media, arising from chemical reactions occurring in the oceans and through combustion of grass, wood, and coal. Methyl chloride currently serves as an industrial intermediate in the production of silicone-based fluids, elastomers, and resins, which are widely used industrially and in consumer products. The State of California's Office of Environmental Health Hazard Assessment (OEHHA) included it as a developmental toxicant on the list of substances known to the State to cause cancer or reproductive toxicity (i.e., Proposition 65), based on the Authoritative Body mechanism: NIOSH determined that methyl chloride is a male reproductive toxicant and developmental toxicant. OEHHA has not established a safe harbor level for methyl chloride for either endpoint. Therefore, this work applied OEHHA's published methodologies to methyl chloride's health effects dataset to calculate a developmental toxicity maximum allowable dose level (MADL) and to update a previously-calculated MADL for male reproductive toxicity. **Methods:** Three key studies identified by NIOSH and included in a U.S. EPA submission were evaluated to identify the critical developmental effect and to establish a point of departure (POD) for the developmental toxicity MADL. The literature search was also updated for both endpoints. Inhalation exposure concentrations were converted from analytical exposure concentrations in units of ppm to continuous exposure concentrations and then to average daily doses in units of mg/kg/day using calculated inhalation rate and study-specific body weight values. From the available studies, the point of departure for each endpoint was selected and the MADLs were calculated using procedures outlined by OEHHA. **Results:** Developmental toxicity studies were performed in rats, mice, and rabbits and involved inhalation exposure during applicable periods of organogenesis. In rats, fetal effects included reduced crown-rump length, reduced body weight, and reduced ossification at a nominal concentration of 1,500 ppm, a concentration that also significantly reduced maternal body weight gain. In two studies with mice, significant maternal toxicity occurred at concentrations of 1,500 and 750 ppm, and fetal heart malformations occurred at concentrations of 500 and 750 ppm. Specifically, the bicuspid or tricuspid valves and their supporting structures were absent or malformed. In contrast, no maternal or developmental toxicities were observed in rabbits. The mouse is therefore the most sensitive species based on the concentrations at which developmental effects not attributable to maternal toxicity were observed. Using time-weighted average body weights and calculated inhalation rates, the mouse NOAECs of 100 ppm and 250 ppm were converted to NOAELs of 1,161 mg/kg/day and 2,876 mg/kg/day, respectively. The corresponding LOAECs were converted to LOAELs of 5,451 mg/kg/day and 5,752 mg/kg/day, respectively. The highest NOAEL lower than the lowest LOAEL was 2,876 mg/kg/day and was selected as the point of departure for the developmental toxicity MADL calculation. This value was multiplied by the default body weight of 58 kg for pregnant women specified in 27 CCR and then divided by a factor of 1,000 to yield a developmental toxicity MADL of 166.8 mg/day for methyl chloride. The literature search for male reproductive effects did not identify any additional studies. The point of departure for the male reproductive toxicity MADL therefore remains the NOAEC of 150 ppm (309.6 mg/m³) based upon testicular effects and reduced fertility observed in a 2-generation rat study. Using the study's reported body weight data and a calculated inhalation rate, the NOAEC of 309.6 mg/m³ was converted to a NOAEL of 50.9 mg/kg/day. When multiplied by the default body weight of 70 kg for adults specified in 27 CCR and then divided by a factor of 1,000, the male reproductive toxicity MADL for methyl chloride is 3.6 mg/day. **Conclusions:** In summary, exposures to methyl chloride less than 166.8 mg/day do not pose a risk of developmental toxicity and exempt responsible parties from Proposition 65 label warning requirements in the absence of agency-established toxicity criteria. Similarly, exposures to methyl chloride less than 3.6 mg/day do not pose a risk of male reproductive toxicity. The large difference between these two MADLs illustrates the importance of considering all relevant endpoints when performing Proposition 65 compliance assessments.

PS 3311 Establishment of Proposition 65 maximum allowable dose levels (MADLs) for ethylene dibromide

J. Ator, B. Wang, and M. H. Whittaker. ToxServices LLC, Washington, DC.

Background and Purpose: Ethylene dibromide has historically been used as a lead gasoline additive and fumigant. Although no longer used as such in the U.S., it remains an industrial intermediate, and exposures to contaminated environmental media, water in particular, may also occur. Originally listed on California's Proposition 65 for carcinogenicity, ethylene dibromide's Proposition 65 listing now includes the male reproductive toxicity and developmental toxicity endpoints as a result of National Institute for Occupational Safety and Health (NIOSH) and United States Environmental Protection Agency (U.S. EPA) assessments. California's Office of Environmental Health Hazard Assessment (OEHHA) has not established safe harbor maximum allowable dose levels (MADLs) for ethylene dibromide. This work evaluates toxicological data available for ethylene dibromide to establish MADLs for use in Proposition 65 compliance evaluations. **Methods:** This work critically assessed data included in agency evaluations, including NIOSH, U.S. EPA, and the Texas Commission on Environmental Quality (TCEQ), and newer data identified from a search of the peer-reviewed literature. Dosimetric adjustments and dose-response analyses identified the critical developmental effect and the critical male reproductive effect associated with ethylene dibromide exposure. Using methodologies

established by OEHA, MADLs were calculated for each endpoint. **Results:** In classical developmental toxicity studies, pregnant female rats and mice were exposed to ethylene dibromide via inhalation during their periods of organogenesis. Statistically significant effects included reduced live litter size, reduced live fetal body weight, reduced ossification, and/or changes in pup neurobehavioral parameters. The incidence of hydrocephalus was increased (not significant) in rats and mice as well. These effects often occurred together with significant maternal toxicity, complicating identification of true no effect levels for development. Additional studies revealed male-mediated developmental effects: male rats were exposed via inhalation to ethylene dibromide and then mated with untreated females, resulting in reduced litter size, pup neurobehavioral effects, or altered brain neurotransmitter enzyme activities in progeny. Considering all available data, a LOAEC of 154 mg/m³, based on hydrocephalus in mice, was selected as the point of departure for the MADL calculation. After adjustment to a continuous dose, application of default inhalation rate and body weight factors, and application of a factor of 1,000 as required by OEHA, a developmental toxicity MADL of 928 µg/day was established. For male reproductive toxicity, testicular degeneration or atrophy was a common finding in chronic studies in rats and mice. Additionally, two epidemiology studies in exposed workers identified effects on sperm quality, such as reduced sperm count and reduced sperm motility. Most of these studies did not assess reproductive function, however. In one study that evaluated functional effects, male rats were exposed via inhalation and then mated with untreated females, and testicular atrophy occurred together with reduced male fertility. In male rabbits, ethylene dibromide inhalation exposure prior to mating resulted in reduced sperm motility but did not affect fertility. Since the MADL is based on the most sensitive health effect, lowest effect levels from studies identifying a potentially adverse effect were converted to mg/kg/day equivalent intake values to facilitate the dose-response assessment. An epidemiology study in papaya workers provided the lowest daily intake estimate of 0.046 mg/kg/day, equivalent by OEHA's definition to a no effect level of 0.0046 mg/kg/day, and served as the basis for the male reproductive toxicity MADL. When multiplied by a default adult body weight of 70 kg, the resulting MADL for male reproductive toxicity is 0.322 µg/day. **Conclusions:** This work establishes safe harbor MADLs that can be used in Proposition 65 regulatory compliance determinations. It also illustrates some of the challenges inherent in the evaluation of reproductive and developmental toxicity, such as distinguishing between secondary effects due to maternal toxicity and primary effects on the developing organism; assessing male-mediated developmental effects; interpreting effects of unclear toxicological significance; and making the best use of limited epidemiology data.

PS 3312 Consideration of Carcinogenicity and Mode of Action Information by an Independent Expert Panel to Support Derivation of No-Significant-Risk-Level Values for Vinyl Acetate Monomer

C. R. Kirman, and S. M. Hays. SciPinion, Bozeman, MT.

Background and Purpose: The carcinogenicity and cancer mode of action (MOA) of vinyl acetate monomer (VAM) has been well-studied. VAM was recently placed on the Proposition 65 list as a carcinogen by the state of California, and prompting the need for the derivation of a No-Significant-Risk-Level (NSRL) value. **Methods:** A triple-blinded, independent panel of five experts was engaged to review information on the carcinogenicity and MOA of VAM to provide input on key decisions for the calculation of NSRL values using best available science. Combined, this panel possessed more than 200 years of relevant experience and more than 1,000 scientific publications. Based upon the weight of evidence (including considerations for study quality), the panel expressed higher confidence in using effects observed at the point of contact, rather than relying on those observed in systemic tissues, as the critical effects supporting NSRL derivation. **Results:** The panel considered a cancer MOA involving increased cell replication to be best supported by the weight of evidence (mean confidence score of +3.8±1.1, on a scale of -5 to +5). In contrast, a cancer MOA involving direct genotoxicity was not supported for VAM (mean confidence score of -3.6±2.0, on a scale of -5 to +5). Because VAM produces effects at the point of contact (i.e., upper respiratory tract following inhalation exposures; upper gastrointestinal tract following oral exposures), separate NSRL values were derived for inhalation and oral routes of exposure. **Conclusions:** Based upon the decisions recommended by the panel at each step of the derivation process (endpoint/dataset, dosimetry, point of departure, low-dose extrapolation), inhalation and oral NSRL values of 20,000 and 110,000 µg/day were calculated, respectively. Confidence in the inhalation NSRL value was considered high by the panel (mean confidence score of 9±1 on a scale of 0 to 10), whereas confidence in the oral NSRL was considered medium (mean confidence score= 6.4±3.8, on a scale of 0 to 10). Based upon best available science (data and methods), human exposures below these NSRL levels are not expected to pose a significant cancer risk.

PS 3313 Confidently determining reliable intake limits from robust carcinogenicity studies

S. O. Odebamowo, G. Kocks, D. J. Ponting, and A. Thresher. Lhasa Limited, Leeds, United Kingdom.

Background and Purpose: The assessment of carcinogenic potency is crucial for ensuring human safety, particularly within the pharmaceutical industry where the therapeutic benefit of a drug can justify the presence of low levels of carcinogenic impurities. In such cases, the acceptable intake (AI) is determined by the carcinogenic potency of the impurity. For carcinogens, the potency is expressed as the TD₅₀, which is the dose at which the probability of remaining tumour-free over a lifetime exposure is halved, and serves as the basis for deriving AI limits. This work aimed to improve the reliability and transparency of TD₅₀-based AI derivation. **Methods:** The original Carcinogenic Potency Database (CPDB) TD₅₀ model proved irreproducible due to its unpublished methodology, ambiguities in the workflow, and errors in data curation prior to TD₅₀ calculation. This has prevented the calculation of TD₅₀s from new studies and as a result a new implementation of the TD₅₀ model ("Lhasa TD₅₀") was developed [Thresher *et al* 2019] and made freely available via the Lhasa Carcinogenicity Database (LCDB). To further strengthen safety assessor confidence, a comprehensive reassessment has been conducted which has led to significant enhancements to the Lhasa TD₅₀ model, enabling more robust results to be produced. In addition, applicability metrics such as the Akaike Information Criterion and X² goodness-of-fit are available to assessors to evaluate the appropriateness of TD₅₀ calculations for specific dose-response datasets to support expert review. Additionally, the framework for assessing study reliability has been refined through the incorporation of an A+ grade, allowing confirmation of which studies are suitable for the assessment of potency. Building on this information, a two-stage approach combining top reliability grading and Pareto optimization has been developed to identify the 'most sensitive site in the most robust study', the preferred point of departure (PoD) for AI limits under ICH M7. **Results:** This method correctly identifies a single preferred study in 98% of the time (with no more than three being proposed in any case), dramatically reducing the time needed for selecting the PoD. For validation of this method, the studies from the ICH M7 addendum and the regulatory guidance on nitrosamines were correctly identified. **Conclusions:** These improvements provide a transparent workflow that supports more efficient decision making.

PS 3314 Systematic Evaluation of the Carcinogenic Potential of Di-isononyl Phthalate in Humans

A. N. Buerger¹, I. A. Lea², M. J. Vincent¹, B. N. Rivera³, N. Y. Choksi², J. Britt⁴, S. Fitch⁵, S. Rogers³, H. Schaefer⁶, L. Haws⁵, H. Nyamengo⁷, C. M. Palermo⁸, D. Wikoff⁹, and S. J. Borghoff². ¹ToxStrategies LLC, Cincinnati, OH; ²ToxStrategies LLC, Research Triangle Park, NC; ³ToxStrategies LLC, Asheville, NC; ⁴ToxStrategies LLC, Tallahassee, FL; ⁵ToxStrategies LLC, Katy, TX; ⁶ToxStrategies LLC, Annapolis, MD; ⁷ExxonMobil Biomedical Sciences, Inc., Spring, TX; and ⁸ExxonMobil Biomedical Sciences, Inc., Annandale, NJ.

Background and Purpose: Di-isononyl phthalate (DINP) is a high molecular weight phthalate widely used in the manufacture of polyvinyl chloride and other commercial products. This assessment aims to systematically evaluate the evidence base for DINP, including human and animal cancer studies and mechanistic data, to inform an overall conclusion regarding the carcinogenic potential of DINP in humans. **Methods:** Peer-reviewed DINP literature were identified from systematic searches conducted in PubMed and Embase, supplemented by hand searching. Publicly available good laboratory practice and/or guideline laboratory reports were identified through review of regulatory documents. Mechanistic data were organized according to the key characteristics of carcinogens (KCCs). All identified data underwent critical appraisal. Data were integrated using principles of WHO IPCS for human and animal cancer data alongside concepts for activity assessment of mechanistic data. **Results:** Four epidemiological studies that evaluated the association between DINP exposure (via DINP-specific metabolites) and cancer were identified. Three studies reported no statistically significant (SS) positive increases in breast cancer incidence or mortality risk associated with DINP exposure. A case-control study found a SS increase in prostate cancer risk associated with DINP exposure, but this finding was determined to represent an imprecise association because it was based on a very small sample size and lack of consideration of confounding or covariates except matching on age. Current evidence from human studies does not support an association between DINP and cancer in humans. Four reliable dietary rodent cancer bioassays (3 in rats, 1 in mice) were identified. Inconsistent SS increases in liver and kidney tumors, and mononuclear cell leukemia (MNCL) were reported. A SS increase in hepatocellular adenomas, carcinomas, and/or their combined incidence was observed in 3 of the 4 studies. Mode of action (MoA) analysis supports that DINP elicits liver tumors via the peroxisome proliferator-activated receptor alpha (PPARα) MoA, which is widely considered to lack human relevance. A small but SS increase in renal tubular carcinomas was observed in 1 of 2 studies in male F344 rats; it is postulated that DINP acts through the non-human relevant α2u-globulin nephropathy MoA. In the F344 but not SD rat bioassays, a dose-dependent and SS increase in MNCL was observed. MNCL is a common lesion in aging F344 rats and is not considered relevant in predicting human cancer. Collectively, these animal data provide strong evidence that DINP is unlikely to be a human carcinogen. A robust mechanistic dataset of 127 studies was identified, with endpoints mapping to 9 of 10 KCCs. Reliable data in exposed

humans from 42 studies showed inconsistent findings for KCC2 (genotoxicity), KCC4 (epigenetic alterations), and KCC5 (oxidative stress). Reliable data from *in vivo* animal studies, *in vitro* assays (human and mammalian), and *in silico* models from 85 studies showed DINP was neither genotoxic (KCC2) nor immunosuppressive (KCC7). Inconsistent signals of activity were reported for KCC1 (electrophilic), KCC4 (epigenetic alterations), KCC5 (oxidative stress), and KCC8 (modulates receptor-mediated effects). Activity related to KCC10 (alters cell proliferation, cell death and nutrient supply) was evident in liver and kidney of *in vivo* rodent models, consistent with studies that demonstrated rodent-specific MoAs for kidney and liver tumors described above. **Conclusions:** Limited epidemiological data do not support an association between cancer outcomes in humans and exposure to DINP. While rodent bioassays have shown tumor formation following DINP exposure, the underlying MoAs are not considered relevant to humans. Mechanistic data support this interpretation, demonstrating a lack of genotoxicity and only inconsistent activity across the other 9 KCCs. Collectively, this systematic evaluation suggests that DINP is unlikely to be carcinogenic in humans.

PS 3315 Setting Occupational Exposure Limits (OELs) for Carcinogens: A Focus on Benzene

M. Pedrozo¹, and M. M. Paoliello². ¹Lisam Ecodvisor, São Paulo, Brazil; and ²Albert Einstein College of Medicine, Bronx, NY.

Background and Purpose: Since the 1950s, regulation of occupational carcinogen exposure has progressed from hazard identification to quantitative evaluation, driven by advances in cancer biology. This narrative review compares two approaches for setting Occupational Exposure Limits (OELs) for carcinogens, focusing on benzene. **Methods:** A narrative review was conducted to qualitatively synthesize and summarize the occupational limits established by different regulatory agencies and researchers. **Results:** The first approach applies the carcinogenic mode of action (MOA), using linear extrapolation for primary genotoxicants and non-linear extrapolation for secondary genotoxicants. The second approach quantifies *in vivo* genotoxicity data, employing mathematical modeling to define the point of departure (POD) for non-linear extrapolation, regardless of the MOA. As benzene is an indirect genotoxicant, it is considered to have a threshold value. Based on the MOA approach, different European institutions and commissions have proposed OELs ranging from 0.05 to 0.25 ppm, and the ACGIH has recommended a TLV/TWA of 0.02 ppm (with skin notation). Based on quantitative genotoxicity approach, the proposed OELs range from 0.021 to 0.07 ppm for benzene. **Conclusions:** Current evidence indicates that workplace benzene concentrations above 0.3 ppm do not adequately protect the health of exposed workers. Extending follow-up of existing cohorts and conducting well-designed epidemiological studies are essential to reduce uncertainties and to confirm the most sensitive toxic effect, thereby supporting the establishment of a more realistic OEL for benzene and minimizing the likelihood of over- or underestimating the associated risks.

PS 3316 Establishing an Endogenous Threshold for AICAR to Support NSF Certified for Sport® Compliance

S. L. Cousineau¹, K. A. Magurany², J. C. Travis¹, C. C. McGuire¹, A. N. Jurezic¹, and T. D. Vincent-Hall¹. ¹NSF, Ann Arbor, MI; and ²Verto Solutions, LLC (formerly NSF), Washington, DC.

Background and Purpose: The NSF Certified for Sport® program (NSF 306) verifies that certified products do not contain athletically banned substances (ABS), including, but not limited to, those prohibited by the World Anti-Doping Agency (WADA). WADA includes substances on its Prohibited List if they meet at least two of the following criteria: potential to enhance performance, potential to cause adverse effects, or violation of the spirit of sport. Once banned, the default acceptability criterion in finished products is absence of the substance at the analytically feasible detection threshold. Although adulteration is typically considered the source of ABS, in some cases, ABS may naturally occur in supplement ingredients as unintended constituents, or may be naturally produced by the body at low background concentrations. In either case, these endogenous levels may be above the analytical detection limit, but would be unlikely to meet WADA criteria for a prohibited substance. 5-Aminoimidazole-4-carboxamide riboside, also known as AICAR or acadesine, is banned in sport as a metabolic modulator and has been detected in dietary supplements (>20 ng/g). However, AICAR occurs endogenously in humans, plants and yeasts, and as a by-product of microbial fermentation due to its role in purine biosynthesis. This evaluation was prompted to determine whether an endogenous level of AICAR in dietary supplements can be scientifically justified to allow certification of products with a detectable level of AICAR that still complies with anti-doping policies. **Methods:** This evaluation integrated data from published human and animal studies, including population biomonitoring, pharmacokinetic assessments, performance enhancement models, and toxicity studies to characterize endogenous levels in humans and dietary supplement ingredient sources and to confirm absence of performance enhancement and adverse effects at the expected levels of exposure. **Results:** Although a definitive endogenous level for AICAR in humans could not be established due to limited exposure-controlled data, athlete population studies (with unreported supplement use) suggested that the fifth percentile of background

urinary concentrations was ~60 ng/mL and the 99th percentile was ~1,500 ng/mL. Oral bioavailability of AICAR was reported to be low (~5%) based on plasma AUC comparisons following oral and intravenous dosing. In healthy volunteers, a 167 mg/kg oral dose (~10 g) yielded peak urinary concentrations of 9,800 ng/mL at 8 hours, indicating therapeutic exposure and rapid elimination. Animal studies showed increased endurance after repeated intraperitoneal doses of 500 mg/kg in mice (~60 mg/kg or 3.6 g human equivalent) and no adverse effects after repeated intraperitoneal doses of 750 mg/kg in rats (~180 mg/kg or 10.8 g human equivalent). Intravenous doses of 50-210 mg/kg (3-12.6 g) were well-tolerated in patients with chronic lymphocytic leukemia. Concentrations of AICAR in yeast were reported to be ~2.4 mg/g, far exceeding supplement detections of 30-60 ng/g. Normalized to relevant supplement serving sizes, supplement detections equated to ~2×10⁻⁵ to 1×10⁻³ mg/day exposures. A qualitative threshold of 0.5 mg/day (~0.008 mg/kg-day) was proposed as an acceptable exposure limit to allow variability in endogenous ingredient concentrations while remaining well below doses linked to performance enhancement, toxicity and those that would contribute meaningfully to background urinary concentrations. A margin of exposure analysis indicated that consumer exposure at the endogenous threshold was > 7,500 times lower than human equivalent intraperitoneal doses with performance enhancing effects in mice, which were expected to be exaggerative of typical oral exposure considering low bioavailability. **Conclusions:** The proposed threshold of 0.5 mg/day AICAR is expected to be protective of toxicological effects, performance enhancement, and the risk of a positive doping test. Adopting this threshold within NSF 306 supports accurate interpretation of analytical findings, enables differentiation between AICAR presence consistent with levels naturally occurring in food and exogenous adulteration intended for performance enhancement, and ensures compliance with banned substance policies.

PS 3317 Database calibrated toxicity values for human health assessment based on existing toxicology data for one thousand chemicals

D. Krewski¹, S. Hagiwara², C. A. Weitekamp³, J. T. Wall³, P. C. Stanish², K. Paul Friedman³, G. Paoli², and R. S. Thomas³. ¹University of Ottawa, Ottawa, ON, Canada; ²Risk Sciences International, Ottawa, ON, Canada; and ³UL Research Institutes, Marietta, GA.

Background and Purpose: Traditional human health assessments rely upon expert judgment of dose-effect linkages observed in animal toxicology or human studies and can take considerable time and resources to complete. In this presentation, we describe a new database-calibrated assessment process (DCAP) to generate oral, non-cancer human health toxicity values using a new computational method without the need for expert input. This computational approach to chemical risk assessment greatly decreases the time needed to complete human health assessments. **Methods:** The DCAP approach converts information in the US EPA Toxicity Values Database (ToxValDB) that contains dose-response summary values (DRSVs) from *in vivo* toxicity studies to oral, chronic human equivalent doses using a series of standard conversion factors. A point-of-departure (POD) is then calculated for a given chemical using a calibration percentile that is benchmarked to critical effect PODs from previously published human health assessments. Traditional and process-specific uncertainties are incorporated to derive a calibrated toxicity value (CTV) that is likely to be without appreciable risk of adverse non-cancer health effects over a lifetime. **Results:** Application of the DCAP approach is illustrated by through the development of 1,001 CTVs for chemicals that currently lack human health assessments. **Conclusions:** The DCAP computational approach has the potential to establish toxicity reference values for environmental chemicals currently lacking human health assessments in a fraction of the time required for traditional expert-based assessments.

PS 3318 Component-based toxicological screening of spearmint (*Mentha spicata*) aerial parts essential oil and safe-supported exposure limits for humans.

J. T. Dawson, S. A. Shah, D. T. Carter, D. I. Saavedra, A. Poudel, P. Satyal, and C. Bascoul. Doterra International, Pleasant Grove, UT. Sponsor: C. Mitchell

Background and Purpose: Dose-response assessment is an important application of toxicology used in translational medicine and human health risk assessment. While sufficient evidence for dose-response assessment is available for many discrete compounds, the toxicology of many natural complex substances (NCS) is understudied. When there is insufficient NCS data, risk assessment protocols instruct evaluation of the NCS on a component basis. Component-based dose-response assessments can be performed when the composition of an NCS is characterized and adequate constituent toxicological data is available. Here, a component-based toxicological assessment of spearmint (*Mentha spicata*) aerial parts essential oil (EO) was performed to estimate exposure limits for use in human health risk assessments. Additionally, findings from this assessment are compared to research on spearmint EO. **Methods:** Spearmint EO was characterized using gas chromatography mass spectrometry analysis of 21 material lots. Constituents were organized into toxicological groups and descriptive statistics were derived for each compound group. Toxicological data was evaluated for all constituents ≥1% including repeated dose systemic toxicity, developmental toxicity, fertility toxicity, and genotoxicity.

Constituents with insufficient data to determine a point of departure (POD) were considered “not assessed” for that endpoint. The percentage of assessed constituents was calculated as a normalized value for each endpoint. Constituent POD values were obtained from toxicological risk assessments, safety dossiers, and expert opinions. Reference doses (RfD) were extrapolated for each constituent using body surface area scaling to convert POD to a human equivalent dose (HED). An uncertainty factor of 10 was used for interindividual variability. Risk-based exposure limits for the NCS were calculated for each constituent by dividing the constituent RfD by its normalized percentage in the NCS. From there, an adult safe-supported daily exposure value for the NCS was determined. For the purposes of this assessment, an adult safe-supported daily exposure value is defined as the greatest exposure to the material from a discrete route of administration that does not exceed the risk-based exposure limit of any constituent. **Results:** The main constituents evaluated in spearmint EO were carvone and limonene. Altogether, sufficient data was available to evaluate most constituents in spearmint EO for repeated dose systemic toxicity (91%), developmental toxicity (90%), fertility toxicity (89%), and genotoxicity (94%). No genotoxic compounds were identified. Carvone was identified as the primary exposure-limiting constituent for repeated dose systemic, developmental, and fertility toxicity. Of these endpoints, repeated dose systemic toxicity exposure limits for carvone were the most restrictive. Assuming a dermal absorption value of 100% for carvone, the safe-supported exposure limit for healthy adults and sensitive populations was determined to be 103 mg/person/day (RfD: 1.7 mg/kg bw/day) spearmint EO for all routes of exposure combined. **Conclusions:** The critical study for spearmint EO repeat dose toxicity is a 90-day oral subchronic study (OECD 408) in rats that concluded a NOAEL of 100 mg/kg bw/day. This equates to an RfD of 1.6 mg/kg bw/day for spearmint EO, which agrees with the RfD found in this compound-based assessment. No genotoxic constituents were identified in spearmint EO, which aligns with findings from bacterial reverse mutation and *in vivo* micronucleus assays showing that spearmint EO is not genotoxic. As limitations, read-across data was not included in this analysis unless read-across was used to derive POD values in reputable toxicological risk assessments. Also, thresholds of toxicological concern and Cramer classifications for constituents were not considered. Given the GRAS status of spearmint EO and its widespread use in cosmetic and food products, this research may be used to inform posology for clinical trials and human health risk assessments. Furthermore, this research serves as an example comparing the toxicological profile of a mixture to its components.

PS 3319 A physiologically-based pharmacokinetic (PBPK)/ pharmacodynamic (PD) model for rats and humans for the insecticide acephate

R. Reiss¹, A. Locissano¹, M. Schutte², J. Mehta², and R. Kapre². ¹Exponent, Alexandria, VA; and ²ADAMA, Cologne, Germany.

Background and Purpose: Acephate is an organophosphate insecticide and its most sensitive toxicological endpoint is acetylcholinesterase (AChE) inhibition. The uncertainty of regulatory risk assessments can be reduced by better understanding the difference in pharmacokinetics and AChE inhibition in rats, the species for which there is the most toxicology data, and humans, which is the focus of risk assessment. **Methods:** A PBPK/PD model was developed to simulate acephate dosimetry and pharmacokinetics in rats and humans for oral and inhalation exposures. Acephate is metabolized *in vivo* to methamidophos, which is the primary cause of AChE inhibition, though acephate itself also contributes. The model simulates tissue dosimetry and clearance, including conversion of acephate to methamidophos, metabolism of acephate and methamidophos to other metabolites, and urinary excretion, which is the primary mode of clearance for both acephate and methamidophos. The model was fit using both rat and human pharmacokinetic data, and the model's ability to estimate AChE inhibition was tested with rat *in vivo* studies. Fitting was accomplished using Markov Chain Monte Carlo, and the posterior distribution of the fitted parameters was used for uncertainty analysis. **Results:** The model successfully simulated both rat and human plasma concentrations following oral doses. The model also provided good estimates of AChE inhibition in a series of rat *in vivo* studies for acephate and methamidophos and for oral and inhalation exposures. The fitted human model was applied to estimate points-of-departure (PODs) for risk assessment. **Conclusions:** A PBPK/PD model was built for acephate. The model adequately simulated dosimetry and AChE inhibition in rats and dosimetry in humans. It was applied to estimate PODs for human risk assessment.

PS 3320 Quantifying Variability in Chemical Sensitivity Attributable to Social Non-Chemical Stressors: an Approach Using a Systematic Review of Human Studies

R. Thilakarathne¹, J. Trowbridge², C. Ortiz², E. Delker¹, R. Joglekar², L. August¹, and T. Woodruff². ¹CalEPA/OEHHA, Oakland, CA; and ²Program on Reproductive Health and the Environment, San Francisco, CA. Sponsor: H. Bolstad

Background and Purpose: The extent to which social non-chemical stressors (SNCS) (e.g., poverty, discrimination, perceived stress, etc.) contribute to variability in the human response to chemical exposures is not well-characterized. Quantification of this variability in chemical risk assessment is needed to establish protective default

factors when creating health guidance values (HGVs). **Methods:** We propose a novel approach for quantifying the variability attributable to SNCS. We first developed and registered a protocol to implement the Navigation Guide systematic review methodology, a structured and transparent framework tailored to incorporate environmental health data into decision-making. Using this method, we conducted literature searches in PubMed and Web of Science to identify human studies that quantified the combined effects of one of several key chemicals (lead, particulate matter, or organophosphate chemicals) with SNCS on child cognition. We included studies that assessed interactive effects of chemicals and SNCS, or that stratified chemical effects by SNCS, so that susceptibility attributable to SNCS could be quantified. **Results:** From a previous systematic review, we *a priori* identified 64 studies as eligible according to our inclusion criteria. Our current literature search yielded 4,232 eligible studies, which will allow us to expand the number of relevant included studies. From our included studies, we will calculate the ratio of chemical effects in high- versus low-SNCS subpopulations (within a given study) for a standard chemical contrast (i.e., one standard deviation), to derive a “modification factor”. Considering a unitless ratio of effects allows us to synthesize across diverse epidemiologic study populations, chemicals and dose ranges, and SNCS indicators and constructs, to estimate a general magnitude and range of the modification factor. We will use meta-regression to estimate how the factor varies by chemical, type of SNCS, developmental stage of exposure and outcome assessment, geography, and other factors, allowing the factor to be extrapolated to specific health risk-related scenarios. **Conclusions:** Our quantitative results, based on a rigorous systematic review, may strengthen chemical risk assessment approaches to better account for SNCS and lead to more health protective HGVs. Furthermore, our results can inform the practice of cumulative risk assessment broadly, which currently does not adequately account for SNCS.

PS 3321 Human Health Risk Evaluation of Pesticide Residues on Fresh Fruits and Vegetables in California: An Integrated Statewide Monitoring and Enforcement Program

D. J. Bonnar, J. Adragna, B. Brown, B. Darsie, P. Dodmane, Q. Dong, M. C. Geier, A. Kalashnikova, A. L. Rubin, S. Tiscione, C. Zhang, M. Armstrong, P. N. Lohstroh, S. E. Koshlukova, and S. DuTeaux. Department of Pesticide Regulation, California Environmental Protection Agency, Sacramento, CA.

Background and Purpose: To protect public health and enforce pesticide regulations, the California Department of Pesticide Regulation (DPR) operates the California Pesticide Residue Monitoring Program (CPRMP), a globally unique program that combines real-time health risk evaluation with regulatory enforcement. CPRMP samples both domestic and imported fresh produce to identify illegal pesticide residues and ensure compliance with US Environmental Protection Agency (US EPA) established tolerances. A pesticide tolerance is defined as the highest residue levels of a pesticide legally permitted on a specific commodity. Samples are collected statewide from wholesale and retail outlets, distribution centers, and farmers markets, with an emphasis on commodities frequently consumed by children and diverse demographic groups. Each sample is quantitatively analyzed for approximately 500 different pesticides to identify violations. Two types of violations are monitored by CPRMP: 1) “over tolerance” (OT), where residue levels exceed the established tolerance limit, and 2) “no tolerance established” (NTE), where a pesticide is detected on a commodity without an approved tolerance. DPR conducts rapid health risk evaluations for both types of violations to protect the public. **Methods:** When produce has been identified that exceeds a tolerance, a human health risk evaluation is initiated, focusing on assessing acute dietary exposure as chronic consumption of the same lot of fresh produce is considered unlikely. Exposure is estimated using commodity-specific consumption rates derived from National Health and Nutrition Examination Survey (2003-2018) data for the most sensitive subpopulation. These estimates are then compared to pesticide-specific acute oral reference doses (aRfDs), which are the maximum oral safe doses established by regulatory agencies including DPR, US EPA, European Food Safety Authority, World Health Organization and others. The aRfDs established by DPR are preferred when available, otherwise those established by US EPA, EFSA, WHO, or other agencies are used in order of preference. Estimated exposures that exceed the aRfD indicate potential acute health risks to consumers and trigger more stringent enforcement actions than those taken when no health risk is identified. When a sampled commodity contains residues from multiple pesticides known to share a common mechanism of toxicity, a hazard index approach is used to calculate cumulative risk. **Results:** In 2023, CPRMP collected 3,544 produce samples from over 500 locations across California. Analysis showed that 97% of samples were compliant with US EPA pesticide tolerances, while 3% of samples contained illegal pesticide residues. Notably, of those violations, 83% involved imported produce. Among California-grown samples, fewer than 1% had violations. Only 20 samples out of 3,544 (0.6%) had residues at levels posing a potential health risk; nineteen of these were imported. Ultimately, fewer than 1% of all samples, both domestic and imported combined, were determined to pose a potential acute health risk. **Conclusions:** This work highlights real-time evaluation of human health risk associated with pesticide residues on fresh produce. The case studies presented demonstrate the ongoing need for surveillance and health risk evaluation of pesticide residues on agricultural commodities. This integrated program serves as a model for other regulatory entities seeking to protect public health through science-based enforcement.

Z. Weng, V. Singh, M. Weng, and T. Preble. Clarkstown High School South, West Nyack, NY.

Background and Purpose: Existing models for evaluating lung cancer risk associated with cigarette smoke typically depend on epidemiological data or a limited range of toxicity endpoints. These approaches may not adequately account for cumulative risks arising from extended exposure to multiple carcinogens, such as "Cohort of Concern" (CoC) substances, which are known to pose elevated cancer risks even at low concentrations. There is a need for a more comprehensive framework that incorporates mutagenicity, carcinogenic potency, and duration of exposure. This study was designed to develop and implement such a model for identifying CoCs among cigarette smoke constituents and quantifying the corresponding lung cancer risk. **Methods:** A risk assessment framework using data from the CPDB and LCDB was developed. Carcinogenic potency was quantified by calculating the Cancer Risk Specific Dose (CRSD) from the TD_{50} (tumorigenic dose rate 50%). Substances with a CRSD < 0.025 $\mu\text{g/kg/day}$ were classified into the CoC. Mutagenicity was assessed via Ames test data. The relationship between carcinogenic potency and acute toxicity was analyzed using the metric $\text{Log}(0.5/TD_{50})+7$. A theoretical mutational model was applied to estimate lung cancer risk (P), factoring in the mutation slope of key chemicals, the number of driver gene mutations required ($k=7$), and stem cell division frequency (d). This model, $P=1-(1-(1-(3E-06*(1+\text{mutation slope})))^d)^k)^8*1.5E+07$, was used to evaluate the risk contribution of major cigarette smoke constituents: Benzo[a]pyrene (B(a)P), NNK, NNN, acrolein, and nicotine. **Results:** B(a)P, NNK, and NNN were identified as potent CoC substances due to their low TD_{50} values (0.1-1.8 mg/kg/day), resulting in CRSDs below the 0.025 $\mu\text{g/kg/day}$ cutoff threshold, and their strong positive Ames test results. In contrast, acrolein and nicotine were excluded from the CoC; acrolein due to a lack of a definitive TD_{50} and weak mutagenicity, and nicotine due to the absence of a TD_{50} and a negative Ames test. Application of the mutational model demonstrated that exposure to the CoC substances (B(a)P, NNK, NNN) leads to a substantial increase in cumulative risk. The model estimated a **10- to 25-fold increase in lifetime lung cancer risk** for individuals smoking one cigarette per day compared to one pack per day, after one year of continuous exposure. **Conclusions:** This study establishes a multi-parameter framework that integrates carcinogenic potency, mutagenicity, and exposure duration to refine lung cancer risk assessment from cigarette smoke. By moving beyond traditional models, this approach provides a more mechanistic basis for risk quantification and highlights the significant risk posed by prolonged exposure to a potent Cohort of Concern, even at low daily intake levels.

PS 3323 Comprehensive Toxicological Evaluation of a Novel E-Vapor Product Using a Multi-Tiered Risk Assessment Framework

F. Gravino, F. Zanetti, F. Vonmoos, S. Majeed, E. Gottardo, A. Stucky, P. Pratte, and D. Sciuscio. Philip Morris International, Neuchâtel, Switzerland.

Background and Purpose: Understanding the toxicological profile of electronic nicotine delivery systems (ENDS) is essential for evaluating their potential health risks. This study presents a structured toxicological risk assessment of a new close-pod ENDS that utilizes a novel induction-heating technology (VEEV inPRIME™, Philip Morris Products S.A., Neuchâtel). **Methods:** All flavor and base e-liquid ingredients met food or pharmaceutical grade quality. Their inclusion levels were evaluated based on regulatory requirements and a rigorous toxicological risk assessment, outlined in the four-step human health risk assessment process of the United States Environmental Protection Agency. Any potential leachable compounds from the device's components that might come into contact with the e-liquid or aerosol were evaluated under exaggerated temperature and pH conditions using extractable analysis. Analytical techniques included gas chromatography-mass spectrometry (GC-MS) for semi-volatiles, liquid chromatography-mass spectrometry for non-volatiles, and headspace GC-MS for volatile compound detection. In addition, a stability study has been conducted up to the e-liquid shelf life to assess whether or not any new hazards emerge over time. Aerosol chemical analysis focused on ENDS aerosols' performance analytes (e.g., propylene glycol, glycerol, and nicotine) and included the measurement of the 39 harmful and potentially harmful constituents (HPHCs) listed by the World Health Organization (WHO) in their *Report on the Scientific Basis of Tobacco Product Regulation*. Droplet size distribution (DSD) was measured using cascade impactor and laser diffraction methods that aimed to assess aerosol respirability. *In vitro* toxicological testing, comprising the Water-Soluble Tetrazolium 8 (WST-8) assay, the Ames test, and the micronucleus assay, were conducted in accordance with internationally accepted guidelines, comparing the e-vapor aerosol fractions to reference cigarette smoke fractions. Notably, the studies employed two distinct puff collection patterns to account for potential variability in aerosol generation over the full pod lifetime. This approach enables the puffs collected at the beginning, middle, or end of a pod to be assessed separately, as some ENDS may generate higher HPHC levels towards the pod's end, a factor that can influence the toxicological profile of the aerosol fractions. **Results:** The results demonstrate that all e-liquid ingredients were deemed toxicologically acceptable at their intended use levels, indicating low concern for consumer safety under the evaluated conditions. The device materials were found to be toxicologically acceptable, with no concerning chemical leaching observed under exaggerated usage condi-

tions or over the e-liquid shelf-life. Additionally, the aerosol produced by the product contained undetectable or below-quantifiable levels of all 39 HPHCs listed by the WHO, resulting in an average reduction of more than 99% compared to cigarette smoke for 9 representative HPHCs. DSD measurements highlighted that the aerosol emitted is within the respirable range, and no significant differences in DSD were identified compared to other benchmark ENDS products. *In vitro* studies showed that, under the conditions of the tests, the aerosol fractions exhibited no mutagenic, genotoxic, or cytotoxic effects under either puffing collection patterns. On the contrary, cigarette smoke fractions induced cytotoxicity and positive responses in the micronucleus and Ames tests. **Conclusions:** In summary, the applied risk assessment approach robustly substantiated the safety profile of the e-liquid formulations, device materials, and the collected aerosol of this novel ENDS, suggesting that the product is a better alternative for adult smokers who do not wish to quit nicotine use.

PS 3324 Mode of action and human relevance assessment for diisononyl phthalate (DINP)-induced liver tumors in rodents

A. N. Buerger¹, M. M. Heintz², L. C. Haws³, H. Nyambogo⁴, C. M. Palermo⁵, and C. M. Thompson³. ¹ToxStrategies LLC, Cincinnati, OH; ²ToxStrategies LLC, Asheville, NC; ³ToxStrategies LLC, Katy, TX; ⁴ExonMobil Biomedical Sciences, Spring, TX; and ⁵ExonMobil Biomedical Sciences, Annandale, NJ.

Background and Purpose: Diisononyl phthalate (DINP) is a high molecular weight phthalate widely used as a plasticizer in flexible PVC products. Chronic bioassays have indicated that DINP induces liver tumors in mice and rats. Rodent liver tumors are hypothesized to occur via the rodent-specific peroxisome proliferator-activated receptor alpha (PPARα)-activator mode of action (MOA). PPARα activation is the first and only key event shared across species; the downstream biological responses leading to tumor formation are widely considered to be unique to rodents and not relevant to humans. To further inform whether rodent liver tumors observed following DINP exposure are occurring through the rodent-specific PPARα MOA, a comprehensive assessment of the evidence base for DINP was conducted. **Methods:** The animal and human evidence base for DINP was evaluated in the context of the key events (KEs) and associative events outlined in a published MOA framework for PPARα activator-induced rodent hepatocarcinogenesis. The PPARα MOA for rodent liver tumors includes four KEs: (KE1) PPARα Activation, (KE2) Alteration of Cell Growth Pathways, (KE3) Perturbation of Cell Growth and Survival, and (KE4) Clonal Expansion. First, the weight of the evidence (WoE) for each KE and liver tumors (the adverse outcome [AO]) was evaluated for DINP and its metabolites. Next, the human relevance of this MOA and the potential for alternative MOAs for DINP-induced liver tumors were critically examined. The analysis incorporated aspects of the modified Bradford Hill Criteria and characterization of data gaps and uncertainties. Studies from the peer-reviewed literature and unpublished laboratory reports related to DINP and liver carcinogenesis were first identified from existing authoritative assessments of DINP, followed by literature searches in PubMed to identify literature pertaining to DINP, its metabolites and each KE and potential alternative MOAs. **Results:** WoE for KEs 1 and 3 and the AO strongly support the PPARα MOA for rodent liver tumors. Although limited data were available to inform KEs 2 and 4, these events can be reasonably inferred given the strong evidence for the other KEs and AO. Regarding alternative MOAs for liver tumors, evidence for genotoxicity and the aryl hydrocarbon receptor were not supported. DINP activation of PPARγ and constitutive androstane receptor/pregnane X receptor were weakly supported based on limited *in vitro* studies. Evidence possibly consistent with cytotoxicity (e.g., elevated serum liver enzymes and focal necrosis) occur at later timepoints and at higher DINP doses than those that elicit PPARα activation—indicating they are likely secondary to the PPARα MOA. Rodent liver tumors resulting from a PPARα MOA are generally regarded by the scientific community to lack human relevance. Comparative data from human and non-rodent mammalian models indicate decreased sensitivity and responsiveness to DINP and its metabolite MINP compared to rodents. Limited data for humans (*in vitro*) and monkeys (*in vivo*) suggest perturbation of cell growth and survival is not elicited by DINP or its metabolite. Further, no evidence was identified regarding DINP exposure and liver cancer in humans. Collectively, DINP-specific evidence supports a lack of human relevance for this MOA. **Conclusions:** Overall, the WoE for DINP strongly supports that the liver tumors observed in rodents following DINP exposure are occurring via the rodent-specific PPARα MOA. Moreover, based on quantitative and qualitative species differences in KEs of this MOA, the WoE indicates liver tumors observed in rodents following DINP exposure are likely not relevant to humans.

PS 3325 A Reassessment of Chronic Kidney Inflammation as the Critical Effect for Dimethyl Terephthalate

M. Lewis, M. Weng, S. Wu, X. Dai, E. Rufer, R. F. Shulfer, and M. Kamberi. Abbott Laboratories, Saint Paul, MN.

Background and Purpose: Dimethyl terephthalate (DMT) is primarily used as a monomer in the production of polyethylene terephthalate which is widely used in medical devices. Kidney related effects after exposure to DMT have been identified as the critical effect through multiple reviews and reports. Metabolism of DMT to terephthalic acid (TPA) is a crucial step in the adverse outcome pathway of DMT.

Previous studies have reported kidney inflammation in female rats at doses of 125 mg/kg/d, while similar findings in mice lacked statistical significance. The U.S. EPA's 1989 IRIS assessment identified a LOAEL of 125 mg/kg/d for DMT, and Ball et al. (2011) derived a BMDL₁₀ of 148 mg/kg/d. Ball et al. suggested that the highest doses administered in the NCI (1979) study may have been insufficient to saturate urine with TPA, yet high enough to initiate an inflammatory response in renal tissue. Dai et al. (2005) further demonstrated sediment and precipitate formation associated with TPA, reinforcing the need to consider urinary chemistry in evaluating nephrotoxicity. Additional factors such as retrograde nephropathy, rodent-specific susceptibility to chronic progressive nephropathy (CPN), alpha-2u-globulin accumulation in male rats, and infectious disease influences complicate interpretation of kidney effects. CPN, a spontaneous and age-related disease of rodents, may be exacerbated by chemical administration and is a confounding factor in the interpretation of renal findings. Given the complexity of kidney effects observed across *in vivo* studies, further scrutiny of the critical effect is warranted. **Methods:** Considerations for risk assessment under ISO 10993-17:2023 framework are explored for these substances. We reviewed chronic kidney inflammation incidence data from 7 NTP studies on various chemicals cohoused with DMT to evaluate dose-response and trends. Chronic toxicity studies with known inducers of urolithiasis were reviewed for kidney related effects. Critical effects for different chemicals across the NTP cohoused studies were compared with those of DMT. Alternative PODs were proposed based on mechanistic plausibility and threshold considerations. **Results:** An increasing trend of chronic kidney inflammation was observed in female rats for 5 other substances studied concurrently with DMT by NTP. Male rats showed a high background incidence rate of chronic kidney inflammation across all studies likely attributable to alpha-2u-globulin. TPA and melamine showed increased incidence of chronic kidney inflammation compared to DMT as well as observed uroliths. Route specific metabolic differences after exposure to DMT are based on hydrolysis to TPA in the GI tract after oral exposure and a lack of first-pass metabolism and a slower esterase driven hydrolysis in the plasma/tissues after parenteral exposure contributes to differing urine chemistry dynamics which is critical to understanding potential kidney related effects. Further interspecies differences of rodent susceptibility to calculus formation, and sensitivity of human infants also warrant careful consideration within medical device risk assessment and application of uncertainty factors. If possible, re-examination of kidney histopathology from NTP would offer additional certainty over proper identification of chronic kidney inflammation in the cohoused studies. An alternative POD of decreased body weight observed across multiple studies may be relevant depending on exposure route and patient population. **Conclusions:** Selection of decreased body weight gains from a subchronic rat study can be justified as the critical POD. Preliminary analysis suggests that chronic kidney inflammation may represent a secondary effect linked to urinary chemistry rather than a primary toxicodynamic response. Rodents are more sensitive to urinary chemistry effects based on propensity to crystal formation and higher protein concentration. Reexamination of kidney histopathology from previous NTP studies could offer more confidence in interpretation of kidney related effects. Pathogenic infections cannot be ruled out as a factor in incidence of chronic kidney inflammation in the cohoused NTP studies. Threshold-based approaches incorporating urinary saturation data and considering crystal formation conditions could provide a more biologically relevant POD for DMT, reducing uncertainty in medical device safety evaluations.

PS 3326 Safety evaluation of hair straightening products containing glyoxylic acid with respect to formaldehyde release and oxalic acid formation

R. Justiniano¹, J. Diller², A. Fuchs², R. Fautz², N. Hewitt³, C. Schmidt⁴, S. Langhoff⁴, C. Goebel⁵, K. Schwarz⁶, K. Bluemlein⁶, and G. von Bölcsházy⁴. ¹Wella Company, Calabasas, CA; ²Kao Germany GmbH, Darmstadt, Germany; ³SWS, Erzhausen, Germany; ⁴Wella Company, Darmstadt, Germany; ⁵BBCGTox, Mörfelden-Walldorf, Germany; and ⁶Fraunhofer Institute for Toxicology and Experimental Medicine ITEM, Hannover, Germany.

Background and Purpose: Human health concerns due to heat-activated hair straightening product (HSP) use are debated as the active ingredient, glyoxylic acid (GA), is argued to cause acute kidney injury (AKI) via oxalic acid (OA) crystal formation. Furthermore, heat-decomposition to formaldehyde (FA) might expose users to airborne FA. This study evaluates FA and OA exposure from GA-based HSPs under realistic and worst-case use scenarios to assess consumer and stylist safety.

Methods: Airborne FA was measured using a realistic simulation test in a non-ventilated 15 m³ room. The HSP ($\pm$ GA) was applied to a mannequin head and the hair straightened using a flat iron (230°C). Air concentrations of FA were measured in the breathing zones of the stylist, mannequin head, and in the far field zone on the floor. FA concentrations were also measured following HSP treatment to mannequin heads or consumers in 2 salons. Stylist exposure to GA was measured in a realistic salon simulation test. Hand rinsing and sampling were performed prior to HSP treatment, after HSP application and rinse-off, and after flat ironing. Skin absorption of GA was assessed under realistic application conditions (20 mg/cm² HSP containing 16% GA, 20 min exposure), but also after unrealistic excessive HSP use (increased exposure duration or application amount) to investigate systemic exposure. The highest absorbed amount was used in a PBPK model to estimate the OA excretion after HSP application. Endogenous GA and OA levels were measured in skin from 4 donors. HSP safety was assessed by comparing (a) the OA systemic exposure of the consumer and stylist after HSP use with that from endogenous and dietary sources

and (b) OA urine levels after worst-case HSP use with those linked to normal endogenous and dietary sources, plus levels above which there is a risk of AKI. **Results:** FA air exposure ranged from 3.1 - 12.3 $\mu\text{g}/\text{m}^3$ for GA-containing HSP and 2.3 $\mu\text{g}/\text{m}^3$ for the placebo. In one salon, the background level reached 37 $\mu\text{g}/\text{m}^3$. Maximum levels measured in 2 additional salons following HSP treatment were 2-61 $\mu\text{g}/\text{m}^3$. All levels are below FA exposure limits: 120 $\mu\text{g}/\text{m}^3$ (ACGIH) and 100 $\mu\text{g}/\text{m}^3$ (WHO indoor air quality). The mean total (external) GA exposure of stylists was 7.72 mg. Most of the HSP was washed off post-exposure (20 min to 3 h) in skin absorption studies. The max bioavailable amount remaining was $17.2 \pm 22.9 \mu\text{g}/\text{cm}^2$ (10% GA with 3 h exposure) representing a worst-case extreme use condition since the HSP is applied to the hair, not the scalp. The total bioavailable amount of GA after application of the realistic HSP treatment (16% with 20 min exposure) was $5.22 \pm 2.39 \mu\text{g equiv.}/\text{cm}^2$ or max 4.41 mg for HSP applied to 580 cm² scalp. This is below endogenous OA levels in the skin ($18.7 \pm 5.1 \mu\text{g}/\text{cm}^2$ or max 381 mg in 16000 cm² total skin surface area, GA was not detected in skin). Assuming 25% of GA is metabolized to OA, the estimated systemic exposure is 0.0145 mg for stylist (3 applications/day) and 1.1 mg for consumers (single use). In comparison, dietary (10-25 mg/day) and endogenous sources (ascorbic acid, GA, glycine metabolism; 12-20 mg/day) contribute 22-45 mg/day which is 20-41 times higher than consumer exposure and >1500-times more than daily stylist exposure. Skin absorption of GA under worst-case conditions (10% GA with 3 h exposure) equates to a systemic exposure of 2326 mg GA. Using this input in a PBPK model (validated using *in vivo* data), the estimated OA renal excretion was 3.46 mg/day (bolus) and 3.42 mg/day (3 h infusion; equivalent to 3 h topical application). These amounts are much lower than the urinary excretion of 18 mg/day based on a high OA diet and the 40 mg/day threshold associated with AKI risk. **Conclusions:** This HSP safety assessment demonstrates that the release of FA under realistic use conditions is well below regulatory exposure limits. Systemic exposure to OA from HSP use is negligible compared to other sources, as well as endogenous levels in skin. Therefore, GA-based HSPs are concluded safe for consumers and stylists.

PS 3327 Incorporating Climatic Relevance Endpoints into GreenScreen for Safer Chemicals Assessments

J. Y. Tanir, J. Rutkiewicz, B. Wang, and M. H. Whittaker. ToxServices LLC, Washington, DC.

Background and Purpose: Clean Product Action's GreenScreen® for Safer Chemicals hazard assessment methodology specifies the evaluation of 18 human health, environmental, and physical hazard endpoints, and assigns an overall benchmark (BM) score of 1-4, with 1 being most hazardous and 4 being least. This project expanded the hazard framework to incorporate two climatic relevant endpoints: ozone depletion potential (ODP) and global warming potential (GWP). The United Nations' Globally Harmonized System of Classification and Labelling of Chemicals (GHS) defines ODP as "the ratio of integrated perturbations to total ozone, for a differential mass emission of a particular compound relative to an equal emission of CFC-11." According to the U.S. Environmental Protection Agency, GWP "is a measure of how much energy the emissions of 1 ton of a gas will absorb over a given period of time, relative to the emissions of 1 ton of carbon dioxide (CO₂). The larger the GWP, the more that a given gas warms the Earth compared to CO₂ over that time period. The time period usually used for GWPs is 100 years." There is precedence for including climatic potential endpoints in chemical hazard assessment tools, such as Cradle to Cradle Certified®'s Material Health Assessment Methodology and ChemFORWARD. These two endpoints would broaden and strengthen GreenScreen® assessments by identifying chemicals that are less hazardous and more sustainable. **Methods:** Chemicals screened for their ODP and 100-yr GWP would use measured or predicted values to assess its climatic potential endpoints. Definitions for Low (L), Moderate (M), High (H), and Data Gap (DG) are proposed. Like other endpoints in a GreenScreen® assessment, the confidence level is designated as high or low. The proposed GreenScreen® ODP criteria are defined as Low: ODP equal to zero or chemical is non-volatile (i.e., BP >250°C or Vapor Pressure <0.1 mm Hg at 20°C) or chemical is solid; High: ODP greater than 0 and/or GHS Category 1 for ODP; or Data Gap: Insufficient data for ODP. The proposed GreenScreen® GWP criteria are defined as Low: 100-yr GWP equal to zero or chemical is non-volatile or chemical is solid; Moderate: 100-yr GWP greater than zero and less than or equal to 10; High: 100-yr GWP greater than 10; or Data Gap: Insufficient data for GWP. For a chemical with a high hazard for ODP or GWP, the overall benchmark score is proposed to be BM-1. The presence of a data gap for ODP and/or GWP would not count toward the data gap rules in a GreenScreen® assessment. **Results:** Ten chemicals (6 BM-2 and 4 BM-1) with existing GreenScreen® assessments were assessed for ODP and GWP hazards, using publicly available ODP and GWP values and were scored following the proposed criteria. Following the proposed criteria, BM scores for five out of the 10 chemicals would change from BM-2 to BM-1, indicating a high hazard. One of these chemicals, 1,1,2,2-tetrafluoroethyl-2,2,2-trifluoroethyl ether (CAS #406-78-0), is currently listed on the TCO Certified Accepted Substances List with a BM-2 score. This illustrates a shortfall in the current GreenScreen® methodology for not considering this chemical's high 100-yr GWP value of over 900 and the chemical's potential impact on climate change. One of the BM-2 chemicals has an unchanged BM score due to data gaps. Of the four BM-1 chemicals, two would receive an additional subscore of BM 1f proposed for denoting the high climatic relevance endpoints, highlighting their potentially high impacts on climate change. **Conclusions:** This pilot project demonstrates that the addition of the ODP and GWP endpoints can have a differentiating impact on a chemical's GreenScreen® benchmark score. Additionally, basing climatic relevant

criteria on GWP or ODP values ensures that the latest science and measurements are utilized compared to checking a list that may represent outdated information. Methyl bromide (CAS #74-83-9) is the only chemical of the 10 chemicals assessed that has a GHS category 1 ozone depletion classification (H-420: Harms public health and the environment by destroying ozone in the upper atmosphere) and the only chemical listed in the Montreal Protocol annexes of ozone depleting substances. The addition of climate potential expands GreenScreen® beyond the traditional human health and environmental toxicology realm and extends the assessment paradigm into planetary health and sustainability endpoints.

PS 3328 Demonstrating the difference between hazard and risk: The relevance of high-dose experimental animal study results to real-world fragrance exposure in consumers

K. Joshi¹, A. Bartlett¹, W. Dekant², I. Sipes³, G. Eisenbrand⁴, and A. Api¹. ¹Research Institute For Fragrance Materials (RIFM), Mahwah, NJ; ²University of Würzburg, Würzburg, Germany; ³University of Arizona, Tucson, AZ; and ⁴University of Kaiserslautern, Heidelberg, Germany.

Background and Purpose: Fragrance safety is very important to consumers and the industries that produce or use fragrances in their products. Since 1966, risk assessment of fragrances has been carried out by a dependable scientific infrastructure that works in full transparency at Research Institute for Fragrance Materials (RIFM). For a risk assessment, exposure and toxicity data are necessary. Risk assessment of fragrances and their constituents for systemic toxicity has been partly based on studies in rodents which were conducted historically or were required for regulatory purposes. Rodents were exposed to discrete fragrances to determine the highest dose level not associated with an adverse effect (no observed adverse effect level or NOAEL). To achieve this, fragrances are experimentally applied up to dose levels largely exceeding the minute levels of real-life exposure in people. The huge spread between the high-dose experimental exposure and real-life consumer exposure is a concept familiar to toxicologists but may be unfamiliar to the typical fragrance consumer. Here, a common fragrance will serve to demonstrate this concept. p-Cymene is a fragrance and flavoring found naturally in raspberries. To demonstrate that the real-life risk of inducing an adverse effect due to fragrance exposure is extremely low, two exposure scenarios were selected. First, exposure through food consumption and second, exposure through use of fragrance/fragranced products. In more detail we ask how many raspberries a person would need to consume to get an adverse effect from p-cymene ingestion, disregarding any potential effect of nutritional imbalances. Second, aggregate exposure to a perfume (or fine fragrances) by humans is calculated to match the dose level associated with an adverse effect seen in animal studies. **Methods:** The most conservative NOAEL of p-cymene from animal studies was identified after evaluating all OECD- and/or GLP-compliant repeated dose/ reproductive toxicity studies, to select the dose associated with an adverse effect. A robust OECD 422 study, which is a combined repeated dose and reproduction/developmental toxicity screening test in rats was selected, showing adverse effects at a dose of 100 mg/kg/day. A human equivalent dose (HED) calculation using an allometric exponent for body surface area (0.67, to account for the difference in metabolic rate between rats and humans), was applied to convert the adverse effect dose into a human equivalent dose. The amount of p-cymene in a raspberry was taken from VCF (Volatile compounds in food) database and reliable research articles. For exposure through use of fragrances, aggregate fragrance exposure the Creme-RIFM Aggregate Exposure model was utilized. The model explores usage data from tens of thousands of consumers in North America, Europe, and Asia and provides realistic exposure estimates that consider all fragrances the population is exposed to across all consumer products that are used. **Results:** Adverse effects at 100 mg/kg/day of p-cymene translated into a HED of 830 mg/day. Further, based on reliable literature and databases, it was determined that raspberries contain a mean of 0.0027 mg of p-cymene. Therefore, following human equivalent dose (HED) calculations and amount of p-cymene in raspberries, a person would need to ingest approximately 307,407 raspberries/day in order to match the adverse effect level seen in animals. For fragrance use, a content of 0.0022% of p-cymene in perfumes based on the 95th percentile (which is exposures from the highest users) values were estimated from the Creme-RIFM Aggregate Exposure model. It turned out that it would take 3722 sprays/day (equivalent to 3 L or 0.8 gal) to match the dose level associated with adverse effects in animal studies. **Conclusions:** In conclusion, the selected exposure scenarios highlight the essential importance of taking real life exposure into account to arrive at a realistic human risk assessment. Exposure science has evolved considerably, and results of high dose animal studies need to be put into perspective with real life consumer exposure. The selected exposure scenarios exemplify and underline the minute health risk associated with fragrance use.

PS 3329 Probabilistic cancer risk assessment associated with implantable medical devices: A case study

M. Weng, X. Dai, E. Rufer, S. Wu, M. Lewis, R. F. Shulfer, and M. Kamberi. Abbott Laboratories, St. Paul, MN.

Background and Purpose: This case study aims to evaluate the lifetime cancer risk associated with residual formaldehyde in medical devices using a probabilistic risk assessment method. Under the ISO 10993 guidance framework, by integrating chemical release data, toxicological thresholds, and probabilistic modeling on cancer risk, the case study demonstrates a more comprehensive risk assessment framework that accounts for implantation duration in relationship to cancer risk. Formaldehyde may be used to preserve biological tissues used in medical devices. Some formaldehyde may remain on or inside the devices after the tissues have been processed. When these devices are implanted in the body, the remaining formaldehyde can leach into nearby tissues, which may result in long-term exposure. This hypothetical case study demonstrates how route and duration of exposure can be integrated to conduct a probabilistic cancer risk assessment. **Methods:** To assess chronic exposure risk, calculations will follow ISO 10993-17: 2023, which provides a framework for determining the cancer risk specific dose (CRSD). CRSD is derived from the TD₅₀ value and normalized with 50,000, which is based on a hypothetical lifetime cancer risk of 1 in 100,000. The Maximum Estimated Exposure Dose (EEDmax) will then be compared to CRSD to determine the Margin of Safety (MOS), where MOS > 1 indicates a negligible carcinogenic concern. For a more refined risk characterization, a probabilistic cancer risk model was applied based on the publication by Abbott (Weng et al., *Regulatory Toxicology and Pharmacology*, 2026, Vol 164, 105976, ISSN: 0273-2300). This model allows estimation cancer risk during the duration of implantation over time. **Results:** McClurg et al. (1996) published a case study of bioprosthetic heart valves treated with formaldehyde initially absorbed about 770-800 nmole/mg dry weight, decreasing to roughly 370 nmole/mg after 16 weeks. Assuming proper washing before clinical use, the residual formaldehyde on the heart valve would likely be around 8 mg remaining within the implanted valves. When only worst-case exposure assumptions are made, the MOS overestimates the risk. To further evaluate cancer risk under clinical use conditions, a probabilistic cancer risk model was applied. The formaldehyde mutation slope of 0.49, determined by Ames assay, was used to evaluate implantation duration versus cancer potency over time. As a result, during the first 20 years of implantation, the probabilistic cancer risk was found to be 2.8 per 10,000,000, indicating that the potential cancer risk is 36-fold lower than the default hypothetical threshold of cancer risk of 1 in 100,000 recommended via ISO 10993-17: 2023. Therefore, the cancer risk for the duration this medical device is likely to be used poses a negligible carcinogenic risk. **Conclusions:** This case study shows that formaldehyde leaching from preserved implanted biological tissue poses a minimal carcinogenic risk when the totality of evidence is considered. It demonstrates how a comprehensive, multi-parameter framework that evaluates cancer potential throughout the lifetime of the device to draw realistic conclusions by combining scientific evidence with regulatory principles to improve the risk assessment in medical devices.

PS 3330 Is it actually dirty? A Probabilistic Risk Assessment of the EWG's Dirty Dozen

I. T. Engel, E. M. Martin, M. Berg, and A. Costa. CTEH, North Little Rock, AR.

Background and Purpose: Consumers often face mixed messages about the safety of the foods they eat. Each year, the Environmental Working Group (EWG) releases a widely circulated report ranking 47 commonly consumed fruits and vegetables based on their levels of pesticide residues. The 12 with the greatest pesticide contamination are designated the "Dirty Dozen." This list is intended to help consumers reduce potential exposure to harmful pesticides. However, guides such as the EWG's only incorporate hazard-based assessments and do not consider exposure assessments - and ultimately risk- during their publication. As such, this study aims to apply human health risk assessment methodologies to the EWG's Dirty Dozen list, utilizing a probabilistic screening-level framework to estimate pesticide exposure among U.S. consumers and assess potential chronic health risks. **Methods:** For each item on the 2025 Dirty Dozen list, the most frequently detected pesticides and its corresponding residue concentrations were obtained from the USDA Pesticide Data Program (PDP). Using the EPA Exposure Factor Handbook (EFH) and National Health and Nutrition Examination Survey (NHANES) consumption distributions were developed for adults and children separately. Next, dietary exposures were calculated for each pesticide-produce combination. These distributions were then compared to the population adjusted dose (PAD) distribution from EPA Office of Pesticide Programs. The distribution for the PAD was defined as a distribution centered on the PAD value with a one order of magnitude SD, per EPA's definition of a reference dose. **Results:** Our results indicated that the estimated chronic exposures were well below levels of concern for the population. We additionally calculated cumulative measures of exposures to multiple contaminants and found these to also be below the level of concern. Lastly, we calculated the quantities of produce required to reach potentially harmful exposure levels and demonstrate that these values far exceed normal consumption based on the distributions provided by EPA, even for children. **Conclusions:** In conclusion, we present a dietary risk assessment for the EWG's "Dirty Dozen" that demonstrates exposure does not exceed levels of concern based upon consumption patterns in the US.

A. Shakya, and M. Stevens. TRC Strategic Health Sciences, Jackson, WY.

Background and Purpose: During the past decade, engineered stone fabrication has become the focus of renewed concern regarding respirable crystalline silica (RCS) exposure and silicosis risk. Several reports have suggested that engineered stone dust exhibits enhanced toxicity due to its finer particle size distribution, higher surface area, and/or resin and metal content, and that conventional exposure limits may be inadequate. Claims have also been made that standard engineering controls are ineffective. This study sought to evaluate the scientific foundation of these claims and determine whether engineered stone warrants a distinct toxicological or regulatory category. **Methods:** A non-systematic review of peer-reviewed publications, governmental assessments, and field exposure investigations during engineered stone fabrication was conducted. Emphasis was placed on toxicological studies comparing particle morphology, surface chemistry, and dose-response relationships across materials, as well as industrial hygiene data evaluating the effectiveness of wet methods, local exhaust ventilation, and respiratory protection. Regulatory evaluations by OSHA, NIOSH, and international agencies were reviewed to contextualize findings within current occupational standards. **Results:** Both quartz, the predominant silica polymorph in natural stone, and cristobalite, present at higher concentrations in some engineered stones, exhibit comparable dose-response relationships for silicosis. A review of current literature, supported by particle characterization studies, suggests that RCS particle size distributions from engineered stone do not materially differ from those generated during natural stone processing when fabrication techniques are equivalent. Dry cutting of both engineered and natural stones yields finer particles than wet methods. No convincing evidence shows that differences in surface area, zeta potential, or resin content translate into increased potency (relative to airborne RCS concentration), specifically for silicosis. Air monitoring data show that RCS concentrations during dry cutting and polishing of high-silica engineered stone (80% by volume or 90% by weight) can exceed OSHA's permissible exposure limit by several orders of magnitude, but similar exposures have been documented in granite (20-60% silica by volume or weight). Exposure assessment data indicate that low-silica content stone like marble (<5%) can generate RCS above the PEL if manipulated under improper controls, particularly during dry cutting without local exhaust ventilation (LEV) or respirators. Conversely, when wet methods, LEV, and proper housekeeping are employed, airborne RCS concentrations are reduced by 80-99%, often achieving levels below 0.05 mg/m³. Respirators with Assigned Protection Factors of 10 or greater provide an additional margin of safety for residual exposures. Clusters of silicosis among engineered stone workers consistently correspond to dry fabrication and inadequate control, not intrinsic material properties. Legal and administrative reviews confirm that existing federal and state standards already require multilingual training, exposure monitoring, and effective use of controls. Field data from California and Washington indicate noncompliance, particularly lack of fit testing and inconsistent use of wet cutting, is the primary cause of overexposures. Evidence from community-based training programs shows immigrant and limited-English-proficiency workers can be successfully trained when materials are accessible and culturally appropriate. **Conclusions:** Toxicological and epidemiological evidence does not support classification of engineered stone as a unique or unusually hazardous source of RCS. The presence of disease is best determined by cumulative RCS exposure, not material composition. Rather, observed silicosis cases reflect lapses in exposure control, training, and enforcement, not limitations of the current regulatory framework. The weight of evidence affirms that existing occupational standards, when implemented through established industrial hygiene practices, are sufficient to protect workers. Continued emphasis on compliance verification, multilingual worker education, and sustained engineering control performance remains the most effective means of preventing silica-related disease across all industries handling RCS.

PS 3332 Conditional Knockdown of USP22 Reveals Target Liability in Adult Mice

S. Zhu¹, V. Bhaskaran¹, J. Zhang¹, S. Rex-Rabe¹, S. Wagh², J. Price¹, S. Moore¹, and K. Augustine¹. ¹Bristol-Myers Squibb Company, Lawrenceville, NJ; and ²Bristol-Myers Squibb Company, Cambridge, MA.

Background and Purpose: USP22 is a histone deubiquitinating enzyme within the SAGA complex, implicated in oncogenesis and physiological functions. Complete USP22 knockout in mice results in preweaning lethality, while heterozygotes display dysregulations of immune and hematopoietic systems, abnormal gait. Reduced USP22 expression has been associated with sporadic cerebral cavernous malformation. To better characterize potential toxicological liabilities associated with USP22 loss-of-function, we employed an inducible USP22 knockout mouse model. **Methods:** 12-16-week-old, male and female mice underwent tamoxifen-induced USP22 knockdown. The mice were monitored over 6 months via clinical observation, body weight, clinical pathology, flow cytometry, serum cytokine release profile, antinuclear antibody detection, histopathology, and Magnetic Resonance Imaging (MRI) assessment of central nervous system (CNS). **Results:** USP22 protein levels were reduced by 90% in peripheral tissues. The knockout mice presented no obvious adverse clinical observations, but the male mice exhibited reduced body weight gain during the study. Serum cytokine profile revealed a progressive increase of pro-inflammatory mole-

cules (IFN γ , IL-2, IL-4, IL-5), with marked elevations at six months. By six months, the mice presented elevations in globulin (male 30%, female 50%), alkaline phosphatase (male 50%, female 34%), and triglycerides (male 26%, female 62%), and anti-dsDNA autoantibody levels were also significantly elevated, particularly in females. Flow cytometry confirmed a mild but insignificant increase in T cell population in both sexes and a significant rise in B cell population in females. Additionally, peripheral blood hematology suggested potential impact to the erythropoietic compartment of the bone marrow, including altered red blood cell parameters and reduced hemoglobin indicative of anemia without regenerative response (decreased reticulocytes) and thrombopenia (lower platelet counts with larger sizes). Histopathological findings included an increase of lymphocytes in mesenteric lymph node and increase of hypertrophy/hyperplasia of goblet cells in gastrointestinal tissues indicating immune-mediated pathological changes in the intestinal tract. Due to limited tamoxifen exposure in brain, only ~50% knockdown was achieved. There were not histological abnormalities identified in the brain and spinal cord, but MRI analysis detected modest but significant (5%; p0.05) total brain volume reduction in male knockdown mice. **Conclusions:** Inducible USP22 knockdown mice presented toxicities indicative of inflammation, immune dysregulation with potential autoimmunity, goblet cell hyperplasia and proliferation in the intestinal track and alteration of the erythroid compartment leading to anemia and thrombopenia. Additional studies will be needed to better understand the role of USP22 in the central nervous system and the implications of reduced brain volume in male mice.

PS 3333 The delay in the completion of vaginal opening induced by Epyrifenacil is a secondary effect caused by prepubertal anemia.

M. Izumi, Y. Hosokawa, M. Shimada, M. Matsumoto, S. Sugaya, K. Ogata, K. Iwashita, R. Matsuyama, S. Fukunaga, and H. Asano. Sumitomo Chemical Co., Ltd., Osaka, Japan. Sponsor: S. Sugaya, Japanese Society of Toxicology

Background and Purpose: Epyrifenacil is a novel uracil protoporphyrinogen oxidase (PPO) inhibiting herbicide developed by Sumitomo Chemical Co., Ltd. In a two-generation reproductive toxicity study of Epyrifenacil in rats, a delay in the completion of vaginal opening (VO), an indicator of sexual differentiation in female rats, was observed. While VO can be influenced by chemicals with endocrine-disrupting (ED) properties, it is also known to vary due to secondary factors such as growth retardation or stress. In this study, no changes were observed in other ED-related parameters, including anogenital distance and estrous cycle, or in body weight during prepubertal period. Furthermore, results from a series of *in vitro* assays (luciferase reporter gene, steroidogenesis, and aromatase assays) did not indicate any ED-related activity. To elucidate the mechanism underlying the delayed VO, we investigated the relationship between anemia, the only apparent systemic toxicity observed, and the completion of VO. **Methods:** Anemia was induced in juvenile female Crl:CD(SD) rats by drawing a certain amount of blood from the jugular vein (Experiment I) or by intraperitoneal administration of phenylhydrazine (PHZ), a well-known inducer of hemolytic anemia (Experiment II). Experiment I: Postnatal day (PND) 15 pups were randomly assigned to each group (control, two blood removal (BR) and satellite groups) based on body weight. In the BR groups, 1.0% or 1.5% of body weight of blood was drawn every 2 days from PND 16 and 28. Experiment II: PND 17 pups were divided into 3 groups (PHZ 10 mg/kg/day, PHZ 20 mg/kg/day, and vehicle control) in the same manner as Experiment I. PHZ was intraperitoneally administered to pups on PNDs 18 and 19. To monitor hematological parameters, blood was also drawn on PND 35 and PND 57 or 58 in the BR and satellite groups (Experiment I) and on PNDs 20, 24, 28, 35, 42, and 56 (Experiment II). Parameters assessed included clinical signs, body weight, food consumption, hematology, observation of VO, necropsy, organ weights (ovaries and uterus), and histopathological examinations (ovaries, uterus, vagina). **Results:** Both BR and PHZ treatment groups showed transient anemia characterized by a significant decrease in hemoglobin levels (approximately 20-35%) compared to the control group. Despite the presence of anemia, there were no noticeable changes in the body weight of these female rats on each postnatal day, indicating that their growth was comparable to that of the control group. Additionally, the anemia did not impact the weights or tissue structure (histopathology) of the reproductive organs after sexual differentiation. However, the age at VO was delayed in the anemic rats compared to the control group. Furthermore, these anemic rats had a higher body weight at the time of VO compared to the control group. These results imply that anemia in prepubertal females could be a contributing factor in delaying puberty. **Conclusions:** Epyrifenacil consistently induces anemia through PPO inhibition in mammalian toxicity studies; yet neither *in vivo* nor *in vitro* data indicate ED-related activity. In the two-generation reproductive toxicity study of Epyrifenacil in rats, and among the ED-related endpoints, only the delay in VO completion (accompanied by increased body weight at VO) was noted, which was associated with more severe anemia than those observed in BR and PHZ treatment groups. Taken together with these results and the weight of evidence, we concluded that the delay in the completion of VO following Epyrifenacil exposure was a secondary effect due to prepubertal anemia and not related to endocrine-disrupting effects.

X. Guo, Z. Nie, Y. Zhao, M. Shi, Z. Cui, Q. Xia, and T. Bing. ICE Bioscience, Beijing, China. Sponsor: T. Bing, American Association for Cancer Research

Background and Purpose: In drug discovery, proactive toxicological risk assessment of candidate compounds is crucial for avoiding clinical-stage failure and post-market withdrawal. However, traditional preclinical safety evaluation strategies have significant limitations: *in vivo* animal studies exhibit low human relevance (translatability) due to significant species differences and face dual pressures of ethics and cost; while conventional *in vitro* binding assays are inadequate for predicting functional biological effects. Notably, approximately 75% of clinical adverse drug reactions (ADRs) originate from dose-dependent off-target effects, highlighting an urgent need for more accurate early-risk identification tools. To address these challenges, the IQ DruSafe consortium—a preeminent alliance of global pharmaceutical companies—has championed the enhancement of preclinical predictive power through the expansion and refinement of secondary pharmacology screening strategies. This study is aligned with this initiative and aims to investigate the implementation of an advanced *in vitro* secondary pharmacology screening system utilizing functional assay formats. By generating richer pharmacological information beyond mere binding affinity, this strategy seeks to enable a more accurate and earlier identification of potential safety liabilities, thereby providing highly translatable safety insights for the optimization of lead compounds. **Methods:** This study adopted a high-throughput screening strategy integrating multiple functional assay technologies (including FLIPR calcium flux, HTRF, ADP-Glo, FP, etc.). The strategy included two modes: single-point primary screening and multi-concentration dose-response curve screening. To achieve high throughput and high precision, the platform integrated automated instruments (such as acoustic liquid handling systems and multi-mode plate readers) to perform curve-based screening tests. We applied this strategy to test the dose-response effects of various antidepressants, pergolide, and osimertinib on a panel covering 77 important safety-related targets. **Results:** The results indicated that this screening strategy can reveal differentiated off-target risk profiles. Testing the antidepressants amitriptyline, citalopram, and bupropion from different generations using the ICSTP SAFETYPANEL™ 77 successfully quantified their off-target interaction risks. The results showed that amitriptyline exhibited off-target activity and strong inhibitory effects on 22 safety-related targets (15 GPCRs, 4 ion channels, 3 transporters); citalopram had 6 off-target interactions (3 GPCRs, 1 ion channel, 1 transporter, 1 nuclear receptor target); while bupropion had the cleanest off-target profile, with activity only at the DAT target, which is its primary target. These findings are highly consistent with their known clinical safety profiles. Furthermore, the dose-response screening mode based on functional assays provided significant advantages, such as effectively differentiating full agonists from partial agonists and identifying complex non-linear biological effects. Multi-concentration testing helped avoid false positive or false negative misjudgments caused by compound solubility limitations or aggregation tendencies. The use of 1 mM ATP concentration in all kinase target assays, a condition closer to the physiological state, improved the predictive accuracy for *in vivo* inhibitory potency. The integration of automated processes significantly increased sample throughput and detection efficiency. **Conclusions:** This study confirms that a secondary pharmacology screening strategy utilizing functional assay formats, multi-concentration dose-response curves, and integrated automation can provide more comprehensive and predictive data for drug safety assessment. This strategy helps identify and mitigate potential safety risks mediated by off-target effects early in compound optimization, thereby improving the success rate and cost-effectiveness of new drug development and promoting the development of safer and more effective drugs.

PS 3335 Pragmatic Modification of Systematic Evidence Map Scope in Support of the ATSDR Toxicological Profiles Program

S. Tariq¹, M. Riccardi¹, K. Zaccaria¹, F. Atif², G. Casillas², and F. Scinicariello². ¹SRC, Liverpool, NY; and ²The Agency for Toxic Substances and Disease Registry (ATSDR), Office of Innovation and Analytics (OIA), Atlanta, GA.

Background and Purpose: The Agency of Toxic Substances and Disease Registry (ATSDR) has recently adopted systematic review methodology into the review of substances under consideration for toxicological profile update or development via incorporation of interactive systematic evidence maps (SEM). SEMs are preferable to previously conducted internal chemical evaluations due to their transparency, repeatability, and resulting publicly accessible interactive databases of health effects studies. However, conducting SEMs proved to be challenging while maintaining schedules and adhering to budgetary constraints. This became especially apparent when the Populations, Exposures, Comparators, and Outcomes (PECO) eligibility criteria developed for the pilot SEM (methylene chloride) was applied to data-rich compounds, resulting in a cumbersome number of studies selected for retrieval and/or data extraction. Therefore, additional compound-specific exclusion criteria were developed to manage scope, narrowing the focus to the intended goal: identifying studies that could potentially impact minimal risk levels (MRLs; i.e., low-exposure studies) and/or filled data gaps identified in profiles. Here, we present two case studies illustrating how ATSDR developed fit-for-purpose modifications to ATSDR's SEM protocol to manage scope for two data rich compounds: carbon tetrachloride (CCl₄) and toluene. **Methods:** Due to the high volume of selected studies, a re-review of

included studies at the title/abstract and full-text stage was conducted to determine if there was a specific study type (or types) that was being included by the pilot PECO criteria that would be uninformative for the intended purpose of the SEM. For CCl₄, it was determined that studies that administered a known toxic dose with the intent to amend (ameliorate or exacerbate) hepatotoxicity and studies that used CCl₄ as a model of toxicity or positive control should be excluded. The rationale for exclusion was 1) studies are uninformative for hazard identification (evaluating a known target of CCl₄ toxicity), and 2) studies are uninformative for low dose extrapolation (evaluating known toxic doses). For toluene, due to a robust epidemiological database, it was determined that only human studies containing quantitative reporting and analysis of measured toluene exposure levels were adequate for data extraction. Therefore, studies that lacked quantitative exposure data, estimated exposure using a job-exposure matrix, or only presented a combined analysis of benzene-toluene-ethylbenzene-xylene (BTEX) exposure were excluded. Case study reports were also excluded. **Results:** Of the initial 11,805 references identified in the literature search for CCl₄, 7,387 studies were excluded as studies designed to amend (ameliorate or exacerbate) the known hepatotoxic effects and 989 studies were excluded as model of toxicity/positive control studies. Together, those study types represented 71% of the studies returned in the literature search. Excluding these studies dramatically narrowed the scope of the SEM to the highly relevant 24 studies identified for data extraction. For toluene, of the initial 5,448 references, 57 case reports, 35 human studies lacking adequate exposure data, and 57 human studies reporting only BTEX analyses were excluded. Exclusion of these studies reduced human data extraction by 62%, from 241 to 92 studies. **Conclusions:** For both CCl₄ and toluene, narrowing the scope of the SEM to the most relevant study types by adding compound-specific exclusion criteria to the PECO criteria saved an extreme amount of effort and resources. By focusing on the intended goal of the project, the systematic review approach can be designed to be fit-for-purpose in order to manage the timeline and budget while still developing a transparent, repeatable, and useful SEM product. **Disclaimer:** The findings and conclusions in this presentation have not been formally disseminated by the Centers for Disease Control and Prevention/ATSDR and should not be construed to represent any agency determination or policy.

PS 3336 Systematic Evidence Map for CCl₄ and Interactive Visualization

F. Atif¹, G. Casillas¹, F. Scinicariello¹, N. Roney¹, M. Riccardi², and K. Zaccaria². ¹The Agency for Toxic Substances and Disease Registry (ATSDR), Office of Innovation and Analytics (OIA), Atlanta, GA; and ²SRC, Liverpool, NY.

Background and Purpose: The Agency of Toxic Substances and Disease Registry (ATSDR) has recently adopted systematic review methodology into the review of substances under consideration for toxicological profile updates or development via incorporation of interactive systematic evidence maps (SEM). SEMs are preferable to previously conducted internal chemical evaluations due to their transparency, repeatability, and resulting publicly accessible interactive databases of health effects studies. The carbon tetrachloride (CCl₄) profile, published in 2005, was selected for application of the SEM. **Methods:** Two independent screeners conducted title and abstract screening of the search results in DistillerSR for references that met the PECO eligibility criteria. References included at title and abstract screening were retrieved and full-text review was conducted by two independent screeners in DistillerSR to confirm PECO relevance. At both title/abstract and full-text review, screening conflicts were resolved by discussion between the primary screeners, with consultation by a third screener (if needed) to resolve any remaining disagreements. It was determined that studies that administered a known toxic dose with the intent to amend (ameliorate or exacerbate) hepatotoxicity and studies that used CCl₄ as a model of toxicity or positive control should be excluded. The rationale for exclusion was 1) studies are uninformative for hazard identification (evaluating a known target of CCl₄ toxicity), and 2) studies are uninformative for low dose extrapolation (evaluating known toxic doses). References that were categorized as PECO-relevant health effects studies in humans and animals advanced to high-level data extraction in DistillerSR. Results of the Literature Screen and Data Extraction were exported into Tableau Public to generate interactive data visualizations. **Results:** Of the initial 11,805 references identified in the literature search for CCl₄, 7,387 studies were excluded as studies designed to amend (ameliorate or exacerbate) the known hepatotoxic effects, and 989 studies were excluded as model of toxicity/positive control studies. Together, those study types represented 71% of the studies returned in the literature search. The literature screening identified 9 human and 15 animal health effects studies. A majority of human studies were chronic-duration, and most animal studies were acute-duration. 100% of the human studies evaluated exposure via biomarkers, so exposure was attributed to multiple/unknown exposure routes. 49% (33) of animal studies focused on the inhalation route and 51% (34) focused on the oral route. The most-studied endpoints in inhalation studies included death, body weight, respiratory, hepatic, and renal. Findings from human and animal studies are consistent with the existing Toxicological Profile for CCl₄ (2005): 1) The hepatic and renal systems are toxicity targets of CCl₄; 2) There is some evidence for respiratory effects in humans and animals; 3) Animal studies generally report effects in cancer studies, but findings from human studies are mixed; and 4) The evidence for effects in other organ systems is mixed. **Conclusions:** The 2025 CCl₄ SEM identified toxic endpoints consistent with the most recent toxicological profile from 2005. The interactive data visualization of these data created in Tableau can be accessed via links in the published SEM available on the ATSDR web page (SYSTEMATIC EVIDENCE MAP (SEM) FOR CARBON TETRACHLORIDE). **Disclaimer:** The findings and conclusions

PS 3337 Dosimetry Refinement for Tiered Screening Human Health Risk Assessment: A Case Study

L. M. Sweeney^{1,2}, T. J. LaLonde^{3,2}, A. J. Keebaugh^{1,2}, and R. A. Clewell^{4,2}. ¹BlueHalo, Wright Patterson AFB, OH; ²US Air Force Research Laboratory, Wright Patterson AFB, OH; ³Henry M. Jackson Foundation for the Advancement of Military Medicine, Inc, Wright Patterson AFB, OH; and ⁴EIS, Inc., Wright Patterson AFB, OH.

Background and Purpose: Military operations frequently involve exposure to chemicals for which suitable health-based exposure limits are often lacking. Human health risk consults to support operational decision-making require quick identification of any serious toxicological concerns. A case study was conducted to demonstrate a modernized, tiered approach to prospective derivation of health-based screening values (HSVs), with a focus on *in vitro* New Approach Methods (NAMs) of varying complexity. Derivation of HSVs from *in vitro* toxicity data, a process known as *in vitro* to *in vivo* extrapolation (IVIVE), is typically performed with highly simplified toxicokinetic models in early stages of a tiered approach. Comparing toxicokinetic models of varying conservatism and complexity provides additional opportunities to refine the prospective risk assessments as envisioned for the individual levels of a tiered approach. **Methods:** This case study used seven chemicals with existing *in vitro* and *in vivo* toxicity information (malathion, malaoxon, diazinon, diazoxon, aldicarb, chlorobenzene, and tris (2-chloroethyl) phosphate). These substances were amenable to high throughput toxicokinetic modeling using the "high throughput toxicokinetics (httk)" R package (based on a conservative, generic model) and had existing "bespoke" (custom or semi-generic) human physiologically based pharmacokinetic models. **Results:** We found that differences in model structure (notably, presence or absence of extrahepatic metabolism), central tendency parameter values, and parameter value distribution assumptions contributed to differences in IVIVE results between httk and the bespoke models. Typically, when httk-based IVIVE was used for this limited suite of substances, HSVs were substantially lower than when bespoke models were used (as much as 64,000-fold in these case studies). **Conclusions:** Substances for which metabolism was the primary route of clearance (rather than elimination unchanged in urine) were especially prone to have highly conservative HSVs when the httk models were used, as would typically be expected in early stages of a tiered assessment of a novel substance. In particular, features such as the potential for extrahepatic metabolism should be considered when interpreting the predictions from generic pharmacokinetic models. No Department of Defense endorsement implied.

PS 3338 Evaluating New Chemicals Under the Toxic Substances Control Act (TSCA): Application of US EPA's ChemInformatics Modules for Identification of Information for Human Health Risk Assessment

K. Schumacher¹, R. Brunner², E. Marques³, K. Salazar⁴, T. M. Martin², and A. J. Williams². ¹US EPA, Lenexa, KS; ²US EPA, Research Triangle Park, NC; ³US EPA, Narragansett, RI; and ⁴US EPA, Washington, DC.

Background and Purpose: US Environmental Protection Agency's Office of Pollution Prevention and Toxics, New Chemicals Division (NCD) is responsible for conducting human health and environmental risk assessments for new chemical substances submitted under the Toxic Substances Control Act (TSCA) prior to their entry into US commerce. Typically, limited to no toxicological information is available for submitted new chemical substances. To address data gaps, a read-across approach using similar chemicals with acceptable test data is frequently employed for hazard identification and selection of toxicity values for quantitative risk assessment. The ChemInformatics Modules (CIM), developed by US EPA, is a publicly available web-based platform that provides a centralized location for chemical information (e.g., physicochemical properties, hazard and safety data, structural alerts) typically used in a new chemical human health risk assessment, which includes information from federal, state, and international sources. CIM integrates search functions for structure, substructure, and similarity. This poster presents the framework used by NCD to incorporate systematic use of CIM into read-across assessments for new chemical substances. **Methods:** NCD has developed a framework leveraging CIM to facilitate identification of analogues for which publicly available toxicological test data are available, as well as chemical category information for read-across that provides coverage of the hazard endpoints and toxicity value needs of a NCD human health risk assessment for a new chemical substance. The search strategy is iterative and includes both hierarchical analogue searches and analogue/chemical category exploration approaches with visualization of available toxicological information for hazard coverage. Standardized reports are generated that present the curated information in a user-friendly format for hazard assessment and toxicity value selection. **Results:** Systematic use of CIM by NCD human health assessors, in accordance with the newly developed framework, has led to more standardized identification of relevant toxicological information from publicly available sources to address data gaps in hazard identification and toxicity value selection. This has improved the

efficiency, consistency, and transparency of human health risk assessments for new chemical substances. The framework will also provide a resource for stakeholders preparing new chemical submissions to US EPA under TSCA. **Conclusions:** Application of a newly developed hierarchical framework incorporating systematic use of CIM in read-across assessment has improved the efficiency, consistency, and transparency of NCD human health risk assessments for new chemical substances submitted under TSCA. *These views are those of the authors and do not reflect views or policies of US EPA.*

PS 3339 Skip to Recipe: the importance of food disaggregation in performing lifestage-specific dietary exposure assessments

D. Hoer¹, A. Niman², and C. Tan¹. ¹US EPA, RTP, NC; and ²US EPA, Washington, DC.

Background and Purpose: Characterizing dietary exposure is a critical part of the risk assessment for chemicals that are intentionally added to or are unintentionally present in a nation's food system (e.g., food additives, contaminants, pesticide residues, etc.). In the USA, nationally representative food consumption data is available from the What We Eat in America (WWEIA) survey, which is the dietary intake portion of the National Health and Nutrition Examination Survey. WWEIA contains data from two non-consecutive days of 24-hour dietary recall, where many of the consumed foods being reported are mixed dishes (e.g., cracker, cake). However, in many cases, the concentration information that would inform chemical exposure (e.g., pesticide residue data) is collected on the constituent parts of these foods (i.e., wheat flour, sugarcane sugar). Thus, a reliable means to disaggregate mixed foods into food commodity ingredients provides a critical link between dietary recall information and accurate exposure assessments. The objective of this study is to characterize how these recipes used to disaggregate mixed foods can impact consumption estimates and to demonstrate the importance of understanding the implications of recipe assumptions when characterizing lifestage-specific sensitivities. **Methods:** To examine the impact of recipes on dietary exposure assessment, consumption estimates were generated for the approximately 1000 unique ingredients using two unique databases to break down the mixed foods reported in the WWEIA surveys: the US Environmental Protection Agency's Food Commodity Intake Database (FCID) and the US Food and Drug Administration's (FDA) Food Disaggregation Database (FDD). This required methodically translating ingredients utilized in FDD to an identical or analogous item in FCID to ensure the same nomenclature was used across datasets. The translation was performed from FDD to FCID because the latter consistently provided more granularity, and further disaggregation of FDD could be more reliably and consistently performed than reaggregation of FCID ingredients. Thus, the result of this translation was frequently an increase in the granularity of FDA's disaggregation by using existing FCID recipes to extend those in FDD. Once translation was complete, the recipe databases were used to generate bodyweight-normalized, per capita commodity consumption estimates for dietary intake data from the 2005-2010 WWEIA surveys. These consumption estimates were then evaluated to identify areas of divergence. **Results:** The consumption estimates were largely similar for the 2005-2010 WWEIA surveys, regardless of whether the recipes from the translated version of FDD or FCID was used for mixed food disaggregation. This indicated that corresponding exposure assessments would likely be robust across the whole of the surveyed population. However, the FCID recipes include numerous ingredients in very small amounts to account for various plausible preparations of a given food. These commodities introduce low volume consumers to FCID-generated consumption estimates that are almost entirely absent from those generated with FDD. Likewise, FDD does not include specificity for ingredients in baby foods, which may reduce lifestage-specificity if data are available for ingredients within that specific production chain. Given that infants and young children may be a sensitive subpopulation, this represents a critical divergence and one that would warrant consideration in cases where exposure is being evaluated on commodities that are heavily utilized in baby food or infant formula. **Conclusions:** A database of recipes for disaggregating mixed foods is a critical component of dietary exposure assessments, particularly for chemicals that are measured in or added to the constituent ingredients. Because of their translational use, the assumptions made at the various levels of recipe development will have downstream impacts on consumption estimates and exposure. It is therefore critical that the recipes themselves are readily available for review and evaluation, but it is similarly important that the underlying assumptions are transparently characterized and that the impact of recipes on exposure is assessed during development and testing. Likewise, a consensus approach to recipe development has the potential to introduce greater precision in dietary exposure assessment, particularly in a regulatory context.

PS 3340 Application of the Threshold of Toxicological Concern (TTC) to Evaluate New Chemicals under the Toxic Substances Control Act (TSCA)

K. Salazar, R. Brunner, and M. Feshuk. US EPA, Washington, DC.

Background and Purpose: The US Environmental Protection Agency (EPA) is responsible for conducting human health and environmental risk assessments for new chemicals submitted under the Toxic Substances Control Act (TSCA) prior to their entry into US commerce. For every new chemical submission, EPA must make

an affirmative finding on the safety of the new chemical substance. There are no minimum data requirements for a new chemical submission, so human health risk assessments typically employ a number of approaches to fill data gaps such as *in silico* predictions, read-across from analogues, and chemical categorizations. For some chemistries, these methods may not provide sufficient information to derive a point of departure (POD) to quantify risk. The Threshold of Toxicological Concern (TTC) method provides a conservative estimate of human exposure limits for chemicals with limited toxicological data, ensuring minimal risk to human health at or below specific exposure thresholds. The proposed TTC approach addresses a type of new chemical submission, known as Low Volume Exemptions (LVEs) under TSCA, for chemicals characterized by low production volumes, a limited number of use sites, and short review periods (30 days). Building upon recognized practices from the U.S. EPA Office of Pesticide Programs, U.S. Food and Drug Administration, European Food Safety Authority, and Health Canada, use of the TTC approach in new chemical review offers an alternative method for risk determination for chemical submissions with limited exposures and no quantitative data. **Methods:** The proposed framework contains a decision tree and step by step instructions to facilitate rapid and consistent evaluation. The framework begins by evaluating whether the new chemical substance lacks sufficient information to quantify oral routes of exposure based on read-across from analogues or chemical category. Next, if the substance's structure is defined, a decision tree framework is applied, considering chemical class (e.g., inorganic metals, high-toxicity substances, or endocrine disruptors) and predicted bioaccumulative properties to exclude substances from the TTC approach. Cramer classification is determined using the OECD QSAR Toolbox. Combining this information with the predicted genotoxicity potential, an oral POD can then be determined with uncertainty factors (interspecies and intraspecies) included to account for variability. **Results:** This approach has been applied to several LVE new chemical submissions since May 2025. By adapting a well-established framework to fit within the constraints of an LVE submission process, this TTC approach helps quickly identify chemicals that can be reliably assessed using a threshold method. By comparing the TTC value with the exposure estimates, EPA can quantify potential risks of the new chemical substance when analogue data lack sufficient quantitative information. The process increases efficiency for LVE reviews, where more complete toxicological testing may not be warranted if TTC thresholds remain protective. **Conclusions:** Implementing a TTC-based workflow for LVE risk assessments can expedite decision-making and reduce testing burdens without compromising public health objectives. By systematically determining whether a chemical meets established criteria (e.g., known structure, non-excluded category, low exposure potential), regulators can apply transparent, consistent, and science-based thresholds. This approach supports the goals of minimizing animal testing while providing clear, and protective benchmarks for risk assessment. *These views are those of the authors and do not reflect views or policies of US EPA.*

PS 3341 A Human Health Risk Assessment Approach for Evaluating Carbon Nanotubes under the Toxic Substances Control Act (TSCA)

E. Mutlu¹, R. Beardslee², Y. Chen², E. Marques³, K. Salazar², and R. Brunner¹. ¹US EPA, RTP, NC; ²US EPA, Washington, DC; and ³US EPA, Narragansett, RI.

Background and Purpose: The U.S. Environmental Protection Agency (EPA), Office of Pollution Prevention and Toxics (OPPT), New Chemicals Division (NCD) is responsible for conducting human health and environmental risk assessments for new chemical substances submitted under the Toxic Substances Control Act (TSCA) prior to their entry into U.S. commerce. In recent years, there has been an increase in carbon nanotube (CNT) new chemical submissions with high production volume, largely due to their potential use in electric vehicle batteries. Each new CNT has unique morphology and may contain metal impurities which are residual catalysts introduced during CNT production. CNT materials may contain a single layer or multiple layers of graphene. These nanomaterials exhibit high thermal and electrical conductivity, high surface area, and low density, and may differ in number of CNT walls, diameter, length, and agglomerate type. These properties may impact the toxicity of the CNT with respect to human health. CNT-related hazards potentially include respiratory effects, carcinogenicity, eye irritation, genetic toxicity, immunotoxicity, and/or cardiotoxicity. Moreover, metal impurities, (e.g., cobalt and nickel) introduce additional hazards that must be considered during risk assessment. Because TSCA does not mandate a minimum dataset for new chemical submissions, many CNT filings lack adequate case-specific data to address these potential hazards. The approach described here aims to deliver a more efficient, standardized framework for hazard characterization, deriving points of departure (PODs), and risk characterization. **Methods:** The human health risk assessment approach for CNTs includes both standard and fit-for-purpose hazard language based on percent content of specific metals within the new chemical submission. For each route of exposure, there are multiple candidates for CNTs and the individual metals available for POD selection. The criterion for each POD is dependent, in part, on the morphology of the CNT, for inhalation (tangled- vs. straight-type) or oral and dermal exposures (single- vs. multi-walled). Additional metal-specific PODs are considered depending on the percent of metal impurities in the CNT material. This approach for CNT inhalation exposure ensures consistent selection of the following risk calculation parameters: 1) Average Daily Dose (ADD) to reflect need to protect for chronic inflammation in the lungs, and 2) selection of a respirable fraction exposure value, if available, as local lung hazards are dependent on respirability. **Results:** EPA has received multiple CNT material

submissions since October 2023 that cumulatively represent over 400,000 kg/year of CNT materials that would enter US commerce. The application of this approach has resulted in decreased time to complete human health assessment of new CNT material submissions under TSCA. Notably, this approach also includes a POD for the assessment of tangled-type CNT, a component of the approach requested by stakeholders, that EPA also considers protective for cancer following inhalation exposures. **Conclusions:** This approach provides a more clear, consistent, and efficient method to identify hazards, select points of departure, and assess risks for a carbon nanotube submitted under TSCA, that considers both the submitted CNT dimensions and metal content. As additional toxicological information becomes available in this emerging chemical space, this approach will be updated as needed to stay up to date with the latest science. These views are those of the authors and do not reflect views or policies of the U.S. EPA or other respective organizations.

PS 3342 Utilizing Toxicokinetic and Mode of Action Information to Evaluate the Human Relevance of Ovarian Toxicity Data for 1,3-Butadiene

K. Jacobs, A. Sasidharan, A. Huang, and S. Healy. US EPA, Washington, DC.

Background and Purpose: 1,3-butadiene is a widely used industrial chemical associated with various adverse health effects, including cancer. 1,3-butadiene was designated by EPA as a high priority substance subject to risk evaluation in 2019 under the Toxic Substances Control Act (TSCA) and EPA finalized the risk evaluation in 2025. Prior assessments from EPA and other organizations had previously identified ovarian atrophy (observed in mice) as the most sensitive health effect. However, there is increasing evidence that ovarian toxicity may be a mouse-specific health effect. 1,3-Butadiene has a well-characterized metabolic pathway in rodents that demonstrates significant species-specific differences; exposure biomarkers indicate that overall oxidative metabolism is significantly higher in mice compared to rats or humans, resulting in much higher internal levels of the reactive 1,2,3,4-diepoxybutane (DEB) metabolite in mice. Given the evidence and DEB's proposed causal role in ovarian atrophy, in accordance with TSCA's requirements to consider the best available science, EPA re-examined whether ovarian toxicity represents the most appropriate critical effect for characterizing human hazard from repeated-dose exposure to 1,3-butadiene. **Methods:** To support EPA's Risk Evaluation for 1,3-Butadiene under the Toxic Substances Control Act, information on 1,3-butadiene toxicokinetics and mechanistic data for each endpoint were evaluated to determine whether species differences inform the human relevance of these non-cancer endpoints. EPA first considered published assessments for 1,3-butadiene including those by ATSDR, EPA Integrated Risk Information System (IRIS), California Environmental Protection Agency (CalEPA), and Texas Commission on Environmental Quality (TCEQ). EPA also conducted systematic review of the available literature in 2019 that was supplemented with newer information either provided to the Agency through public comments or otherwise identified by the Agency, with a focus on toxicokinetic and mechanistic information relevant to ovarian toxicity. EPA integrated the evidence from all of these sources to evaluate the mechanistic basis for the observed effects in each species (i.e., rats, mice, and humans). This process included comparing mechanistic and toxicokinetic evidence across species, analyzing whether a mode of action (MOA) could be established, and considering whether the mode of action was species-specific. EPA then determined whether the effects were quantitatively relevant to humans using the International Programme on Chemical Safety framework for analyzing the relevance of a noncancer mode of action for humans (IPCS, 2008). **Results:** Ovarian toxicity, observed exclusively in mice, acts through a well-defined MOA based primarily on the bifunctional metabolite DEB. While specific estimates of metabolite levels are variable, increased oxidative metabolism in mice and greater hydrolysis rates in rats and humans results in DEB levels up to two orders of magnitude greater in mice compared to rats and humans, respectively. Additionally, evidence on 1,3-butadiene and an analog suggests that mice are more toxicodynamically sensitive than rats to similar doses of epoxide metabolites. **Conclusions:** Therefore, EPA determined that while physiological, mechanistic, and toxicokinetic pathways are all qualitatively similar across species, the hazard values for ovarian atrophy in mice cannot be extrapolated to humans with reasonable certainty and it is not an appropriate endpoint for use in human health risk assessment.

PS 3342a Mechanistic In Silico Model of Global and Local Reactivity to Predict Ready Biodegradation in Small Molecules

D. P. Garnica Acevedo, and J. Kostal. The George Washington University, Washington, DC.

Background and Purpose: Readily biodegradable (RB) compounds degrade rapidly under aerobic conditions, typically within 28 or 10 days in standardized assays (OECD 301 and 302, respectively), indicating low environmental persistence. In regulatory risk assessments, RB substances do not undergo further testing, while non-RB classifications require additional evaluation, as they do not inherently indicate persistence. Computational models have emerged as complementary tools to enable rapid screening of large libraries, identifying potentially non-RB chemicals while accounting for physicochemical and mechanistic factors in microbial degradation. Although Structure-Activity Relationships (SARs) exist for predicting

biodegradation, current models have key limitations such as biases towards non-RB predictions; limited structural diversity in training data; and descriptors lacking mechanistic interpretability, impacting accuracy. To address this, the goal was to develop a Random Forest (RF) algorithm to classify compounds as RB or non-RB based on descriptors more closely aligned with the biodegradation process. This approach estimates degradation potential using curated 3D representations of neutral species with known classifications as inputs for QM/MM/MC simulations and linear-response (LR) calculations in aqueous solution; and a physics-based framework using Density Functional Theory (DFT) to capture molecular response to electron-density flux via frontier molecular orbital theory (FMOT) and an atomistic approach integrating FMOT with the Fukui function. **Methods:** Solute-solvent energetics for 919 molecules (460 RB and 459 non-RB) were computed using QM/MM/MC simulations in water and propane. Representative ground-state conformations were extracted from ensemble averages and saved as PDB files for further analysis. Physicochemical and pharmacokinetic properties were calculated via linear response methods and a rapid prediction tool. DFT optimizations and single-point calculations were performed using the mPW1PW91 functional with the MIDIX+ basis set. Atomistic charges, used to evaluate the Fukui index across atomistic positions, were performed with the Hirshfeld and natural population analyses (NPA). A binary decision tree classifier was developed using Random Forest (RF) with nested 5×3 cross-validation, combining global and site-specific SARs to emulate enzyme oxidation/reduction with a physics-oriented model based on DFT. RF models were saved as pickle files for reuse and distribution. **Results:** The Fukui f^+ and f^- indices were computed as local reactivity descriptors, indicating the propensity of atoms to accept or donate electron density and thereby identifying potential sites of nucleophilic or electrophilic attack. These descriptors, derived from QM/MM/MC simulations and DFT calculations, provide a mechanistic framework linking oxidation potential and molecular stability to biodegradation formed the computational basis of the predictive model, with a balanced test accuracy of 71% from a decision tree model based on Electron Affinity, HOMO-LUMO Gap, Electrophilicity Index, and solute-solvent interactions described by Coulombic and Lennard-Jones terms. **Conclusions:** A robust model can be developed using global and local electrophilic/nucleophilic susceptibilities to estimate RB potential more accurately than existing SAR tools by quantifying molecular response to electron-density flux, a proxy for redox processes in Phase I/II transformations *in vivo*. Descriptors related to electron loss, such as HOMO energy and localized Fukui indices (f^+ , f^-), are particularly relevant as they capture oxidation processes, which are critical because biodegradation often begins with electron withdrawal from electron-rich sites. Global descriptors like softness, chemical potential, and electrophilicity provide key indicators of susceptibility to electron transfer, while solvent accessibility descriptors such as localized surface area or volume ensure vulnerable sites are sterically accessible to enzymatic nucleophiles.

PS 3343 A New Approach Methodology (NAM) Based Workflow to Address Systemic Toxicity for Chemicals Including Fragrance Materials

S. Donthamsetty, X. Huang, D. Sancho, and G. Ladics. International Flavors and Fragrances, Hazlet, NJ.

Background and Purpose: With increasing global restrictions on animal testing, New Approach Methodologies (NAMs) have gained traction for chemical safety assessment. While NAMs are effective for acute endpoints like skin and eye irritation, their application to systemic toxicity—requiring whole-organism context—remains limited. The European Partnership for Alternative Approaches (EPAA) recently started the NAM designation challenge which is a research exercise aiming to develop an appropriate risk management action based on the level of concern (high, medium and low) for systemic toxicity for chemicals based on NAM's. This study explores a NAM-based hazard classification system for chemicals, including fragrances, aiming to assign a level of concern (high, medium, low) based on toxicodynamic and toxicokinetic data. A secondary goal was to evaluate High-throughput Transcriptomics (HTTr) as a standalone assay for broad biological screening. **Methods:** A hazard classification system was developed using DNEL/ADI/RfD values for ~150 chemicals. The system categorizes chemicals into low, medium, and high concern. Low concern implies unrestricted use, medium requires refinement, and high concern indicates a need for risk management. An IVIVE workflow was built using HTTK PBPK models and ToxCast assay data to calculate Equivalent Administered Dose (EAD), which informs the concern level. Separately, HTTr using HepaRG cells was tested as a standalone bioactivity assay, integrated with PBPK modeling, and compared to ToxCast data. **Results:** Case studies showed >80% accuracy in predicting concern levels for industrial and fragrance chemicals. The workflow also performed well for unknown chemicals. HTTr results showed >95% concordance with ToxCast data, supporting its use as a standalone tool. **Conclusions:** This NAM-based workflow effectively categorizes chemicals by systemic toxicity concern level. HTTr shows promise as a standalone assay. The approach offers a screening-level assessment and a foundation for future NAM-based safety evaluations.

PS 3344 Modernizing Inhalation Testing and Assessment: Bridging Exposure Modeling with Regulatory Acceptance

M. M. Hargrove, A. Pecquet, T. Ramanarayanan, and A. Goetz. Syngenta, Greensboro, NC.

Background and Purpose: Evaluation of inhalation toxicity is a requirement in the regulation of agrochemicals by both state and federal government. New approach methodologies (NAMs) including *in vitro* and *in silico* methods are being utilized to assess inhalation (IHL) safety and to determine relevant human endpoints without the use of animals. Syngenta recently developed a decision framework, which incorporated US EPA's risk-based waiver guidance with NAMs to replace 28/90-day IHL toxicity studies. This framework was applied to a case study active ingredient (AI) and combined with exposure modelling in a weight of evidence assessment (WoE) to demonstrate a low level of concern via the IHL route. **Methods:** An IHL hazard assessment was conducted using a combination of *in vitro* data (MucilAir), *in vivo* acute IHL toxicity data, *in vivo* 5-day IHL tolerability studies, and comparative TK/PBK modeling, to identify the potential for IHL toxicity. Exposure was modeled using human occupational IHL exposures from the US EPA exposure activity worksheet, then forward dosimetry was used to generate a margin of exposure from the identified hazard data. **Results:** MucilAir and *in vivo* data demonstrated no concern for IHL portal of entry effects. PBK modeling predicted highest systemic exposure would occur from oral routes, which were adequately assessed in the toxicity database. Worst-case occupational IHL exposure of 5.2×10^{-3} mg/kg-day was estimated for handheld application to greenhouse crops, with standard PPE. This exposure was converted to an animal equivalent internal exposure using rat body weight and minute volume, resulting in the animal equivalent IHL exposure of ~0.02 mg/m³. In comparison to the IHL database, the margins of exposure were ~5000-fold, demonstrating no concern for IHL toxicity at the worst-case occupational exposure. Further, a NOAEC threshold of 2 mg/m³ passed for risk assessment and is below the minimum concentration that would be used in a 28-day IHL study. **Conclusions:** This case study utilized a WoE approach incorporating PBK modelling, *in vitro* and *in vivo* toxicity data, and reverse dosimetry to identify low IHL risk from the proposed uses of a case study AI. Using an exposure threshold approach, conducting further animal IHL toxicity studies would not provide any additional information to change the risk assessment conclusions, and would be an unnecessary use of animals. Currently, the implementation of these framework approaches and gaining regulatory acceptance remains at a crossroad.

PS 3345 Identification of functional amino acids in a tricellular tight junction modulator, angubindin-1

S. Kimura, T. Kuzu, Y. Niwa, and M. Kondoh. the University of Osaka, Suita, Japan.

Background and Purpose: The growing prevalence of central nervous system (CNS) disorders highlights the urgent need for new therapies. However, CNS drug development is severely hampered by the blood-brain barrier (BBB). While a major role of the BBB is to safeguard the CNS by preventing harmful or toxic substances from entering the brain, this protective function also limits the penetration of therapeutic agents into the CNS. Thus, the successful development of CNS therapeutics depends on strategies that enable efficient BBB translocation. At the same time, because BBB opening or dysfunction is implicated in CNS pathology, rigorous safety and efficacy evaluations are essential when attempting to cross or modulate the BBB. To overcome this barrier, our approach focuses on the modulation of tight junctions (TJs) between cerebral endothelial cells. TJs comprise two architectural subtypes: bicellular TJs (bTJs) formed at the contacts between two cells, and tricellular TJs (tTJs) formed where three cells meet. Although we have developed and evaluated more than ten TJ modulators, most of our modulators act on bTJs, and only one modulator, angubindin-1, specifically targets tTJs. However, angubindin-1 exhibits insufficient selectivity, binding not only to angulin-1 but also to angulin-3. In this study, we identified the essential amino acids of angubindin-1 that bind to angulins in order to improve binding specificity, reduce toxicity risk, and support the development of safer BBB-modulating therapeutics. **Methods:** We predicted the specific amino acids of angubindin-1 that bind to angulins by comparing the binding component of *Clostridium difficile* transferase (CDTb), which was reported to bind angulin-1 (Nat Microbiol, 2020:102-107). Therefore, we first estimated the angulin-binding amino acids of angubindin-1 based on the structural information of CDTb and performed alanine scanning. The angulin-binding ability was assessed by flow cytometry using cells expressing angulin-1/-2/-3. Furthermore, the effects on barrier function were evaluated by measuring the transepithelial electrical resistance (TER) and paracellular permeability using fluorescein (332 Da) and FITC-dextran (4 kDa, FD-4) in monolayer cultures of angulin-expressing cells. **Results:** First, we performed BLAST search based on the amino acid sequence of angubindin-1, namely binary iota toxin binding subunit Ib 421-664, and found its amino acid sequence of angubindin-1 was the most similar to that of CDTb, whose crystal structure has been solved. Among a total of 244 amino acids of angubindin-1, 197 amino acids (80.7 %) were identical to CDTb. Also, it is reported that CDTb binds to angulin-1. Then, we tried to estimate the amino acids residues involved in the binding of angubindin-1 to angulin-1 using CDTb 3D structure and performed functional domain mapping on 24 amino acids in angubindin-1 by alanine substitution. Flow cytometry analyses of angulin-1 and angulin-3-expressing cells demonstrated that reduced binding activity for the mutants L562A, L598A, E638A, V640A, Y643A, and K644A. Notably, the combined L562A/L598A/

E638A/V640A/Y643A/K644A (6A) mutant completely abolished its binding activity to angulin-3, but still had slight binding activity to angulin-1. In contrast, L562D/L598A/E638A/V640E/Y643A/K644A (4ADE) mutant showed a complete loss of binding to both angulin-1 and angulin-3. Furthermore, unlike angubindin-1, these mutants no longer induced a decrease in TER or an increase in paracellular permeability to small molecules such as fluorescein and FD-4 in angulin-1/-3 expressing cells. **Conclusions:** Our results suggest that the six amino acids mutated in the 6A and 4ADE mutants are involved in the mechanism by which angubindin-1 affects the barrier function of tTJ. Furthermore, the modification of these identified amino acid residues may enable the development of novel modulators that selectively target angulin-1 or angulin-3. Such modulators could serve as valuable tools for the precise regulation and assessment of barrier function in *in vitro* BBB models, thereby facilitating the elucidation of disease mechanisms associated with BBB dysfunction and the development of new therapeutic agents. In addition, these modulators are expected to contribute to the establishment of a reliable safety-evaluation platform, paving the way for their potential translation into real-world biomedical applications.

PS 3346 Understanding Mechanisms of Acute Iron Toxicity and Ferroptosis on *C. elegans* Energetic Activity

A. R. Straut, B. P. Lawrence, M. K. O'Banion, and J. O. Onukwufor. University of Rochester, Rochester, NY.

Background and Purpose: Ferroptosis is an increasingly important mechanism for studying cell death in chronic diseases such as cancer and neurodegeneration. Iron(II) is the main iron species driving ferroptosis, and its role in generating lipid peroxides has been well-characterized. Iron(II) is mainly trafficked to mitochondria for functional use in heme biosynthesis and iron-sulfur cluster formation. These constructs are not only essential for respiratory function but are also necessary for other cellular enzymes to function. This implicates mitochondrial iron trafficking as an essential part of cellular health. **Methods:** We approached this by exposing *C. elegans* to ferroptosis inducers (RSL3) and suppressors (N-acetylcysteine and Ferritin II) for 24 hours. Worms were then assessed for pharyngeal pumping (feeding) rate as an energetic behavioral readout. We then used iron (2 mM) to induce ferroptosis and assess its impact on worm pharyngeal pumping rate. Next, we used pharmacological interventions (N-acetyl cysteine and Ferritin II) to rescue iron-induced ferroptosis. Next, we measured whole worm respiration in Clark electrode to recapitulate conditions observed with pumping rates. We followed this with an assessment of mitochondrial function with acute iron(II) exposure to better characterize the mechanisms of these behavioral deficits. We tested the hypothesis that iron(II) exposure impairs bioenergetic function in a dose-dependent manner. Mitochondrial isolates were exposed to a range of iron(II) doses (0, 1, 5, 10, 20, 50, 100 μM) and respiration measured in a Clark-type electrode chamber. After exposure and respiration measurement, mitochondria were collected for iron burden quantification by ICP-MS. To determine the mechanism for iron inhibition, isolated mitochondria were incubated with iron doses selected from the dose response (1 μM, 50 μM) according to different apparent effects on the mitochondrial respiration states. Incubated mitochondria were assessed by enzyme activity measurements of metabolic enzymes (citrate synthase and respiratory complexes I and II). **Results:** Ferroptosis inducers decreased pumping rate while suppressors rescued the behavioral phenotype back to baseline. Iron exposure decreased whole worm respiratory rate. Acutely exposing isolated mitochondria resulted in a dose dependent increase in state 4 leak respiration and a biphasic impairment of state 3 respiration. Two doses (1 μM, 50 μM) were selected for the enzyme activity assays to represent two potentially different mechanisms of iron toxicity. Metabolic enzyme activity showed impaired function with iron incubation. Mitochondrial iron burden was not different from the control. **Conclusions:** Overall, we report a biphasic dose-response of iron toxicity on mitochondrial bioenergetics that likely impacted ETC function and a role for ferroptosis in mitochondrial dysfunction.

PS 3347 Integrating high-content technologies with exposure and toxicokinetics for screening applications

S. Ng¹, J. Leedale², T. Ramanarayanan¹, A. Szarka¹, W. Chen¹, R. Currie², and A. Karmaus¹. ¹Syngenta Crop Protection, LLC, Greensboro, NC; and ²Syngenta Crop Protection Research, Bracknell, United Kingdom.

Background and Purpose: Screening prioritized molecules using high-content (HC) technologies can help identify potential toxicological concern at earlier stages in the development pipeline. Leveraging HC technologies such as cell painting, transcriptomics, and metabolomics applied to *in vitro* test systems allows for broad evaluation of bioactivity elicited by pesticidal MOA-unknown or data-poor chemicals. To integrate these bioactivity screening data with predictive exposure information, bioactivity:exposure ratios (BERs) were applied allowing for risk-based prioritization. **Methods:** Two case studies are presented herein summarizing the evaluation of novel chemicals currently in the development pipeline. Chemicals X and Y are unregistered pesticide active ingredient candidates with limited toxicology data. Prior to *in vitro* testing, a cheminformatics approach to evaluate the properties of chemicals for any characteristics that may confound aqueous based *in vitro* screening in plasticware was conducted. Cell painting, transcriptomics, and metabolomics assays

in addition to cytotoxicity evaluation were conducted after 24 hours of treatment in six human cell lines: U20S (bone sarcoma), SHSY5Y (neuroblastoma), iCell (cardiomyocyte), HepaRG (hepatocyte), HEK293 (embryonic kidney), and H295R (adrenal carcinoma). All datasets generated were analyzed using the appropriate, assay-specific analysis pipeline to derive a representative point of departure (POD). External exposure predictions were generated for dietary (food and , drinking water) and occupational scenarios using standard regulatory models using predictive parameters. Physiologically based kinetic (PBK) modeling was conducted to translate external exposures into systemic organ-level internal doses, accounting for potential clearance and accumulation following repeat dosing and population variability. **Results:** The two case studies combining exposure predictions and bioactivity data from several HC assays were developed with the goal of establishing an adaptable approach for addressing chemicals with limited toxicity data and exposure information. The HC assay results were generally in agreement generating PODs within one order of magnitude. Exposure predictions also spanned at least one order of magnitude given the different scenarios. PBK modeling to evaluate organ-level BERs helped narrow down where any toxicological concern may need follow-up. For the most part the exposure ranges were sufficiently lower than the bioactivity dose ranges supporting safety margins for our case studies. The case studies also demonstrate how to overcome challenges whether it be chemical-properties that confound exposure modeling due to limited solubility or limited bioactivity data due to minimal biological response in the assay systems. Overall, by addressing these challenges, we demonstrate that a BER approach can not only help candidate selection but also provide actionable insights regarding which toxicological concerns should be prioritized as follow-up. **Conclusions:** Our use of *in vitro* test systems paired with HC technologies and computational modeling support the development of a predictive risk assessment framework. This approach helps provide insights into potential hazard(s), inform the development of risk-based modernized testing programs, rationalize animal studies earlier in the research and development pipeline, and add confidence in regulatory use of NAMs approaches.

PS 3348 Enabling single-cell transcriptomics from samples with degraded and low-input RNA using TempO-LINC

Z. Chen, and K. White. Biospyder, Carlsbad, CA.

Background and Purpose: Single-cell and single-nucleus RNA sequencing (scRNA-seq/snRNA-seq) technologies enable detailed characterization of cellular heterogeneity, identification of rare cell types, and mapping of transcriptional states in complex tissues. However, their application to many biomedical and clinical samples is limited by RNA degradation, fragmentation, or inherently low RNA abundance. Peripheral blood mononuclear cells (PBMCs) are a common example of low RNA and highly heterogeneous cell populations, while formalin-fixed paraffin-embedded (FFPE) tissues, despite representing an invaluable archive of human samples, often contain degraded RNA of poor quality and quantity due to crosslinking during fixation and embedding. To overcome these limitations, we developed TempO-LINC, a targeted, instrument-free single-cell transcriptomics assay designed for high-throughput gene expression profiling with strong tolerance to low RNA integrity. Here, we report that TempO-LINC enables robust gene expression profiling and rare cell subtype detection in cryopreserved human PBMCs and dissociated FFPE tissues from human and mouse. **Methods:** The TempO-LINC assay utilizes a combinatorial split-pool barcoding approach to uniquely index RNA molecules in hundreds to thousands of fixed cells or nuclei. Cryopreserved PBMCs from three donors were fixed using the TempO-LINC Fixation Kit and profiled with the human whole transcriptome v2.1 probe set. FFPE blocks from human lung and mouse brain were sectioned, two 30 μm thick sections per block, deparaffinized, enzymatically dissociated, filtered, and then processed with the TempO-LINC Fixation Kit. TempO-LINC single cell expression profiling was performed on FFPE lung and brain using the TempO-Seq human whole transcriptome v2.1 and mouse whole transcriptome v1.1 probe set, respectively. Data processing and visualization were performed using the open-source Python Scanpy and R Bioconductor packages for quality control, clustering, and cell type annotation. **Results:** Analysis of 12,027 PBMCs revealed 16 transcriptionally distinct cell populations. In addition to the major classes of blood and immune cell subsets identified, such as CD14+ and CD16+ monocytes, T and B lymphocytes, TempO-LINC also identified rare blood cell populations including hematopoietic stem/progenitor cells (HPSCs) and proliferating CD4+ T cells, demonstrating high sensitivity in low-RNA contexts. For FFPE samples, TempO-LINC successfully generated single cell expression profiles with competitive sequencing performance: average mapping rate ranges from 71% to 93% with close to 1,000 genes detected per cell. UMAP data demonstrated clearly defined cell subtypes from dissociated FFPE human lung and mouse brain tissues. **Conclusions:** The TempO-LINC single-cell transcriptomics assay enables high-resolution gene expression profiling across heterogeneous, low-RNA PBMCs and FFPE samples without the need for specialized instrumentation. These results highlight the assay's compatibility with degraded RNA and its ability to recover rare cell types, establishing TempO-LINC as a powerful scRNA-seq platform for translational, toxicological, and clinical research. By extending single-cell analysis to billions of archived FFPE specimens and previously inaccessible sample types, TempO-LINC unlocks new opportunities in precision medicine, biomarker discovery, and mechanistic toxicology.

M. Matsumoto, K. Yoshida, T. Umano, T. Iso, Y. Omichi, N. Hirose, M. Wakayama, T. Yamada, and K. Masumura. National Institute of Health Sciences, Japan, Kawasaki, Japan.

Background and Purpose: Traditional *in vivo* bioassays, while standard, are resource-intensive and ethically challenging. *In vitro* assays offer efficiency but lack physiological realism. *In vitro* to *in vivo* extrapolation (IVIVE) bridges this gap by converting *in vitro* activity concentrations into *in vivo* dose estimates. This study explores the potential of using the IVIVE method, supported by physiologically based kinetic (PBK) modeling, to derive oral equivalent doses (OEDs) that can serve as points of departure (PoDs) in chemical risk assessment. The objective of this study was to determine whether the OED derived using the IVIVE approach can serve as an alternative to the PoD for assessing short-term chemical effects. **Methods:** We evaluated the applicability of the IVIVE approach in quantitative chemical risk assessment by comparing OEDs with No/Lowest Observed Effect levels (N/LOELs) and Benchmark Doses (BMDs) from mouse uterotrophic bioassays conducted by the Japanese Ministry of Health, Labour and Welfare (MHLW). We selected five chemicals: 2,2',4,4'-tetrahydroxybenzophenone (THBP), daidzein (DZ), 4-cumylphenol (4CP), heptyl 4-hydroxybenzoate (HHB), and 2-ethylhexyl 4-hydroxybenzoate (2EHB) from the MHLW Priority List for endocrine activity. These chemicals were carefully chosen based on the availability of chemical-specific parameters, high-throughput *in vitro* estrogen receptor (ER) pathway assays, and mouse uterotrophic bioassays. The chemical-specific parameters included molecular weight, topological polar surface area (TPSA), intrinsic hepatic clearance (CL_{int}), and octanol/water partition coefficient (log K_{ow}). Absorption rate constants were estimated from TPSA. Tissue partition coefficients and clearance rates were derived from log K_{ow} and CL_{int}, respectively. The mouse six-compartment PBK model was validated using bisphenol A (BPA) data. OEDs were calculated by converting *in vitro* activity concentrations at half maximum response (AC₅₀) and activity concentrations at cutoff (ACC) values using IVIVE conversion factors. Critical key events (receptor dimerization, dimer-DNA binding, RNA transcription, protein production, or ER-induced proliferation) were statistically identified by comparing OED distributions across ER pathway steps to derive OED_{crit} values (OED for critical key event). The BMDs were calculated from the mean and standard deviation of uterine weights for each treatment group using the PROAST web application. **Results:** Of the five chemicals, three (THBP, DZ, and 4CP) showed positive estrogenic activity in mouse uterotrophic bioassays, while two (HHB and 2EHB) were negative. The PBK model validated using BPA data showed acceptable predictive performance. The critical key events were identified as protein production for THBP, HHB, and 2EHB, DNA binding for DZ, and receptor dimerization for 4CP. For the three chemicals that exhibited positive estrogenic activity, the BMD₅₀s were calculated as 480 mg/kg/day (THBP), 550 mg/kg/day (DZ), and 1000 mg/kg/day (4CP). The average and absolute average fold errors of the ratio of OED_{crit} values from the *in vitro* AC₅₀ values to the LOEL and BMD₅₀ of uterotrophic bioassays were less than 2. Moreover, the OEDs of HHB and 2EHB were higher than 1000 mg/kg/day, the highest dose of the bioassay. The results support the potential of IVIVE-derived OEDs as alternatives to PoDs in risk assessment. Variability in assay data and uncertainty in some parameters highlight the need for further refinement. **Conclusions:** The study demonstrates that the IVIVE approach, using a PBK mouse model, can successfully convert activity concentrations from *in vitro* assays into OEDs that are comparable to *in vivo* bioassay endpoints such as LOEL, NOEL, and BMDs. The study concludes that while IVIVE methodology is largely established, further research is needed to validate the approach across a broader range of chemicals, improve identification of critical key events, and improve the reliability of OEDs derived from *in vitro* data for quantitative human health risk assessment.

PS 3350 Multi-Omics Integration of Transcriptomics and Phenomics Reveals Complementary Molecular and Morphological Signatures of Compound Response and Toxicity

A. Coudray, S. Placzek, M. Vallez, D. Cabuzu, V. Hahaut, and D. Alpern. Alithea Genomics, Epalinges, Switzerland. Sponsor: R. Currie

Background and Purpose: Understanding how bioactive compounds affect cellular systems is critical for developing safer, more effective chemical products and for reducing late-stage failures in drug discovery pipelines. Cost-efficient morphological and gene expression profiling enable high-throughput phenotypic analysis for genetic and small-molecule perturbation screens, offering early clues into compound mechanism of action and toxicity. Importantly, these complementary approaches capture distinct yet interrelated layers of cellular response, with great promise to enhance biological interpretation when combined. Historically, comparative studies have relied on legacy probe-based transcriptomic platforms such as L1000. Here, we introduce Total DRUG-seq, an enhanced gene expression profiling method that captures the whole transcriptome with full-length coverage, paired-end alignment, and high multiplexing capability—delivering deeper biological insights and expanding discovery in large-scale screens. **Methods:** We applied Total DRUG-seq and Cell Painting to profile gene expression and cell morphology across two datasets comprising three human cell lines U2OS (osteosarcoma), and hepatocarcinoma derive HepG2 and HepaRG, key models for investigating *in-vitro* drug-induced liver

injury (DILI). In the first dataset, 82 compounds from the JUMP-MoA reference collection were tested to assess the ability of each assay to uncover mechanistic biological insights. The second dataset included 58 treatments with balanced DILI-positive and -negative outcomes. To assess the combined potential of Total DRUG-seq and Cell Painting, we implemented data integration strategies and compared the added value of multi-omics integration against single-modality analyses for clustering and classification of treatments, mechanisms of action, and DILI outcomes. **Results:** Our findings show that combining transcriptomic and morphological profiles provides more biologically coherent insights into drug activity than either modality alone. Unsupervised analyses revealed that integration enhances clustering quality across cell types, outperforming individual assays. Total DRUG-seq showed superior treatment clustering for HepG2 cells, while Cell Painting performed better in U2OS cells. Supervised models further confirmed that integrated multi-omics data consistently outperformed individual assays in predicting compound mechanisms of action and DILI outcome. **Conclusions:** These results underscore the synergy between transcriptomic and morphological profiling and highlight the value of multi-omics strategies for characterizing cellular responses and enabling early detection of toxicity across diverse compound classes.

PS 3351 A Weight of Evidence Framework for the Application of New Approach Methodologies (NAMs) in Genotoxicity Risk Assessment

R. N. Caballero-Floran¹, A. Sleiman¹, B. Lampe¹, K. A. Magurany², Y. Jo³, S. H. Hong³, S. J. Park³, and T. D. Vincent-Hall¹. ¹NSF International, Ann Arbor, MI; ²Verto Solutions, LLC, Washington, DC, WA; and ³Rural Development Administration, Jeonju, Korea, Republic of.

Background and Purpose: Genotoxicity assessments are essential for public health, especially for data-poor chemicals where traditional *in vivo* testing is limited by cost and ethics. Standard assays (e.g., Ames, micronucleus) often lack mechanistic and dose-response insights. New Approach Methodologies (NAMs), including QSAR, read-across, high-throughput *in vitro* screening, DNA damage biomarkers (e.g., γH2AX, p53), and targeted *in vivo* endpoints, offer efficient alternatives. This framework integrates NAMs into a weight-of-evidence (WoE) approach to assess mutagenicity, aneugenicity, and clastogenicity, while supporting potency and mode-of-action (MoA)-based dose-response analysis. It addresses key adverse outcome pathways (AOPs), such as oxidative damage, alkylation, bulky adducts, spindle disruption, and topoisomerase inhibition, emphasizing DNA repair and threshold potential for non-mutagenic genotoxins. **Methods:** Tier 1 (Data Evaluation) reviewed existing studies for GLP compliance, reliability, and relevance to parent compounds, major metabolites (>10%), or degradants. Endpoint consistency and biological plausibility guided conclusions. Tier 2 (NAMs Prediction) aimed to fill data gaps via: (1) *in silico* QSAR tools (OECD Toolbox, Derek Nexus) to identify structural alerts; (2) read-across from analogs (Tanimoto ≥0.7, shared MoA); (3) integration of high-throughput *in vitro* data (Tox21/ToxCast) with IVIVE using PBK modeling to derive human equivalent administered doses (EADs). Tier 3 (Testing Recommendation) prioritized dose-responsive *in vitro* assays (e.g., MultiFlow®, ToxTracker, 3D HepaRG comet assay) before *in vivo* confirmation. Tier 4 (Dose-Response Evaluation) established points of departure (PoD) using BMD, NOGEL, or TTC. MoA analysis distinguished linear extrapolation for DNA-reactive mutagens (e.g., aflatoxin B1) from threshold models for aneugens (e.g., colchicine) and indirect clastogens (e.g., EMS, MMS). **Results:** The framework robustly identified genotoxic potential and derived protective EADs. For carbendazim, *in silico* analyses flagged benzimidazole alerts linked to tubulin binding; read-across to thiophanate-methyl confirmed aneugenicity via spindle poison MoA; and IVIVE of Tox21 microtubule disruption data yielded an EAD within 3-fold of EPA's chronic reference dose. For diuron, urea structural alerts suggested clastogenicity; read-across to linuron and monuron supported DNA damage via reactive metabolites; and the Tox21-derived EAD was 5-fold below the EPA chronic reference dose, ensuring protectiveness. In a case study using spirotetramat as a negative control, no structural alerts for genotoxicity were identified, and the read-across analysis indicated a non-mutagenic profile. NAMs integration achieved >90% concordance with known outcomes in a blinded validation. Dose-response analyses supported non-linear thresholds for both compounds: carbendazim via mitotic checkpoint saturation, diuron via repair-saturable oxidative stress. Underlying model performance (mutagenicity QSAR sensitivity = 88%, specificity = 92%; Tox21 DNA damage pathway specificity >85%) validated predictive reliability. The framework correctly waived further testing for low-concern analogs and prioritized mechanistic follow-up for equivocal cases. **Conclusions:** This transparent, iterative, and mechanistically anchored framework enables defensible, animal-sparing genotoxicity assessments for data-poor chemicals. By integrating exposure context, NAMs predictability, and MoA-driven dose-response, it guides testing waivers, prioritization, and risk characterization with regulatory rigor. The case studies demonstrate practical utility in deriving human-relevant, protective potency estimates using only publicly available NAMs data. This approach supports global efforts to reduce vertebrate testing under ICH, EPA, and EFSA NAM initiatives, while ensuring robust public health protection through scientifically sound, efficient decision-making.

J. W. Hoffman, and H. Kessler. Owens Corning, Granville, OH. Sponsor: A. Madl

Background and Purpose: Our goal is to develop a simple non-animal approach to evaluate the fate of synthetic vitreous fibers (SVF) in the GI tract. SVF are used in insulation and building products as components of thermal and acoustic insulation systems. The SVF used in these applications include glass wool fibers (GW), mineral wool fibers (MW) and alkaline-earth silicate (AES) fibers. Dissolution testing of SVF are typically directed toward evaluating the biopersistence of SVF in the lungs to estimate the clearance half time. Fiber entry into the GI system begets a second question, that of what quantity of dissolved ions may become bioavailable after ingestion? Means of developing this data using dissolution studies can be a facilitator for evaluating risk. In this study, we test static and dynamic dissolution methods to evaluate the extent of dissolution and quantify ion release, leveraging established GI simulant fluids and test procedures designed to evaluate pharmaceutical release rates. **Methods:** A sample of each fiber type (GW, MW, AES) was obtained from commercial sources. Fibers were prepared for testing by low-temperature ashing in oxygen plasma to remove organic material, and in some cases (MW, AES) passed through a sieve to remove gross non-fibrous material. A static dissolution test was conducted with both simulated fasting state intestinal and gastric fluids (FaSSIF, FaSSGF). In all cases ~100 mg of fiber was exposed to 100 mL of simulant fluid at 37 C, for either 2 hrs (FaSSIF) or 6 hrs (FaSSGF). After the exposure time, the supernatant was extracted, filtered and analyzed for pH and ion content (ICP-OES). The dynamic test was based on the USP Apparatus 4, operated in open circuit mode. Either 50 mg or 200 mg of each fiber was exposed first to the FaSSGF fluid (2 hrs exposure) and then FaSSIF fluid (6 hrs exposure). Fluids were introduced to the fiber at 2 mL/minute at 37 Celsius. A 0.22 µm filter in line on the discharge side of the cell to ensure no fiber carryover. There was no flush between the fluids which allowed some mixing. The discharged fluid was periodically sampled via an automated fraction collector and analyzed for pH and ion content (ICP-OES). **Results:** The static dissolution tests showed differences in the extent of fiber dissolution. In the low pH (1.6) FaSSGF, less than 5% of the mass of the GW and AES samples dissolved, with > 70% of the stone wool dissolved. Slight increase in pH occurred with the SW sample (+ ~0.3 pH units) concurrent with significant dissolution of the fibers, suggesting slight neutralization of the fluid by the dissolved ions. In the neutral pH (6.5) FaSSIF fluid, less than 5% by mass was dissolved from any samples over the 6 hour exposure. The dynamic test showed that dissolution of the SW (~30% by mass) was significantly higher than the GW or AES. Sensitivity was noted to sample mass as the lower sample load showed a higher extent of dissolution (~2x). Solution pH, in contrast to the static test, was stable for all fibers and fluids. B₂O₃ release from GW was observed in both FaSSIF and FaSSGF with the total release (~10% of the total) almost 5x greater than the SiO₂ release. **Conclusions:** We demonstrated successful proof of concept around combining biomimetic GI fluids, a static dissolution test, and a dynamic, flow-through test, to develop understanding of the extent of dissolution, and ion release from SVF. Results align well with classic understanding of the impact fiber chemistry, pH, and surface area/volume ratio on SVF dissolution profiles. These methods have potential to inform the fate of fibers entering the GI tract as well as the quantity and rate of elution of ions of potential interest, facilitating weight of evidence and similar evaluations of hazard and risk.

PS 3353 Integrating *in Vitro*, *in Vivo*, and Biomimetic Chromatography Data to Enhance Chemical Toxicity Predictions

J. K. Martin¹, L. Truong¹, K. Valko², B. Rajwa³, and R. L. Tanguay¹. ¹Oregon State University, Corvallis, OR; ²Bio-Mimetic Chromatography Ltd, Stevenage, United Kingdom; and ³Purdue University, Lafayette, IN.

Background and Purpose: Accurate toxicity prediction is essential for drug development, as highlighted by the urgent need for rapid screening during the COVID-19 pandemic. Traditional toxicity assessment relies on *in vitro* and *in vivo* assays, but these often yield discordant results for the same compound due to differences in methodological metabolic competency and in receptor or pathway expression profiles. This leads to unnecessary animal testing or premature elimination of safe candidates. To bridge these gaps, we integrated biomimetic chromatography—a technique that uses reverse-phase liquid chromatography coupled with biologically relevant stationary phases to estimate *in vivo* partitioning and transport—into conventional screening approaches to improve mechanistic understanding and accelerate drug safety assessment. **Methods:** We screened 322 compounds from the Cayman Antiviral Screening Library using 3 complementary approaches. *In vitro* assessment used the AsedaSciences SYSTEMETRIC Cell Health Screen (CHS) with HL60 cells to measure 12 acute cellular stress readouts (including ROS, and mitochondrial function) across 10 concentrations (5 nM - 100 µM) with machine learning predicted human toxicity risk from biological fingerprints. *In vivo* screening exposed individual zebrafish embryos to compounds at 100 µM starting at 6 hours post fertilization (hpf), assessing mortality and embryonic photomotor response at 24 hpf, plus 16 morphological endpoints and larval photomotor response at 120 hpf. Active under-went definitive testing across 10 concentrations (5 nM - 100 µM) and was further screened for morphological and behavioral effects, reported as benchmark doses or lowest effect levels, respectively. Biomimetic chromatography measured compound partitioning using a C18 column at 3 pH values, immobilized artificial membrane

(IAM), human serum albumin (HSA) and α-1 acid glycoprotein (AGP) columns. Retention was reported as the chromatographic hydrophobicity index (CHI) for C18 and IAM and partitioning coefficients for HSA and AGP (log_{K_{HSA/AGP}}, respectively). **Results:** Of the 322 antiviral compounds, 27% (87) were positive hits in the CHS, and 31% (101) showed morphological effects in zebrafish, with only 44 compounds positive in both assays. Notably, 43 CHS hits were non-toxic in zebrafish, while 57 compounds that were negative in CHS caused zebrafish morphological changes, highlighting discordance between the two platforms. Biomimetic chromatography helped explain these differences. Binding to IAM, HSA and AGP columns positively correlated with Cell Health Index, and a multiple linear regression model using biomimetic binding coefficients for these parameters predicted CHS toxicity (p < 0.05) For zebrafish endpoints, CHI at pH 7.4 (p < 0.005) and 10.5 (p < 0.0005), and log K_{HSA} (p < 0.05) were negatively correlated with any-effect BMD₁₀ and LELs in the embryonic photomotor assay. In larval photomotor responses, CHI at pH 10.5 and log K_{AGP} (p < 0.05) correlated with LELs during the light phase. **Conclusions:** Biomimetic chromatography effectively bridges the gap between *in vitro* and *in vivo* toxicity data, helping explain why 27% of compounds show discordant results between assays. Integrating biomimetic partitioning data with *in vitro* screening significantly improved the prediction of *in vivo* zebrafish toxicity. This combined approach offers a practical strategy to reduce reliance on animal testing while advancing the development of safer compounds, with applications across pharmaceuticals and environmental toxicology.

PS 3354 Extraction-Free TempO-Seq Profiling of Dried Blood Spots for Comprehensive Transcriptome Analysis

Z. Chen, and M. Hernandez. Biospyder Technologies Inc., Carlsbad, CA.

Background and Purpose: TempO-Seq gene expression signatures provide a robust approach for evaluating mode of action, and numerous studies have demonstrated their use in high-throughput transcriptomic dose-response analyses for safety and efficacy assessment *in vitro* and *in vivo*. Building on these applications, we recognized that a fingerstick dried blood spot (DBS) assay capable of measuring gene expression signatures, miRNAs, and alternatively spliced isoforms would enhance the platform's diagnostic and monitoring potential. We therefore developed a TempO-Seq workflow to quantify mRNA, miRNA, and splicing isoforms from DBS samples. **Methods:** Whole transcriptome and alternative splicing analyses were performed using the TempO-DBS assay, while the TempO-Seq whole miRNome miRNA assay was used to profile miRNA expression. Whole blood-specific attenuators were incorporated to reduce background signal from highly expressed blood genes. To demonstrate the capabilities of this multi-omic platform, we analyzed samples from Alzheimer's disease (AD) patients and from a donor receiving Zepbound, a weight-loss drug. All samples were collected under IRB-approved protocols. **Results:** Using the whole transcriptome V2.1 panel, we not only identified a classifier of AD, but also identified key genes known to be associated with AD; S100A8, MMP9, and MME. This demonstrates the disease relevance of blood-derived data for a neurodegenerative disease. Using the TempO-Seq whole miRNome miRNA assay, we profiled DBS samples from AD patients and controls. Functional enrichment analysis revealed significant differences in miRNAs associated with aging and inflammation pathways, both linked to AD pathophysiology. DBS samples from three donors were also analyzed using the TempO-Seq DBS assay run with a sentinel splicing panel, which successfully distinguished donors based on alternative splicing profiles alone. Finally, a longitudinal study of a donor self-administering Zepbound injections revealed treatment-associated gene expression changes detectable with the TempO-Seq-DBS assay. Collectively, these results demonstrate that the TempO-Seq platform enables simultaneous measurement of mRNA, splicing isoforms, and miRNA from a single DBS sample. **Conclusions:** Fingerstick DBS collection combined with TempO-Seq multi-omic assays enables self-sampling, eliminates biohazard concerns upon drying, and allows specimens to be safely mailed for analysis. This approach supports remote monitoring of safety, exposure, and disease incidence or risk. Because the TempO-Seq DBS mRNA and miRNA assays can be performed from the same DBS sample, they provide a practical and scalable solution for diagnosis of diseases, evaluating individual responses to drugs, disease progression, and potential adverse effects following exposure.

PS 3355 Phenotype-Anchored Transcriptomic Signatures of Developmental Neurotoxicity (DNT) Compounds in Zebrafish

L. Lin¹, L. St. Mary^{1,2}, D. Phadke³, M. Balik-Meisner³, E. Scholl³, D. Mav³, B. Howard³, R. Shah³, L. Truong¹, and R. Tanguay¹. ¹Department of Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR; ²Exponent Inc., Natick, MA; and ³Sciome, LLC, Research Triangle Park, NC.

Background and Purpose: The NIEHS Division of Translational Toxicology established a 91-compound library to support the development of a battery of assays aimed at elucidating pathways underlying developmental neurotoxicity (DNT). Zebrafish (*Danio rerio*) is a valuable *in vivo* model that offers vertebrate-level biological complexity while reducing reliance on mammalian testing. In this study, we evaluated a subset of 27 compounds from the DNT library, spanning diverse chemical classes including polycyclic aromatic hydrocarbons (PAHs), organophosphates, and

pyrethroid pesticides. Using whole transcriptome sequencing of exposed embryos at concentrations known to cause developmental malformations, we sought to characterize early transcriptional responses that may contribute to the initiation of adverse developmental outcomes. **Methods:** Embryonic zebrafish were statically exposed to DNT compounds at concentrations ranging from 0 to 100 μM in 96-well plates (3 replicate plates, 8 concentrations). For each compound, a concentration-response curve was generated to determine the concentration at which approximately 80% of larvae exhibited morphological malformations at 120 hpf (EC_{80}). Next, embryos were exposed to each compound at its estimated EC_{80} . At 48 hpf, embryo samples (5 pools of 8 embryos) were collected for RNA sequencing using Lexogen's CORALL Total RNA-Seq V2 platform. In parallel, holdback embryos ($n = 16$) were allowed to develop to 120 hpf for assessment of mortality and nine additional predefined phenotypic endpoints. Differential expression and enrichment analyses were performed to identify disrupted biological pathways. Sciome's Transcriptomic Read-Across (TRA) tool was then used to compare the differentially expressed gene (DEG) profiles of the DNT compounds against a large, curated zebrafish dataset from the NCBI Sequence Read Archive. This approach identified additional chemicals outside the current study with statistically similar expression patterns and also enabled comparisons within the current dataset, revealing transcriptional similarities among the 27 DNT compounds. **Results:** The 27 DNT compounds exhibited a wide range of potencies, with estimated EC_{80} values spanning from 0.1 to 100 μM . For example, TCDD at 0.1 μM induced malformations in 62% of zebrafish larvae, whereas dibenz[a,c]anthracene required 100 μM to produce a similar level of malformation. When compared with vehicle control (0.5% DMSO), the number of differentially expressed genes also varied considerably among compounds, ranging from 33 to 994. Pathway analysis revealed distinct enrichment patterns across chemical classes. For the five organophosphates, pathways related to retinoic acid signaling and skeletal development were highly enriched. Among the five PAHs, enriched pathways were primarily associated with xenobiotic metabolism and epidermal development. In the seven biocides, most pathways were linked to immune responses and tissue remodeling processes. TRA analysis identified additional chemicals outside this study that share similar transcriptional profiles. For instance, benzo[k]fluoranthene (a PAH not included in the DNT library) showed a high similarity score with dibenz[a,c]anthracene, dibenz[a,h]anthracene, and TCDD, suggesting a potential common mode of action with these three DNT compounds. The analysis also revealed transcriptional similarities within the 27 DNT compounds. Permethrin and deltamethrin, for example, are both pyrethroid insecticides and grouped together based on their TRA scores. **Conclusions:** Overall, this study demonstrates the utility of phenotype-anchored transcriptomics for identifying early molecular events underlying developmental neurotoxicity in zebrafish across 27 compounds. This approach highlights the value of comprehensive zebrafish transcriptomic databases as tools for discovering chemical-induced adverse effects and elucidating mechanisms of toxicity.

PS 3356 Statistical analysis of multi-endpoint phenotypic screening in the planarian *Dugesia japonica* provides unique value for developmental neurotoxicity testing

D. Ireland¹, L. J. Word², and E. S. Collins^{1,3}. ¹Swarthmore College, Swarthmore, PA; ²Independent Computational Toxicology Consultant, Durham, NC; and ³University of Pennsylvania, Philadelphia, PA.

Background and Purpose: There is an urgent need to replace, refine, and/or reduce ("3Rs") vertebrate toxicity testing. This is especially challenging for neurotoxicity and developmental neurotoxicity (DNT) where the functional relevancy of adverse outcomes needs to be assessed on the whole organism. Invertebrates can provide organismal context and promise to augment existing *in vitro* approaches. To evaluate whether planarian phenotypic screening provides complementary information to existing DNT models, we used new statistical analysis methods to re-analyze published planarian data on the NTP 87-compound library (NTP87). The NTP87 library consisted of known and suspected developmental neurotoxicants from five toxicity domains (pesticides, industrials, drugs, flame retardants, polycyclic aromatic hydrocarbons) and five *in vitro* negative controls. **Methods:** We quantified eight additional behavioral endpoints from the original planarian data for a total of 26 readouts on days 7 and 12 of exposure, evaluated at 5 log-scale concentrations (10 nM-100 μM). Benchmark concentration (BMC) modeling replaced lowest-observed-effect-level analysis. To provide insight into systems-level toxicity, we also calculated a concentration-independent multi-readout summary measure using weighted Aggregate Entropy (wAggE). We compared the planarian BMC data to mammalian *in vitro* data and to developing zebrafish data from independent screens of the NTP87 library that were analyzed using the same BMC pipeline. **Results:** The addition of new endpoints provided additional sensitivity without the cost of more experiments, allowing for the detection of more chemical hits with increased potency and more developmentally-specific hits than in our original analysis. The adaptation of BMC modeling increased screen robustness and allowed for direct comparison of our results with existing *in vitro* and developing zebrafish data available on DNT-DIVER. The wAggE analysis provided contextualization of the severity of behavioral phenotypes and thus complemented the potency determinations from BMC. Planarian and developing zebrafish screens showed similar sensitivity. Regenerating planarian hits helped correctly identify known neurotoxicants of the NTP87 library. Hierarchical clustering showed that organismal models, human neuron outgrowth models, and rat primary cortical neuron firing models were the main contributors to the NTP87 DNT battery's information content, while other human cell culture models added no

extra information. **Conclusions:** Neurotoxicity and DNT testing requires a battery approach, leveraging complementary strengths of multiple systems to approximate the complexity of human brain development, function, and metabolism. The systems comparison presented here emphasizes the importance of including organismal models, such as developing zebrafish and planarians, within a DNT test battery to measure DNT on a systems level while also accounting for xenobiotic metabolism. Using this battery approach, chemicals with more NT/DNT hits across new approach methods from various levels (*in vivo*, *in vitro*, *in silico*) can be prioritized as chemicals of higher interest for further study.

PS 3357 Characterizing lineage specific drug induced injury responses and sensitivity using a mechanism based gene co-expression network approaches and fluorescent reporters.

S. Davidse¹, L. Xu¹, E. Lympieri¹, T. Danilyuk¹, B. Islam², S. Kunnen¹, P. Bouwman¹, L. Wijaya¹, and B. van de Water¹. ¹Leiden University (LACDR), Leiden, Netherlands; and ²Certara, Sheffield, United Kingdom.

Background and Purpose: Current chemical risk assessment relies heavily on animal testing. There is an increasing desire to replace animal based safety testing with safer, cheaper and more human relevant *in vitro* methods. Induced pluripotent stem cell (iPSC) derived *in vitro* models show great promise to replace or supplement animal testing as a human relevant test systems. However, uncertainty remains on the accurate prediction of human toxicity. We have used a systematic toxicogenomics screening of iPSC-derived hepatocyte, renal proximal tubular and cardiomyocyte lineages to define common and different transcriptional programs that represent adverse response with respect to clinical liabilities for hepato-, nephro- and cardio-toxicity. **Methods:** More than fifty compounds were selected from FDA rank lists based on known relation to liver, kidney and/or heart adverse events and covering a wide range of toxicological mechanisms. iPSCs were differentiated into hepatocyte-like cells (HLC), proximal tubule-like cells (PTLC) and cardiomyocyte-like cells (CMLC). All lineages were exposed to the full selection of compounds in identical concentration ranges based on simulated human Cmax values. Cell death was measured as a cell-fate readout through confocal imaging 24 hours after exposure, directly followed by sample collection for high throughput whole transcriptome sequencing (TempO-Seq). Differential gene expression analysis was performed using DESeq2 followed by weighted gene co-expression network analysis (WGCNA) to identify gene networks to facilitate biological interpretation. Sensitivity per compound was determined by concentration response modeling and subsequent benchmark concentration analysis using BMD express. Furthermore, the defined co-regulated gene networks were used to identify potential stress response pathway related biomarkers to be used to generate fluorescently tagged reporter cells for quick insight into stress pathway activation. Several identified reporter options for the oxidative stress response pathway, inflammation pathway, unfolded protein response pathway and DNA damage response pathway were generated and validated using known pathway activating compounds. Following differentiation cells were exposed to a wide dose range of pathway activators and fluorescent protein expression was captured after 24 hours through confocal microscopy. **Results:** Evaluation of the transcriptomics results showed variations in transcriptional responses between lineages. Compounds showed concentration responsive transcriptional changes that differed between HLC, PTLC and CMLC. Several compounds showed transcriptional changes in all lineages, although differences in gene networks and point-of-departure were observed. From the data, 13 representative genes have been identified representing four toxicity-relevant stress response pathways based on dose dependency and specificity. Using CRISPR-based genome engineering and stringent selection and validation, we established nine functional iPSC reporter lines. From these 9 we selected one reporter per pathway was as most representative for use in follow up experiments. ICAM1 for inflammation, CDKN1A for DNA damage response, HSPA5 for unfolded protein response and SRXN1 for oxidative stress response. These reporters showed a dose dependent increase in fluorescent signal in response to activation of the corresponding pathway in the HLC, PTLC and CMLC lineages. Initial data on the functionality of these reporters to assess the activity of selected DILI, DIKI and DICI compounds will be presented. **Conclusions:** Using toxicogenomics, we demonstrate commonalities and differences in the response of DILI, DIKI and DICI compounds in HLC, PTLC and CMLC lineages. Selected biomarkers for critical toxicological pathways were successfully integrated in iPSC reporters and demonstrated functionality with respect to drug-induced adversity liability detection.

PS 3358 *C. elegans* as a model to detect negative-feedback effects on conserved developmental signal transduction pathways

P. R. Hunt. FDA, Laurel, MD.

Background and Purpose: Chemical effects on apical endpoints such as the timing of developmental milestones and locomotion, and the reversibility of these effects, are important components of chemical safety assessments. Signal transduction pathways critical to organismal growth and development, as well as neuromuscular architecture and neurotransmitter function are well conserved across phyla, supporting the use of small model organisms (SMOs) such as invertebrate *Caenorhabditis elegans* for 3Rs-compliant developmental toxicity screening. Additionally, an SMO

assay for the detection of chemicals that modulate developmental pathway feedback regulation and thereby make critical signaling processes less responsive to endogenous signals would be a useful addition to developmental toxicity test batteries. **Methods:** At 20°C, *C. elegans* reach the mid-third larval stage (mL3) at about 36 h post-initiation of feeding after hatching (first feeding, FF), and chemically induced changes in time to developmental stage or locomotor activity are indications of developmental toxicity. Wild-type *C. elegans* monitored for developmental stage acquisition timing and locomotor activity were exposed from FF either continuously or for 24 h. *C. elegans* data from three representative chemicals was analyzed and compared: 5-fluorouracil (5FU), which has irreversible effects on fetal growth and induces hypoactivity in mammals, ribavirin (RV), which has partially reversible effects on mammalian development, and cannabidiol (CBD), which modulates endocannabinoid signaling, a pathway critical for mammalian embryonic, fetal, and pubertal development. **Results:** In *C. elegans*, all three chemicals induced dose-responsive delays to mL3. Continuous exposures to 5FU and CBD also induced hypoactivity at mL3, albeit at ~100-fold higher concentrations for CBD relative to 5FU. RV induced a non-significant trend towards slight hyperactivity at mL3 in both continuous and 24 h exposure groups. Relative to continuous exposures, removal of 5FU 24 h after FF did not alter subsequent delays to mL3 or 5FU-induced hypoactivity, consistent with irreversible developmental effects. Removal of RV at 24 h post-FF reduced the delays to mL3 by about 50% relative to continuous exposures, consistent with partially reversible effects on developmental timing. Removal of CBD at 24 h post-FF nearly doubled the delays to mL3 relative to the delays induced by continuous CBD exposures. In contrast, the mL3 hypoactivity observed during continuous CBD exposures returned to normal levels after removal of CBD. **Conclusions:** *C. elegans* juvenile growth patterns were able to distinguish between two anti-proliferative drugs with irreversible vs. partially reversible developmental effects in mammals. The increase in developmental delays after removal of CBD suggests that *C. elegans* growth patterns can also detect desensitization of critical developmental pathway(s) that induce a refractory period resulting in delayed development. Additionally, the resumption of normal locomotor activity levels after removal of CBD indicates that CBD influences developmental timing and locomotion via different pathways.

PS 3359 Reproducibility of points of departure derived from high throughput transcriptomic assays with four species of aquatic organisms.

D. L. Villeneuve¹, K. Bush², G. Casciano³, J. Cavallin¹, S. Daley², A. Kasperek⁴, M. Nash², J. Stewart², and K. Flynn¹. ¹US EPA, Duluth, MN; ²US EPA, ORISE participant, Duluth, MN; ³US EPA, ORISE Participant, Duluth, MN; and ⁴SpecPro Sustainment and Environmental, Duluth, MN.

Background and Purpose: US EPA is evaluating ecological high throughput transcriptomics (Eco-HTT) assays as a new approach methodology for estimating concentrations of chemicals or mixtures that would not be expected to cause adverse ecological effects. An important aspect of assay performance is the inter-assay reproducibility and variability of points of departure (PODs) derived from the assay. An understanding of assay reproducibility is important for determining suitability for risk assessment applications and informing data interpretation. **Methods:** Larval *Pimephales promelas* (a fish), *Daphnia magna* (a crustacean), *Chironomus dilutus* (an insect), and *Raphidocelis subcapitata* (a green algae) were exposed to seven concentrations of cyanazine (0.016-100 µM; fish and daphnia), imidacloprid (16-7200 ng/L; insect), or atrazine (6-32,350 µg/L; algae) for 24 h in a 96-well plate format. A single replicate consisting of RNA pooled from three individuals (or populations of cells in the case of algae) exposed in separate wells, was generated per concentration, per assay (five replicates for controls) and each assay was repeated 9-12 times over a period of weeks. Upon completion, all the collected samples, per species were sequenced on a single sequencing lane (minimizing technical variation associated with the sequencing process) and PODs were derived from concentration-response modeling of either targeted TempO-Seq (fish and daphnia) or whole transcriptome 3' RNAseq (insect and algae) data. **Results:** The number of concentration responsive genes (CRGs) detected, relative to plate-matched controls, varied among the various repeats of the assay. For cyanazine, the number CRGs ranged from 17-678 (40-fold; n=10) for *P. promelas* and 27-760 (28-fold; n=11) for *D. magna*. For *C. dilutus* exposed to imidacloprid the number of CRGs ranged from 6-34 (5.7-fold; n=9), while those for *R. subcapitata* exposed to atrazine ranged from 237-900 (3.8-fold; n=12). It could not be determined whether the greater variability in the number of CRGs identified for *P. promelas* and *D. magna* was due to the species, reference chemical selected, the use of the targeted TempO-Seq method or other factors. Regardless, the PODs derived based on the 10th percentile of the distribution of benchmark concentrations for the CRGs ranged from 5.6-97 µM cyanazine for *P. promelas*, 7.7-67 µM cyanazine for *D. magna*, 22-293 ng imidacloprid/L for *C. dilutus*, and 65-879 µg atrazine/L for *R. subcapitata*. Overall, across all the repeated assays for the four species, the PODs varied by a factor of 13.2, or 1.12 log units. **Conclusions:** The current results indicate that PODs derived from ecological high throughput transcriptomics assays have around an order of magnitude of uncertainty. The ability to calculate a POD based on one replicate per concentration for these transcriptomic data sets, as demonstrated in the current study, provides a computationally tractable approach for calculating and reporting variability estimates for PODs that incorporate both uncertainty of the curve fitting and variability in the CRGs identified into the estimate, which has not been common practice to date. Additional *in silico* re-sampling of both the current

and new data sets may provide even more robust estimates of variability and reproducibility that better reflect the study designs commonly used for testing. *Contents of this abstract neither constitute, nor necessarily reflect US EPA policy.*

PS 3360 Transcriptomic Points of Departure from Whole vs Targeted Transcriptome Sequencing

M. Nash¹, K. Flynn², D. Villeneuve², P. Schumann³, and M. Hazemi⁴. ¹Oak Ridge Institute of Science and Education/Environmental Protection Agency, Duluth, MN; ²US Environmental Protection Agency, Duluth, MN; ³Environmental Protection Agency, Duluth, MN; and ⁴US Environmental Protection Agency, Durham, NC.

Background and Purpose: Transcriptomic points of departure (tPODs) derived from analysis of global gene expression change after short-term assays have been proposed as an alternative to long-term animal studies for evaluating chemical toxicity and risk. Targeted RNA sequencing (RNA-seq) is an attractive alternative to whole-transcriptome RNA-seq because it focuses sequencing depth on a subset of transcripts selected a priori, which reduces cost per sample and streamlines the bioinformatic analysis. However, it is unclear if targeted RNA-seq, examining just a fraction of the overall transcriptome, will provide comparable tPOD estimates to that of whole transcriptome RNA-seq. **Methods:** To address this, we analyzed whole transcriptome data from previous high-throughput exposure studies with *Chironomus dilutus* (an aquatic insect) and *Raphidocelis subcapitata* (a microalgae). In each study, the test species was exposed to multiple concentrations of chemicals with various modes of action for 24 hours in 96 well plate format. To simulate the data that would be obtained from a targeted transcriptome sequencing approach, subsets of the whole-transcriptome data were created *in silico* in three ways: 1) randomly selecting gene targets; 2) using the gene IDs from a commercial targeted sequencing platform based on KEGG pathway coverage; 3) deriving species-specific, effects-driven gene lists with an approach similar to that used to create the human S1500+ targeted RNA-seq gene list. Each of the three types of subsets were equal in number of genes included, each having 1,450 and 856 genes for *C. dilutus* and *R. subcapitata*, respectively. Using a standard analysis pipeline, benchmark concentration-response modeling was applied and tPODs were calculated from both whole and simulated reduced transcriptome data for each chemical. **Results:** Results suggest that while targeted approaches tended to produce tPODs similar to the whole transcriptome, the effects-based target selection tended to perform better than the random and pathway-based selections, having a tPOD within a 10-fold difference to the whole transcriptome for 85% and 72% of exposures, respectively. The effects-based targets also had on average 2.5-fold and 4.4-fold more genes responsive to the exposure than the random and pathway-based targets, respectively. With increased concentration-responsive genes, the tPOD agreement between the subsets and the whole transcriptome tend to improve. In cases of large tPOD differences greater than 1 order of magnitude, the majority (83%) also have 10 or fewer responsive genes. **Conclusions:** A species-specific, effects-driven gene selection subset tends to perform better than both the commercial subset based on pathway coverage and random subsets, which is likely driven by quantity of responsive genes detected. For species with largely unannotated genomes, such as the present test species, there may be insufficient annotated pathways to produce a reliable set of sequencing targets. Future analyses will explore these approaches in species with better annotated genomes, such as *Pimephales promelas* and *Daphnia magna*. Overall, this study demonstrated that targeted sequencing is a viable alternative to whole-transcriptome sequencing that could expedite chemical hazard screening.

PS 3361 Implementation of a New Approach Methods (NAMs)-based Framework to Evaluate Skin Irritation of New Chemicals under TSCA

R. Brunner¹, R. A. Beardslee¹, A. Bettmann², A. J. Clippinger², E. G. Costin³, H. Raabe³, K. Salazar⁴, A. van der Zalm², and A. Lowit⁴. ¹US EPA/OCSPP, Research Triangle Park, NC; ²PETA Science Consortium International e.V., Stuttgart, Germany; ³Institute for In Vitro Sciences, Inc., Gaithersburg, MD; and ⁴US EPA/OCSPP, Washington, DC.

Background and Purpose: US EPA Office of Pollution Prevention and Toxics, New Chemicals Division (NCD), is responsible for making human health and environmental safety determinations for new chemicals submitted under the Toxic Substances Control Act (TSCA) prior to their entry into US commerce. During each new chemical human health assessment, the potential to cause skin irritation/corrosion is determined to support evaluation of chemicals by regulatory authorities. This determination has historically been performed using animal testing. As new approach methodologies (NAMs) have been developed and accepted by national and international entities, there has been significant work across the risk assessment community to implement NAMs into regulatory frameworks and encourage adoption by industry stakeholders. Several publications support this transition from animal (*in vivo*) studies to NAMs for evaluating skin irritation/corrosion. These publications demonstrate that NAMs provide superior reproducibility and greater biological relevance to mechanisms of human skin irritation/corrosion when compared to testing using animals. TSCA section 4 (h)(2)(A) states that EPA must "develop a strategic plan to promote the development and implementation of alternative test methods and strategies to reduce, refine, or replace vertebrate animal testing and provide

information of equivalent or better scientific quality and relevance for assessing risks of injury to health or the environment [...]. In support of this legal directive, NCD has collaborated with colleagues at PETA Science Consortium International and the Institute for In Vitro Sciences to develop an approach that prioritizes and encourages the submission of human-relevant reproducible NAMs data for the evaluation of skin irritation/corrosion for new chemicals. **Methods:** The key principle of this approach is the use of the best available science for the prediction of skin irritation/corrosion hazard in humans. In applying this framework to a new chemical review, NCD first prioritizes human cell-based tissue model NAMs that have been demonstrated to be reproducible and relevant to skin irritation/corrosion. If data from human cell-based tissue model NAMs are not available or there are data gaps, NCD then prioritizes data from other skin irritation/corrosion NAMs that have been demonstrated to be reproducible and provide information on the mechanisms of toxicity relevant to skin irritation/corrosion. If no acceptable information on skin irritation is available, the framework allows for consideration of other information, such as physicochemical properties. *In vivo* data are only used in the absence of sufficient NAMs data. **Results:** This decision framework has been implemented for assessment of skin irritation/corrosion potential within NCD, including for 42 skin NAMs studies provided by submitters in 2024. The application of this framework has resulted in clear, consistent prioritization of reproducible, human-relevant data from NAMs, as well as facilitated the assessment of this hazard for new chemical substances, resulting in increased efficiency and consistency in approaches across new chemical assessments. **Conclusions:** This approach prioritizes reproducible and human-relevant data for assessing skin irritation/corrosion potential and is expected to encourage the submission of these data from members of industry. In addition, this approach has improved the efficiency, consistency, and transparency of the assessment of skin irritation/corrosion potential within NCD. Once finalized, it will serve as a resource for stakeholders preparing new chemical submissions to EPA under TSCA. These views are those of the authors and do not reflect the views or policies of the U.S. EPA or other respective organizations.

PS 3362 Longitudinal high-throughput phenotypic profiling using live-cell staining in U-2 OS cells over a 72-hour period.
